GPS network stations and monitoring the changes in geographical locations and heights at the control points (Jouanne et al. 1998). GPS can measure movement of faults or tectonic plates to within the precision of a few millimeters to approximately 1 cm over baseline separations of hundreds of meters to thousands of kilometers (Segall and Davis 1997). The three-dimensional nature of GPS measurements allows one to determine vertical as well as horizontal displacement at the same time and place. Field methods such as the use of strain meters can provide far greater strain sensitivity than does GPS. However, strain meters cannot offer the spatial coverage and long-term stability as GPS do. InSAR measurements are tremendously exciting because of their unparalleled spatial coverage. InSAR and GPS are complementary in that GPS provides long-term stability, vector displacements, and better temporal coverage as compared to the extensive spatial coverage provided by SAR/InSAR and thus results from one system are directly relevant to the others (Segall and Davis 1997).

Tectonic Studies

Tectonics deals with large-scale deformations of the Earth's lithosphere. The lithosphere is broken up into several tectonic plates that move relative to one another. Plate tectonics theory explains the formation of the plates and the origin of the forces responsible for the motion of these plates. There are three types of plate boundaries characterized by their relative motion: each having different types of surface phenomena including volcanic activities, earthquakes, and faults. The tectonic styles at the different plate boundaries are:

- Extensional tectonics that results in the formation of normal faults (Fig. 3) and associated tectonic processes due to the thinning/stretching of the lithosphere.

Remote Sensing and GIS Techniques for Tectonic Studies, Fig. 3

Fault block models and their equivalent outcrop-scale structural features from field study formed by different tectonic processes: (a) Normal faults, (b) strike-slip faults, and (c) thrust faults. In the sketches, the maximum principal stress (σ_1), the vertical stress (σ_v), and minimum principal stress, (σ_3) are shown. Field structures in (a) and (c) are cross-sectional views and (b) is plain view

- Strike-slip tectonics that results in strike-slip faults (Fig. 3b) in zones of lateral displacement within the lithosphere.
- Compressional tectonics that results in the formation of thrust faults (Fig. 3c) and associated tectonic activities due to the shortening and thickening of the lithosphere.

The difference between structural geology and tectonics is the scale of observation. Structural geology deals with small-scale rock deformation, while tectonics is more concerned with larger features. Thus, remote sensing methods help in detecting large-scale tectonic features while field studies are necessary in investigating how the mapped lineaments control the tectonics of a region by looking into the details at mesoscopic-scale. All remote sensing methods used for lineament extraction cannot describe the nature of the tectonics in a region without ground truthing. It is generally recognized that lineament or fracture trace analysis used in conjunction with tectonic investigations is not credible without field verification. In regional scale studies, although field checking of each lineament is impossible due to significant cost and time involved (Mabee et al. 1994), systematic field checking is still necessary to decipher and derive confidence estimates of the nature of lineaments. The field data include observation and measurement of orientations of joints, dykes, and faults. Field evidences presented in the form of figures and sketches (e.g., Fig. 3a–c) can provide good support for tectonic

interpretation. The structural data collected from the field need to be grouped according to rock type and proximity of sampling points to take into account the geographic locations of observation points. In order to understand the structural–geological significance of fracture arrays, it is a common practice to subdivide them into separate sets on the basis of orientation. Rose diagrams are commonly used to reveal the orientations of vertical and steeply dipping joints, faults, and dykes observed at different scales. Many workers (e.g., Arlegui and Soriano 1998; Solomon and Ghebreab 2006) have effectively used remote sensing data supported by field studies to map regional spatial distributions of lineaments toward understanding their tectonic origin.

Geographic Information System (GIS)

GIS is a tool in spatial data management and analysis that can assist users in organizing, storing, editing, analyzing, and displaying positional and attribute information about geographical data. GIS facilitates integration of all data types and allows a better understanding of the tectonic interpretation of a region under study. The full potential of remote sensing and GIS can be utilized when an integrated approach is adopted. Integration of the two technologies has proven to be an efficient tool in many studies, specifically in tectonic studies (e.g., Ratzinger et al. 2006; Gloaguen et al. 2008).

For instance, different geomorphic indices derived from DEM and a number of factors influencing each index can be integrated in a GIS that will allow a better interpretation of the results. Backed with remote sensing data and ground-checking, it is possible to outline the deformed area and the local strain intensity (relative uplift rates) and thus infer the neotectonic history of a region. Jain and Verma (2006) applied a combination of remote sensing and GIS for mapping active tectonic intensity zone in India. Superimposing a lineament map over a lithological map in a GIS environment provides an insight into the nature of tectonics of a region. Visible horizontal displacement along lineaments (e.g., Fig. 3b) as evidenced from movement in rock units can be used to depict strike-slip fault tectonism.

Draping the lithological map or digitally enhanced color image over a three-dimensional DEM data in a GIS environment can also reveal the faulting mechanisms such as normal faulting due to visible subvertical displacement of lithological units (Fig. 4). In order to classify the fault mechanics involved in deformation, an overlay of historical earthquake data on mapped tectonic features or lineaments can be integrated in a model derived from remote sensing data with results such as from differential radar interferometry in a GIS environment. A GPS-derived parameters can be easily integrated in a GIS framework to provide a powerful means of directly measuring the dynamics of present-day crustal deformation by monitoring the changes in geographical (horizontal) locations and heights (vertical displacements) at well-positioned control points. All these examples demonstrate the application of remote sensing and GIS techniques for mapping both active and passive faults. However, to better understand the types of faults involved, field checking still remains a requirement.

Remote Sensing and GIS Techniques for Tectonic Studies, Fig. 4 Three-dimensional synoptic view of a digitally processed remote sensing data created by draping from ASTER bands (13, 5, and 3) in red, green, and blue order over the SRTM DEM data in a GIS environment. Note the east-west normal fault that dips to the north

Summary

Remote sensing and GIS are complementary to each other and efficient techniques for lineament mapping, and hence for tectonic studies. Advanced remote sensing techniques such as InSAR and GPS have revolutionized tectonic studies by directly measuring the motion of faults associated with earthquakes and rates of uplifts. Field studies are, however, needed to identify the types of lineaments and correlate them to the remotely acquired data. Comparison of orientations of major structures or lineaments such as joints, dykes, and faults obtained from field measurements, and plotted on rose diagrams facilitates their tectonic interpretation. GIS is a very time-saving and cost-effective tool once the database is established. Integrating data of different layers such as lineament and lithological maps, and geomorphic indices acquired, for example, from DEM, GPS measurements and field studies in a GIS environment followed by spatial analysis of the data allows correlation between different parameters for unraveling the nature of the tectonics of a region. Moreover, integrating historical dataset from past earthquake events, if any, including an understanding of the regional tectonic setting is essential in facilitating interpretation of results. Overall, combining remote sensing, GIS, and field techniques provides a powerful tool for understanding the tectonic framework of a region, and assessing the resulting fault mechanisms.

University of Kerman, Kerman, Iran

Definition

Remote sensing is defined as the acquisition of data using a remotely located sensing device, that relies on the measurements of electromagnetic energy (EM) in the range of 0.4 μm to 1 m, and extraction of information from the data (Gupta 2003; McCloy 2006). Remote sensing can be multilevel (i.e., sensing the surface of material from a distance of few centimeters to millions of kilometers). Taking a spectrum of a leaf by using a spectroradiometer to taking an image by Hubble telescope from a star at a distance of few light years fall in the realm of remote sensing. However, here, we mean the imaging of the Earth's surface.

Introduction

The remote sensing systems can acquire images from the surface of the Earth by either passive or active methods.

Passive systems use the electromagnetic energy that is produced by the sun or any other process like anomalous heat buildup within the Earth. Active remote sensing systems create their own electromagnetic energy that (1) is transmitted from the sensor toward the terrain, (2) interacts with the terrain producing a backscatter of energy, and (3) is recorded by the remote sensor's receiver (Jensen 2000). The sending and receiving of signals are largely unaffected by atmospheric conditions. Therefore, radar satellites can record the details of the Earth's surface in cloudy weather condition and any time of the day and night. LIDAR (LIght DEtection and Ranging) and SONAR (SOund NAVigation Ranging) are also the active remote sensing systems. It should be noted that remote sensing is a geophysical method as it uses the electromagnetic spectrum as a medium for surveying the Earth's surface. It is now recognized as a separate branch of science and engineering.

The electromagnetic spectrum that is used by remote sensing systems is named according to the wavelength ranges. Gupta (2003) has classified the electromagnetic spectrum into visible (0.4–0.7 μm), near infrared (0.7–1.0 μm), Shortwave infrared (1.0–3.0 μm), mid-infrared (3.0–35 μm), far-infrared (35–1.0 mm), and RADAR (1–100 cm).

A remote sensing system that allows sensing the Earth in any wavelength and in any time makes an ideal remote sensing system. An ideal remote sensing system cannot be achieved due to the absorptions of the electromagnetic energy from the Earth's atmosphere.

Each object has unique sets of absorption and reflectance features concerning the wavelengths. The plot is known as spectral signature. Figure 1 shows the spectra of the common surface materials. Although each material at the surface of the Earth has many absorption and reflection features, the present remote sensing systems can only image these materials in limited wavelengths because the atmosphere is not clear for all the wavelengths.

There are different sensors that are used onboard the satellites or in an aeroplane. The present remote sensing systems that orbit the Earth are imaging the Earth's surface in visible, near infrared, shortwave infrared, thermal infrared, and RADAR regions of EM spectrum. The reader can refer to Jensen (2000) and Lillesand et al. (2004) for different sensors and platforms specifications.

A digital image consists of pixels. Each pixel is representative of a surface area that defines the spatial resolution of the system. Enhanced Thematic Mapper Plus (ETM+) multispectral data has a resolution of 30 m (each pixel is equivalent to 900 m² ground area), while Quickbird has a resolution of 60 cm for its panchromatic image (each pixel is equivalent to 0.36 m² on the ground).

As these images are in digital formats, several simple or complex mathematical operations can be applied on them in order to enhance specific features from these images. This is

Remote Sensing, Applications to Geophysics, Fig. 1 Typical spectral reflectance curves for selected common natural objects (Gupta 2003)

Remote Sensing, Applications to Geophysics, Fig. 2 Enhancement of faults and other linear features by using directional filter. (a) Original satellite color image, (b) filtered image

called image processing operation. Image filtering (Mather 2001) is a common image processing technique that enhances the linear features. Figure 2 shows the enhanced faults in the southern part of Iran in a filtered image.

Application of Remote Sensing to Geophysics

Remote sensing data can be used for designing the survey grid and line in geophysical surveys, verifying, and helping a better interpretation of the geophysical methods. Remote sensing images can be combined to form color images in various scales that depend on the spatial resolution of the

remote sensing system. These color images can be draped over a digital elevation model (DEM) to give a three-dimensional (3-D) model of the area (Fig. 3). These 3-D models can be used in both land and airborne geophysical surveys for designing the survey lines. The 3-D model can provide information such as the terrain ruggedness, man-made installations, surface conditions, transportation routes, etc.

The surface of the Earth is continuously deformed due to the tectonic activities over geological time that causes the formation of structures such as fold and fault. Geophysical methods such as magnetic, magneto-telluric, gravity, and seismic methods are used for studying these structures.

Remote Sensing, Applications to Geophysics, Fig. 3 3-D view of folding due to the movement of Arabian plate against Iranian microplate. The force direction is shown by an *arrow*. Landsat color image (Band 7 in red, band 4 in green, and band 2 in blue) is draped over DEM of the area

These methods are subsurface methods. Remote sensing techniques are useful in order to study these structures and to interpret the tectonic activities in the regional and local scale at the surface of the Earth. In order to obtain a clear picture of the structures, the combined interpretation of remote sensing and geophysical data is helpful, if the geological structures have any trace in the satellite images. Remote sensing applications to tectonic and structural studies are reported by many researchers (e.g., Harris 1991; Philip 1996; Saintot et al. 1999; Chernicoff et al. 2002; Chatterjee 2003; Raharimahefa and Kusky 2006; Walker 2006). Figure 3 shows a part of Zagros simply folded belt that the folds axis directions indicate a force direction because of the subduction of Arabian plate beneath the Iranian plate. These structures are also studied by using gravitational, magnetic, and seismic methods.

Remote sensing is also useful for interpretation of geophysical data. Alteration process causes the changes in mineralogical content of rocks due to the reaction of hot solution with the rocks. Porphyry copper mineralization is associated with these alteration zones (Evans 1993). Both radiometric and remote sensing methods can be used for alteration detection (Ranjbar et al. 2001, 2010; Ranjbar and Honarmand 2004). The minerals present in sericite and k-feldspar have a higher gamma radiation. We cannot differentiate these minerals by geophysical methods. Remote sensing method is capable of recognizing the minerals responsible for the higher radiation in geophysical data. There are also minerals in the alteration zones that have very low radiation to be detected by geophysical methods. Kaolinite, Calcite, epidote, and chlorite are such minerals. These minerals are recognized by remote sensing methods. Remote sensing techniques can also be used in combination with other geophysical methods such as magnetic, electromagnetic, and electrical methods in helping with the interpretation.

Remote Sensing, Applications to Geophysics, Fig. 4 An interferogram that shows the deformation along a fault due to the Bam earthquake in Iran. The rings that are closer, indicating more deformation. (After Ye 2005)

Another area that received much attention is the field of active faults study by the combined use of interferometry and geophysical data. RADAR (Radio Detection And Ranging) images are more useful for detection of the geological structures than the images acquired in the optical ranges of EM spectrum, because the RADAR pulses are illuminating the ground from a specific direction. The RADAR wavelengths are in order of few tens of centimeters. Synthetic Aperture Radar interferometry (INSAR) is a branch of remote sensing that has emerged in the recent years that deals with the deformation in the Earth's crust. There are several papers published about INSAR method in structural and tectonic fields (e.g., Klees and Massonnet 1999; Wright et al. 2001, 2004; Ye 2005; Bürgmann et al. 2006; Taylor and Peltzer 2006). Figure 4 shows an interferogram of a fault in Bam area that triggered an earthquake in 2003. This fault is detected by remote sensing and geophysical methods.

Summary

Remote sensing images due to their multi-temporal, multi-spectral, and synoptic views are extensively used for solving problems related to mineral exploration, tectonics, vegetation cover studies, surface changes, earthquake studies, weather and volcanic eruption forecasting, etc. The images can be acquired in different wavelength ranges such as visible, near infrared, thermal, and Radar ranges of electromagnetic spectrum. We are now able to recognize many minerals from the space by using their spectral properties. Remote sensing data can be used for designing the survey grid and line in

geophysical surveys, verifying, and helping a better interpretation of the geophysical methods. Small and large structures are easily recognizable in the images, although we often need to enhance the images for recognizing these structures.

University, Sapporo, Japan

Synonyms

Differential InSAR (abbreviated as D-InSAR); Interferometric SAR (abbreviated as InSAR); Radar interferometry; SAR interferometry

Definition

- Radar** Acronym standing for Radio Detection and Ranging. A technique to detect any targets and measure the distance to them, based on the round-trip time of microwave (radio wave) pulses between the antenna and the targets. *SAR*. Acronym standing for Synthetic Aperture Radar. A technique to image any ground surfaces, using airborne or spaceborne radar sensor. Its high spatial resolution is achieved by collecting numerous return pulses from each target in sight and by effectively synthesizing large antenna size.
- InSAR** Acronym standing for Interferometric SAR. A technique to image surface topography and ground displacements, using phase values of two or more SAR images.

Introduction

Crustal deformation data have been traditionally acquired by ground-based geodetic techniques such as leveling, triangulation, and electro-optic distance measurement. More

recently, global positioning system (GPS) has become a standard tool for high-precision crustal deformation measurement, and provided us with a wealth of data to study plate tectonics, earthquakes, volcanic activities, and atmospheric and hydrological loading deformation. All these techniques, however, require in situ benchmarks, and thus prevent us from observing inaccessible areas. Interferometric SAR (InSAR) was, therefore, regarded as a surprising and revolutionary technique when Massonnet et al. (1993) first showed an image of the co-seismic deformation associated with the 1992 M7.3 Landers earthquake, because the raw data was completely acquired on a spaceborne sensor. Another big surprise for the community was its incredibly high spatial resolution, which no other geodetic techniques were possible to achieve in practice.

Nowadays, InSAR users have proliferated in a worldwide community and applied to a variety of geophysical problems. A number of excellent and extensive reviews for advanced students and researchers are already published (Bamler and Hartl 1998; Massonnet and Feigl 1998; Burgmann et al. 2000; Hanssen 2001; Pritchard 2006; Simons and Rosen 2007; Zhou et al. 2009). I therefore tried to make this article much shorter and more introductory, but it still includes necessary and useful concepts, ranging from the fundamentals of SAR/InSAR imagery to more up-to-date topics.

Fundamentals of SAR Imaging and SAR Data

SAR satellite flies over at an altitude of hundreds of km, repeating transmission and reception of microwave pulses. The along-track and across-track axes are almost identical to the *azimuth* and *range* axis in the acquired radar image. The area illuminated on the ground is called *swath*, whose width spans roughly 50–100 km in the standard *stripmap* (or *strip*) mode with an incidence angle of 20–50° (Fig. 1). While previous SAR applications are mostly derived from the stripmap mode, another imaging mode, *ScanSAR*, is also promising because it covers much wider swath width,

SAR Interferometry, Fig. 1 Geometry of SAR imaging. SAR sensor transmits microwave pulses in slant range direction, and receives their reflected pulses. While stripmap mode achieves high spatial resolution

with a fixed off-nadir angle, ScanSAR mode achieves wider imaged area (swath) with multiple off-nadir angles at the expense of the resolution

300–500 km, by illuminating multiple swaths at the expense of reducing the resolution. ScanSAR is useful for imaging long-wavelength signals associated with, for instance, a magnitude-8-class earthquake (Motagh et al. 2008).

Although it was not strictly necessary, satellite-based SAR system has been often placed on a sun-synchronous and near-polar orbit with an inclination angle of slightly greater than 90° . When the satellite moves to the north (south), we call it is in *ascending* (*descending*) orbit.

The raw data acquired on SAR sensor are impossible to visually interpret, and require a bit involved processing algorithms; those algorithms are detailed in a couple of text books (e.g., Curlander and McDonough 1991; Cumming and Wong 2005). The first interpretable SAR image is a single-look-complex (SLC) image, whose important difference from other optical images is that each pixel consists of a complex (real and imaginary) value, i.e., amplitude and phase. This is because the waveform of each repeated pulse is precisely controlled to be identical, and hence the received pulse provides us with not only a scattering (reflection) *intensity* but also a *phase*. The phase data do contain the geometric information from the antenna to the ground targets, and are fully exploited in generating InSAR image as discussed later. However, the phase image itself is usually not as useful as the intensity image because it is again impossible to visually interpret the physical meaning. Meanwhile, the intensity image is often useful and derived from a square-root magnitude of SLC data with spatial averaging called *multi-looking*. By single-look, it means the finest spatial resolution for both

range and azimuth axis. In the standard stripmap mode, the range and azimuth resolutions are derived as,

$$\Delta r = \frac{c}{2B}, \text{ and } \Delta a = \frac{L}{2}, \quad (1)$$

respectively; the c , B , and L are the speed of light, the frequency bandwidth of the microwave pulse, and the antenna length along azimuth axis, respectively (Curlander and McDonough 1991; Cumming and Wong 2005). The waveform of each microwave pulse is called *chirp signal*, whose instantaneous frequency linearly changes by as much as the frequency bandwidth B over the duration of each pulse. It should be noted that the spatial resolution depends neither on the sensor altitude nor the carrier frequency of microwave. Intensity images are often shown in gray scale images, in which strongly (weakly) reflected objects/areas are usually colored as bright (dark). Although they simply look like black-and-white photographs, we should keep in mind that they could be acquired regardless of weather and time because SAR is actively transmitting and receiving microwaves. Also, intensity images are indispensable for high-precision image matching prior to a generation of InSAR image.

Fundamental Principles of InSAR

Interferometric SAR (InSAR) is a technique to generate a digital elevation model (DEM) or a ground displacement

SAR Interferometry, Fig. 2 (a)

Geometry of the Young's experiment. Depending on the path difference, the two coherent waves from the slit, S1 and S2, are in-phase or out-of-phase on the screen, and interference fringes are observed on the right screen. (b) Orbital fringe (flat earth fringe) can be regarded as a 3-D analogue of the Young's experiment

image from a *pair* of SLC images. The term *interferogram* is often used to represent InSAR image. We can understand the principle of InSAR, recalling the classical Young's experiment that is known to be a proof of the wave characteristics of the light (Ghilia and Pritt 1998). Two coherent waves out of the slits will generate "stripes" on the wall, called *interference fringe* (Fig. 2a). We can simulate the fringe if we know the separation of the slits, the distance from each slit to the wall, and the wavelength of the coherent wave. Depending on the path difference, the two coherent waves are in-phase or out-of-phase when they reach the screen. Namely, the difference of the phases generates the interference fringe. We may regard the imaging geometry of InSAR as the 3-D Young's experiment (Fig. 2b). The repeat orbit tracks, the ground surface, and the microwave correspond to the double slits, the screen, and the coherent wave, respectively. Once we get two SLC images, we can generate an initial interferogram, multiplying one SLC image with the complex conjugate of the other SLC image. We then observe similar fringes in the initial interferogram as illustrated in Fig. 2b, which is literally a map of the difference of two SLC phases. For descriptive purposes, the former SLC image is often denoted as *master*, and the latter SLC image is called *slave*. At this moment, the slave image must be precisely co-registered (or matched) to the master image (Fig. 3); we will come back to this *image co-registration* (or *image matching*) procedure later on.

While Fig. 2b shows an initial interferogram over flat areas with parallel orbits, the fringe will appear undulated if the areas are not flat. The fringe over flat areas is called *flat Earth fringe* (or, *orbital fringe*), and can be precisely simulated from the pair of orbit data. If we subtract the flat Earth fringes from the initial interferogram, we can extract *topographic fringe* that can be used to generate DEM. The Shuttle Radar Topography Mission (SRTM) was carried out along this idea in 2001, and generated 3-s resolution DEM over $\pm 60^\circ$ latitudes (Farr et al. 2007). In the case of SRTM, they carried two SAR antennas on the same platform, and thus were able to generate DEM without repeating the previous orbit track. In contrast, all the present SAR satellite systems carry only one

SAR Interferometry, Fig. 3 Image registration (matching) of the master and slave images prior to interferogram generation, and the principle of pixel-offset technique to derive large displacements. While long-wavelength distortion can be corrected, localized huge displacement remains as residual offset. Courtesy of Tobita et al. (2001a)

antenna with a repeat-pass period of several weeks, which are 11 days for TerraSAR-X, 16 days for COSMO-SkyMed, 24 days for Radarsat-1/2, 35 days for Envisat, and 46 days for ALOS. Therefore, if ground surface undergoes significant deformation during the repeat orbit cycles due, for instance, to earthquake and volcanic eruption, the interferogram will include *deformation fringe* as well. To extract deformation fringe, we must take out both orbital fringe and topographic fringe, which can be simulated from satellite orbit data and DEM. The deformation fringes represent slant range changes along the radar line-of-sight (LOS), and thus projections of the 3-D displacement vector on the ground along the unitary vectors toward the radar LOS (Fig. 4). The range changes should be interpreted as relative displacements to the

reference point(s) inside each interferogram. Depending on literatures, they denote differential interferometric SAR (D-InSAR) when the technique is used to detect deformation signals. Recently, however, the term InSAR is often and simply used to represent D-InSAR.

Even if no significant ground displacements take place during the repeat-pass period, however, we usually encounter other non-negligible fringes due to the spatial heterogeneities in the propagation delay of microwaves through the atmosphere, the errors in satellite orbit data, and those in DEM. Because these fringes limit the precision and accuracy of SAR-based crustal deformation measurement, a couple of correction approaches have been proposed. More advanced time-series analysis techniques have also been developed to overcome the issues, which will be introduced in the last section.

InSAR Processing

Image registration (Matching): Before we get an initial interferogram, we must register (or, match) each imaged target in one SLC image to the same target in the other SLC image with a sub-pixel level accuracy, because any ground objects do not usually locate at the same pixel coordinates in each SLC image. This pre-processing is called *image registration* (or *image matching*) and prerequisite to be performed prior to generating an initial interferogram. Although a simple polynomial transformation between the range and azimuth coordinates of two SLC images is sufficient in most cases, we need to take into account the effects of 3-D topography when the terrain surface is rugged to eliminate a stereoscopic effect (Michel et al. 1999).

When large ground displacements on the order of meters or more take place locally, and if we correct for the long-wavelength image distortion using the polynomial transformation, we can detect and quantify those localized displacements as a by-product of image registration without viewing InSAR image (Fig. 3; Tobita et al. 2001a). This approach to detect large displacements is called *pixel offset* or *feature tracking* technique, and has been applied to earthquakes, volcanic eruptions, and glacier movements. The advantages of pixel-offset data are twofolds. First, pixel-offset data can quantify large displacements even in such areas that completely loses interferometric coherence, where InSAR data cannot be unwrapped; we describe *coherence* and *unwrapping* later below. Secondly, in contrast to InSAR data, pixel-offset data provide us with not only range offset but also azimuth offset component. While the range offset has the same sensitivity to the 3-D displacement vector as InSAR data (Fig. 4), the azimuth offset is a projection of the displacement vector onto the unitary vector perpendicular to the LOS. Hence, the azimuth offset data are complementary to the range offset or InSAR data. Taking advantage of this property,

SAR Interferometry, Fig. 4 InSAR observable is a projection of the displacement vector along the radar line-of-sight (LOS) direction

Fialko et al. (2001) derived a full 3-D displacement map for the 1999 M7.1 Hector Mine earthquake, combining the InSAR data from both ascending and descending track with the azimuth offset data. Using pixel-offset data from both descending and ascending track, Tobita et al. (2001a, b) inferred a 3-D displacement map associated with the 2,000 eruption episode at Usu volcano.

Interferometric phase and its relation to geometry: Suppose we have two co-registered SLC images, E_1 and E_2 , acquired from different ranges r_1 and r_2 :

$$E_1 = e^{j\phi_{\text{Scatter}}} e^{-\frac{4\pi r_1}{\lambda}} \quad (2a)$$

$$E_2 = e^{j\phi_{\text{Scatter}}} e^{-\frac{4\pi r_2}{\lambda}} \quad (2b)$$

Here we assume that the reflection magnitude and scattering phase are constant during the data acquisition time. Then, the interferometric phase ϕ is derived as

$$E_1 E_2^* = e^{-\frac{4\pi(r_1 - r_2)}{\lambda}} \quad (3)$$

or

$$\phi = \frac{4\pi}{\lambda} (r_1 - r_2) \quad (4)$$

The last one is the fundamental equation for InSAR, which describes “unwrapped” phase in the initial interferogram. The actual phase in the initial interferogram is “wrapped” into an interval $[-\pi, \pi]$, and thus has ambiguities of $2\pi N$; N is integer. In order to quantify the ground displacement along radar LOS, we have to perform 2-D *phase unwrapping* on the interferogram, which is not necessarily straightforward (Bamler and Hartl 1998; Ghilia and Pritt 1998). While the interferometric phase is strictly a phase “difference” of two SLC phases, it is conventional to simply call phase. The factor 4 is to take into account the round-trip distances.

Figure 5 is a cross section that is perpendicular to the satellite repeat tracks and passes through the Earth’s center,

SAR Interferometry, Fig. 5 Geometry of InSAR data acquisition and its relation to the baseline. The A1 and A2 are the satellite's repeat orbits, and the spatial distance between the A1 and A2 is the baseline B . The initial InSAR phase is proportional to the difference between the ranges, r_1 , and r_2 , and hence the B_{para} (Eq. 5). The fringe rate (density) along the range axis is proportional to the B_{perp} (Eq. 6)

and shows a geometry of InSAR data acquisition. The spatial separation of the repeating orbits is termed baseline (or spatial baseline), B ; the temporal separation of data acquisition is sometimes called temporal baseline. Because the baseline B is usually much shorter than the ground range distance R , a parallel ray approximation holds (Zebker et al. 1994) and the fundamental Equation 4 can be approximated as follows:

$$\phi = \frac{4\pi}{\lambda}(r_1 - r_2) \approx -\frac{4\pi}{\lambda}B_{//} = B \sin(\theta - \alpha), \quad (5)$$

where ϕ and α are defined in Fig. 5, and $B_{//}$ (or B_{para}) is a baseline component parallel to the radar LOS. The angle θ is

called *off-nadir angle*, and is identical to incidence angle if the Earth's curvature is negligible. The other baseline component $B_{\perp}$ (or B_{perp}) is perpendicular to radar LOS and gives us an important criterion for successful InSAR processing as we discuss below.

Decorrelation (Coherence): In the actual InSAR data processing, we do not necessarily get clear fringes over the entire area. Depending on the data pairs and places, it is not uncommon that no fringes are observed. To detect clear fringes, the reflected waves received at master and slave acquisitions must be more or less correlated to each other. The degree of correlation is quantified as *coherence*, and there are two independent decorrelation sources.

The first source of decorrelation originates in the imaging geometry. As Fig. 6 indicates, we observed higher (fewer) fringe density as becomes longer (shorter); imagine the case of zero baseline length. The fringe density can be derived from the gradient of phase (Eq. 5) along the range axis:

$$\frac{\partial \phi}{\partial R} = -\frac{4\pi B_{\perp}}{\lambda R \tan \theta} + \frac{4\pi B_{\perp}}{\lambda(r_e + H) \sin \theta} \approx -\frac{4\pi B_{\perp}}{\lambda R \tan \theta}. \quad (6)$$

Namely, the fringe density is proportional to the perpendicular baseline $B_{\perp}$, and inversely proportional to the wavelength λ ; see Simons and Rosen (2007) for the case with topography. If the fringe density becomes too high to be counted within a range resolution of SAR image, we will not be able to identify any orbital fringes. This type of decorrelation is termed *baseline decorrelation* (or *spatial decorrelation*). The *critical baseline* is given as such a perpendicular baseline that gives a phase gradient 2π over the range resolution Δr ;

$$B_{\perp}^c = \frac{\lambda R \tan \theta}{2\Delta r}.$$

For a typical value of ALOS/PALSAR with $\lambda = 23(\text{cm})$, $R = 870(\text{km})$, $\theta = 34^\circ$, $\Delta r = 5(\text{m})$, the critical baseline becomes $B_{\perp}^c = 135,000(\text{m})$, which gives an upper limit of $B_{\perp}$. However, we practically prefer much shorter $B_{\perp}$, generally less than $\sim 2,000 \text{ m}$ for ALOS/PALSAR, because in more realistic situations the effect of topography also comes in. The longer the B , the more sensitive to rugged terrain as Fig. 6 indicates. To eliminate topographic fringes, we need more accurate and higher resolution DEM if the $B_{\perp}$ becomes longer. Massonnet et al. (1996) proposed an alternative approach that could effectively reduce the $B_{\perp}$ by a combination of integer multiplied (wrapped) interferograms. For instance, if one interferogram with perpendicular baseline of 300 m is combined with the other interferogram with perpendicular baseline of 290 m with factors 1 and -1 , the effective perpendicular baseline becomes 10 m. The scaling operation,

SAR Interferometry, Fig. 6 The fringe rate (density) depends on the B_{perp} ; see Eq. (6). The shorter the B_{perp} , the fewer the observed fringes, and thus better to detect deformation signals. In order words, there is a

limit in the B_{perp} over which we cannot count the number of fringes. The InSAR image is based on JERS data over Izu-Oshima volcano island, Japan. Original SAR data is copyrighted by JAXA and MITI, Japan

SAR Interferometry,

Fig. 7 Comparison of two interferograms at Izu-Oshima volcano, derived from (left) L-band HH JERS data and (right) C-band VV ERS data. While clear fringes are observed to the left even with 2.5 years temporal baseline, we can recognize the fringes only around the caldera that are covered with few vegetations

however, also scales the amount of noise, and thus the approach is limited to small integer numbers.

The second type of decorrelation is termed *temporal decorrelation*, which is related to the scattering phase in the Eq. (2a), and originates in how the microwave pulses interact with the physical objects near the ground. We often encounter the temporal decorrelation problem over vegetated areas with C-band (shorter-wavelength) SAR data and/or snow-covered areas; see Fig. 7. It should be recalled that each pixel value in SLC image is a superposition of all the reflected microwaves from all scatterers inside each resolution cell ($\sim 5 \times \sim 10$ m). Short-wavelength microwave pulses tend to be reflected on the vegetation canopies before reaching the ground surface, and their random motion will result in different scattering phases at different acquisition time, causing temporal decorrelation. On the contrary, long-wavelength microwave pulses can more easily reach the ground, which does not move as rapidly as vegetations, and thus the resulting scattering phases will be also stable over time. Besides the selection of wavelength, the polarization of microwave is also essential for better coherence over time. While, most presently, operated satellite-SAR sensors are capable of multi-polarization modes, it was shown that HH-polarization gives better coherence than VV-polarization (Cloude and Papathanassiou 1998). This is because the HH-polarized pulses can more easily penetrate through vegetations.

Outlook for InSAR Geodesy

Limitations of present InSAR: Although it has a potential to detect tens of km-scale or even larger-scale secular deformation signals on the order of mm/year, InSAR technique has been most successfully applied to detection of spatially localized signals on the order of centimeters or more, such as those associated with earthquakes, volcanic eruptions, and ground subsidence. This is because the artifacts due to inaccurate satellite orbit data and/or microwave propagation delays (advances) in the troposphere (ionosphere) can mask small-amplitude, long-wavelength deformation signals that are similar in both their amplitude and the spatial scale.

Although high-precision orbit data are indispensable to correct for the orbital fringes in the initial interferograms, their errors even on the order of 10 cm or less will generate non-negligible long-wavelength artifacts, which usually look like curved surfaces in the entire interferogram (e.g., Hanssen 2001). Conventionally, they are fitted with low-order polynomials and simply taken out unless any sort of stacking or time-series analysis discussed below is applied. While this procedure works to eliminate the artifacts due to orbit errors, it will also take out any long-wavelength geophysically interesting signals such as the inter-seismic, post-seismic, ocean tidal loading, solid-Earth tide, and post-glacial rebound signals. Alternatively, if the ground control points (GCP) are available, where the precision ground deformation data are

available, we can reestimate the baseline, based on those GCP data (e.g., Rosen et al. 1996), but such data are often unavailable in remote areas.

One approach to correct for the tropospheric delay signals is to employ the other independent estimates derived from either the GPS-based tropospheric delay estimates (e.g., Onn and Zebker 2006) or the output results from high-resolution numerical weather model (e.g., Foster et al. 2006). These so-called calibration approaches are, however, not easily applicable. The dense ground-based GPS network is limited to a few areas in the world. Also, high-resolution numerical weather model still needs significant computational resources.

Besides the tropospheric delay problem, the effects of ionosphere on both interferograms and pixel-offset images were clearly recognized in the results of the 2008 Wenchuan earthquake (Mw7.9), China, derived from ALOS/PALSAR (Kobayashi et al. 2009; Raucoules and de Michele 2010), although they were pointed out in polar region many years ago (e.g., Matter and Gray 2002). It is well known that the lower the carrier frequency is, the more significant the ionospheric dispersion impacts on the propagation delay. Thus, in many of the previous applications of C-band SAR data, the effects of ionosphere could have been neglected. While GPS also employs L-band, the high-precision GPS geodetic survey corrects for the ionospheric effect with the use of dual frequency, L1 and L2, observation data. In contrast, PALSAR is a single frequency SAR sensor and incapable of the standard ionosphere-correction approach. Empirically, however, we will encounter the ionospheric signals more frequently in the ascending data acquired in the local nighttime than in the descending data acquired in the local daytime. We also recall that the JERS, the other L-band SAR operated during 1992–1998, did not reveal any significant ionospheric signals at least in mid-latitude regions, and that most of the JERS data were acquired in the descending track. Besides the latitude, the effects of ionosphere on SAR image might, therefore, significantly depend on the data acquisition time. Like the tropospheric effects, detailed studies of ionospheric impacts on the SAR data are also currently underway.

A simple approach to eliminate those noises is *stacking*, in which several interferograms are stacked to isolate small-amplitude signals, because those noises can be regarded as temporally random, whereas the deformation signals are spatially persistent. Two important prerequisites for successful stacking are: (1) the data acquisition dates of those interferograms should not be overlapped, in order not to enhance the noises of any particular acquisition date(s), and (2) each temporal baseline should be as long as possible so that each interferogram can include as much deformation signals as possible. In reality, it is not easy to gather many independent interferograms that have desirably long temporal baselines because the available data often encounter the spatial and temporal decorrelation. Also, the simple stacking approach

inherently assumes temporally linear evolution in the ground deformation, preventing us from deriving time-series data.

Time-Series Analysis: Ferretti et al. (2000, 2001) proposed a new analysis technique called *Permanent Scatterer InSAR (PS-InSAR)*, in which they take advantage of even such data pairs whose spatial baselines are longer than the critical values. Thereby, they could expand the temporal coverage, and thus could estimate the long-term deformation signals on the order of mm/year. Key idea of PS-InSAR is to pick up only such pixels that will exhibit long-term coherence due to the existence of corner-reflector-like targets, which Ferretti et al. called “permanent scatterers.” Based on those pixels alone, they generate a stack of differential interferograms, using available DEM and orbit data. The phase values include not only deformation signals, but also such topographic signals that were not initially taken into account, because the longer spatial baseline pairs are so sensitive to the topography that the available DEM could not account for. In PS-InSAR and its variants (Werner et al. 2003; Hooper et al. 2004), they fit the differential interferogram stack to a phase model that describes not only temporal evolution of deformation but also corrections to the available DEM. Deviations from the phase model can be filtered into either non-linear deformation or atmospheric signals because the former signals are correlated and thus low-pass filtered along temporal axis, while the latter signals are temporally random; the orbit data must be assumed to be correct. A known limitation of PS-InSAR is its rather lower sampling density over non-urban areas. However, despite a lack of man-made objects, Furuya et al. (2007) succeeded in detecting active salt tectonic motion, applying a similar technique to Canyonlands National Park, Utah, presumably because the area was non-vegetated and the exposed surface rocks behaved like corner-reflector-like targets.

Another time-series analysis approach was devised and known as small baseline subset (*SBAS*) algorithm (Berardino et al. 2002). Key idea of the SBAS algorithm is *least-squares inversion* of unknown deformation at each SAR data acquisition epoch, based on the available unwrapped differential interferograms (e.g., Lundgren et al. 2001; Schmidt and Burgmann 2003). Using small baseline interferometric pairs, the SBAS approach is free from spatial decorrelation and allows us to take advantage of the fine spatial resolution of InSAR data. If the number of interferograms is greater than or equal to the number of SAR acquisitions, the inversion problem becomes an over-determined or well-determined problem, and can be easily solved in a least-squares approach. It is uncommon, however, that all the available interferometric pairs have short baselines, and accordingly the temporal sampling rate will decrease. Berardino et al. (2002) proposed to employ several groups of “small baseline subset” to overcome the lower temporal resolution issue, and solved the rank-deficient problem with the use of singular value decomposition (SVD) technique.

The SVD gives the minimum-norm least-squares solution, which is equivalent to minimizing the estimated velocities at any time intervals.

Time-series analysis of SAR data is a promising technique, but almost all previous analyses are based on the C-band ERS1/2 and Envisat data, because not only more-than-decade-long data but also high-precision, well-controlled satellite orbits are available for these satellites. As noted before, not all geophysically interesting phenomena could be detected by C-band and shorter-wavelength SAR data. If the L-band ALOS/PALSAR data are archived for a much longer time, and if the follow-on ALOS-2 and the DESDynI are launched as scheduled, the time-series analysis of SAR data will become feasible even in areas that have never been monitored before. The time-series analysis with ScanSAR data should also be possible. Long-term continuous monitoring with L-band SAR will provide us with more opportunities for new discoveries.

Satellite Altimetry

Stelios P. Mertikas and Constantine Kokolakis
Geodesy and Geomatics Engineering Laboratory, School of Mineral Resources Engineering, Technical University of Crete, Chania, Greece

Synonyms

Earth observation; Marine geodesy; Remote sensing; Satellite monitoring; Sea surface height

Definition

Altimetry is a technique for measuring heights.

Satellite altimetry measures the time taken by an electromagnetic pulse to propagate from the satellite to the surface and back to the satellite

Satellite Altimetry

Satellite altimetry is a technique of measuring heights of the Earth's surface from a satellite flying approximately at an attitude of about 1000 km. The word "altimetry" originates from the Latin "altus," meaning "high" and the Greek suffix "metry" ("μετρία," as in Geo-metry, Trigono-metry, etc.) denoting the science or scientific discipline related to measuring heights. At the beginning, the objective of altimetry has been to measure height principally of sea surface to an accuracy of about ± 1 cm, continuously, objectively, and on a global scale.

Altimeters measure distances, or ranges, from a satellite to the Earth's surface and principally onto the sea, inland water levels (lakes, rivers) and ice surfaces as well (Fig. 1).

Measurements of altimetric heights are thus creating profiles of the Earth's surface along satellite orbits with respect to Earth's center of mass.

Satellite observations coming from altimeters, like those of Sentinel-3, Jason-3, CryoSat-2, IceSat-2, HY-2, and others, address several applications in solid Earth geophysics. Gravity determination, natural resources exploration, ocean circulation and variability, ice topography, hydrology, geodesy, climate change, bathymetry, sea-floor topography, etc., are a few applications of satellite altimetry.

Measurement Principles in Altimetry

Altimeters on board a satellite transmit radar or laser pulses towards the surface of the Earth. Propagated signals are then reflected by this surface and finally are received by the altimeter on the satellite. Ranges are realized by measuring time differences between satellite transmission and reception of these electromagnetic pulses. Each range value is an average of all measurements made within the footprint of the altimeter. Time series of surface height and its change can be constructed for a location along the satellite ground track during its lifetime.

Altimeter ranges require proper measurement reductions to eliminate various error sources arising from orbit determination, atmosphere delays along the propagation path of the signals (wet and dry troposphere, ionosphere), antenna gain pattern, satellite clocks, geoid height, tides (ocean, solid earth, pole), and so on.

Analysis and evaluation of return signals and specifically of their waveforms provides information upon measured range, wind speed, wave heights, and backscatter coefficient (sigma-naught) of observed targets (Fig. 2). Precise heights for oceans, lakes, rivers, sea ice, glaciers, and land surfaces are thus measured from an altitude of 800–1300 km with an accuracy of about ± 1 cm (or better).

Altimetric observations are made independent of night or day, of strong winds or hurricanes, cloudy or clear weather conditions. In this manner, altimetry is producing a wealth of Earth observations continuously, accurately, objectively, repeatedly, and on a global scale.

As of 1992 with its first TOPEX/Poseidon, it has been generating precise time series of altimetric observations for building up a climate data record of ocean topography, sea level, and inland water levels. Time-averaged heights of the sea surface essentially represent the geoid, showing the variability of the gravity field at the earth's surface, caused by the uneven distribution of the density of earth's crust (Fig. 3).

The slope of ocean surface, related to changes in gravity and submarine features, is estimated by differencing height measurements along altimeter tracks. Altimetry has in that

Satellite Altimetry,

Fig. 1 Principle of satellite altimetry. The satellite altimeter transmits signals towards the Earth, which are later received after their reflection onto the Earth's surface. After orbit determination, and several measurement reductions, height profiles of the Earth's surface are established with respect to its center of mass

way revealed subsea mountains and features and made it possible to construct a uniform resolution map of the seafloor topography. A detailed knowledge of seafloor topography is fundamental to the understanding of several Earth processes.

Also, gravity and bathymetry data derived from altimetry have been used to construct global models of marine gravity to a latitude of 85° with accuracies of ± 1 mGal at 7 km resolution. Such models have helped to determine gravity models for remote and inaccessible regions and also

Satellite Altimetry,

Fig. 2 Examples of satellite altimeters for Earth observation ((a) Upper image). The lower (b) diagram presents an example of a waveform for a return signal on an altimeter. Ranges are determined by measuring time difference at the half-power point (point B_0). The slope of the leading edge (AC leg) of waveform defines wind speed. The level of return power represents wave heights (Point C). The rise time of the leading edge (A_0C_0) corresponds to significant wave height

Satellite Altimetry, Fig. 3 The sea surface exhibits slopes, tiny ripples and variations (enlarged in the cartoons above), commonly invisible to human eye, but related to bathymetry and gravity changes underneath it (cartoon by Nikitas Papadoulakis)

Satellite Altimetry, Fig. 4 A global map of marine gravity as produced by combining satellite altimetry and gravity data (Sandwell and Smith 2009; Sandwell et al. 2014)

to identify submarine canyons, faults, and plate boundaries and oceanic plateaus (Fig. 4). These geomorphic features provide evidence to where to look for deposits of natural resources.

Oceanography by Altimetry

Oceans cover around 71% of the Earth's surface and contain about 97% of its water. Their role is crucial in the balance of Earth's climate. They control the amount of CO₂ in the atmosphere through plankton, absorb 90% of the thermal energy of the Earth, form microclimates, regulate fish population by ocean circulation and currents, shape and curb the greenhouse effects, etc.

Before Seasat in 1978, which was the first satellite to observe Earth's ocean, measurements for ocean monitoring were constrained to coastlines with tide gauges and/or along ship's routes. Such ocean observations on the surface are commonly biased as they are subject to and contaminated by local and dynamic effects, bathymetry, and so on. Up to that point, observations made at the Earth's surface have prevented geophysicists from understanding global oceans' mechanisms. So, satellite altimetry came to fill in this gap by providing the global picture with accuracy and objectivity.

In altimetry, information about the radiated ocean surface originates from the received echo of the transmitted satellite pulse. Over ocean, this response has a particular shape, a waveform of the Brown model as shown in Fig. 2 (bottom). The epoch at half-power point (corresponding to the mid-height of sea level) defines the altimeter range; the maximum power return provides the reflexivity coefficient of the altimeter signal on the surface (called sigma-naught and related to properties of the scattering surface); the leading edge slope of the signal return determines the amplitude of sea waves (significant wave height); and the slope of its trailing edge is connected with the off-nadir pointing of the altimeter antenna (Passaro et al. 2014).

Satellite altimetry is thus able to observe ocean surface topography, which is nothing else but the difference between the ocean surface and the geoid (the equipotential surface of the sea level). Mapping ocean surface topography with altimetry enables us to observe ocean currents and circulation. Any variation on ocean surface topography, such as a high (hill) or a low (valley) at a location, implies that currents swirl around it, primarily driven by thermodynamic processes. The Gulf Stream which flows from the Caribbean to the Grand Bank off Newfoundland is such an example. This Stream has been regularly monitored from the onset of altimetry with the TOPEX/Poseidon satellite. During its course, the Gulf Stream warms the ocean and releases heat and water vapors into the atmosphere. So it modifies and

regulates the exchanges of heat between the ocean and the atmosphere and has a straight through impact on the climate and its changes.

Altimetry has also contributed to the improvement of tidal models. Nowadays, these models have an uncertainty of ± 2 cm in open seas. This level of uncertainty allows us to examine and better understand gravity interactions between the Moon (main cause of tidal effects) and the Earth. Daily sea level measurements from altimetry have given the opportunity to adjust model parameters according to real satellite measurements in open seas where no previous observations could have been validated them (Fu and Cazenave 2000). These accurate tidal models are essential in forecasting extreme ocean events, such as tsunamis.

Satellite altimetry supports absolute and undisputable sea level monitoring over regional to global scales, accurate to some [mm/yr] and with respect to the center of mass of the Earth (Mertikas et al. 2018). Sea-level is a key indicator of the impact of climate change over oceans. It is one of the essential climate variables (Downy 2016) that needs to be systematically monitored for maintaining a global climate observing system.

Hydrology by Altimetry

Hydrology is composite word which originates from the Greek "hydro" (ὕδωρ), meaning water and the ending "logy" (λογία), corresponding to "thorough investigation." Thus, hydrology is a scientific field of Geophysics that studies the movement, distribution, and quality of water on Earth. Although the earliest altimetry missions have been dedicated to observing the open ocean and ice, recent altimetry has moved into monitoring every stretch of water on Earth (enclosed seas, lakes, rivers, flooding areas, and so on) provided satellites fly over them.

An altimeter is capable of monitoring these water levels of lakes and their variations. To our advantage altimetry monitors regions difficult or even impossible to access for in situ measurements. Levels of lakes rise and drop throughout seasons, depending upon how much water flows in (e.g., rain, snow melting) or flows out their water bodies (e.g., evaporation, pumping for irrigation). Thus, the level of water is an indicator of regional climate variations, and it is important to monitor it to be able to access quantity of water and stretch of a lake. This is achieved by altimetry (water height and volume) in combination with imagery (lake stretch). The same holds true for enclosed seas, such as the Caspian Sea.

Some altimeters with specific ground tracks are capable of monitoring adjacent lakes, as the African lakes of Victoria, Tanganyika and Malawi, and also correlate their water levels. The European Remote Sensing satellite (ERS) and its

successor Envisat had observed 215 large lakes out of 842 that exist globally. River levels and flooded areas can also be observed by altimetry. Satellite altimeters can observe heights of large rivers such as the Amazon or the Brahmaputra and monitor their changes over seasons.

The recent observation mode of synthetic aperture radar (SAR) altimetry takes advantage of Doppler effect of earth targets with respect to the moving satellite and achieves an improvement in spatial resolution, along track, of about 300 m contrary to 1–5 km in conventional altimetry (also called low resolution mode). The CryoSat-2 satellite and Sentinel-3A and Sentinel-3B implement this SAR technique which allows them to monitor narrow straits, coastal lines, and inland water resources reliably. In SAR mode, the satellite emits a series of coherent pulses (called bursts) and thus multiple signal returns (echoes) are received by the altimeter for the same target on the surface of the Earth. After processing these multiple returns, better resolution and more precise altimeter ranges are produced. SAR altimetry has applications for inland water observations, such as the CryoSat-2 SAR altimetry over the Mekong River in South-east Asia (Bercher et al. 2013). Finally new algorithms, called fully-focused algorithms, are applied for processing altimeter signals to further improve the along track resolution down to half of the antenna length, at about 0.5 m spatial resolution.

Ice and Cryosphere Monitoring

Altimetry can also measure thickness of polar sea ice, floating ice, and glacier topography as well as monitor changes in ice sheets. Altimeters of ERS-1, ERS-2, Envisat, CryoSat-2, IceSat, and IceSat-2 have observed the cryosphere and have allowed us to map Greenland and Antarctica, where about 77% of the Earth's fresh water is located and accessibility has been difficult for surface measurements. Before satellite altimetry, in situ measurements in polar caps were sparse in space and time. This limitation had not permitted us to appreciate the true extend of ice, melting progression, and variations. As of 2010, the synthetic interferometric radar altimeter of CryoSat-2 (as well as IceSat and IceSat-2) has been acquiring elevation data for glaciers and ice caps to assess the consequences of receding ice cover as a result of global warming (McMillan et al. 2014).

Also, the interferometric synthetic aperture radar of CryoSat-2 has allowed a smaller footprint (~250 m) in the along-track (fore- and aft) direction and detection of the position of the source of the echo in its across-track (left and right) direction; thus, CryoSat-2 has been able to distinguish slopes. This characteristic has produced accurate height

measurements in regions of complex topography. Signal parameters in the waveform of the echo are similar with these in Fig. 1, with the exception that the leading-edge width gives information about signal penetration into the ice and about ice roughness.

The amount of ice sheet and their variations are not only indicators of the current climate situation of the Earth but are reliable predictors for the future. If the ice of Greenland and Antarctica melts, for example, the sea level will rise about 80 m (Gardner et al. 2013).

Summary

Satellite altimetry is a powerful observation tool for Geophysics. It has proven extremely useful for uninterrupted, global, and accurate observation of marine geodesy, oceans, ice caps, lakes, rivers, coastlines, natural resources, and many more. It has revealed mechanisms of the Earth, such as global bathymetry and ice melting that no other technique could do in the past. Recognizing that progress, diverse satellite altimeters along with advanced measuring techniques (Nadir, Delay-Doppler, interferometry altimeters, wide swath, Ku-band, Ka-band frequencies, etc.) are placed into orbits and some of them such as Sentinel-6/Jason-CS are to become operational missions. New missions SWOT (Morrow et al. 2019), Quanlan (Chen et al. 2019), CRISTAL (Kern et al. 2020), etc.) are planned by various nations, organizations, and space agencies and are on their way to support Earth observation and drive the advancement of Geophysics.

Acknowledgments We thank Professor David Sandwell of Scripps Institute of Oceanography, USA, for giving us permission to publish the map of Fig. 4.

Seafloor Spreading

Richard N. Hey
Hawaii Institute of Geophysics and Planetology, School of
Ocean and Earth Science and Technology, University of
Hawaii, Honolulu, HI, USA

Definition

Seafloor spreading is the mechanism by which new oceanic lithosphere is created at and moves away from the divergent plate boundaries known as mid-ocean ridges. The seafloor spreading hypothesis led to one of the most important paradigm shifts in the history of the Earth sciences, the plate tectonics scientific revolution.

Introduction

The revolutionary seafloor spreading hypothesis improved and subsumed the continental drift hypothesis, and rapidly culminated in what is now known as plate tectonic theory. First hypothesized by Harry Hess in a 1960 preprint and paper (Hess 1962), he considered so speculative he called it “an essay in geopoetry,” and named in another influential early paper (Dietz 1961), it offered a simple explanation for many problems with the prevailing paradigm that the Earth was a mostly static, slowly contracting planet, with fixed continents and old ocean basins, and no large-scale horizontal displacements. This paradigm had previously been challenged, most notably by Alfred Wegener with his continental drift hypothesis (Wegener 1912), and by paleomagnetic measurements in the 1950s that were consistent with continental drift, but before the 1960s these ideas were not generally accepted.

The Revolution

Hess realized that if mantle convection carried seafloor and continents away from seafloor spreading centers (mid-ocean ridges) toward trenches (subduction zones), with new seafloor formed at ridge axes and destroyed at trenches, this would explain the shallow bathymetry, earthquakes, high heat flow, lack of sediments, and extensional structures characterizing ridge axes, as well as the deep trenches, earthquakes, compressional structures, mountain ranges, and volcanoes characterizing subduction zones.

A key step in the confirmation of seafloor spreading was the recognition by Fred Vine and Drum Matthews (Vine and Matthews 1963) (and independently by Lawrence Morley, in a paper unfortunately turned down as too speculative by both *Nature* and the *Journal of Geophysical Research*, later published in Morley and Laroche 1964), that it offered a simple explanation for the existence of puzzling magnetic “stripes” on the seafloor. The Vine–Matthews hypothesis proposed that a combination of seafloor spreading and episodic reversals of the Earth’s magnetic field (at the time another very speculative idea) would create alternating zones of normally and reversely magnetized crust, and thus, linear positive and negative magnetic anomalies in a pattern symmetric about the spreading axis.

The next key step in the revolution occurred in 1965, when Tuzo Wilson noted that deformation of the Earth’s crust is concentrated in narrow mobile belts, and postulated that these features are all interconnected in a global network, the first qualitative model of plate tectonics (Wilson 1965). The zones

Seafloor Spreading,

Fig. 1 Raff and Mason (1961) magnetic stripes recognized as symmetric about seafloor spreading axes (*arrows*) by Vine and Wilson (1965). (From Vine 1966. Reprinted with permission from AAAS)

of extension and compression are connected by a new class of faults called transform faults by Wilson, which required relative plate motion and turned out to be the most important type of fault on Earth. He showed that seafloor spreading occurring on offset mid-ocean ridge axes would produce relative motion exactly opposite to the motion the sense of offset would predict without seafloor spreading, and that earthquakes should only occur between the offset seafloor spreading axes. These radical predictions, completely different from prevailing wisdom, were soon confirmed seismically. Furthermore, by correctly interpreting the San Andreas fault as a transform fault between the Pacific and North American plates, he predicted the existence of previously unrecognized seafloor spreading offshore western North America. Vine and Wilson (1965) showed that the predicted magnetic symmetry existed in this area, where magnetic stripes had been discovered in the mid-1950s

(Mason 1958; Mason and Raff 1961; Raff and Mason 1961), over what they recognized as the Juan de Fuca Ridge (Fig. 1), and furthermore, that the pattern of stripes corresponded perfectly with the pattern of magnetic field reversals (Cox et al. 1963; McDougall and Tarling 1963), once the Jaramillo anomaly was discovered. Vine (1966) also demonstrated similar symmetry and correlation with the reversal timescale in another important data set, the Project Magnet aeromagnetic data collected over the Reykjanes Ridge south of Iceland. His color figures of these classic data sets and correlations (Vine 1968) became iconic.

The smoking gun for many scientists was the discovery by Pitman and Heirtzler (1966) of near perfect symmetry in the Eltanin-19 profile collected over the Pacific–Antarctic Ridge. Essentially every tiny wiggle seen in the magnetic anomaly profile on the Pacific plate was mirrored on the Antarctic

plate, and correlated perfectly with the magnetic reversal time scale (Fig. 2). The symmetry in these data required a symmetric axial process, with new seafloor carried away on both plates, and thus provided compelling evidence for both the Vine–Matthews and seafloor spreading hypotheses. Vine convincingly summarized this evidence in influential symposia and publications (Vine 1966, 1968), and, by the end of 1966, seafloor spreading was generally accepted by marine geophysicists, who quickly extrapolated the magnetic reversal time scale from ~10 Ma to ~80 Ma and worked out at least the basic recent evolutionary history of every ocean basin.

This scientific revolution culminated in plate tectonics the following year when Jason Morgan (Morgan 1968) and Dan McKenzie (McKenzie and Parker 1967) made the key assumption that plates behave rigidly, and extended Wilson's transform fault geometry to the sphere. They showed that transforms are small circles about rotation poles describing relative plate motion, that seafloor spreading rates increase as the sine of the angular distance away from these poles, and that it was possible to use known patterns of seafloor spreading to quantitatively predict other plate motions and plate boundary evolution.

Ridge Axis Geometry, Morphology, and Crustal Formation

Volcanism along the mid-ocean ridge system has formed the longest mountain chain on Earth (Fig. 3). As the plates slowly (at present ~0–150 mm/yr, or km/Myr, DeMets et al. 2010, with rates remarkably similar whether using magnetic anomalies or geodetic measurements such as GPS) move apart by seafloor spreading, magma from the hot asthenosphere rises to fill the crack at mid-ocean ridge axes, elevated because of the higher temperatures. Both axial depth and morphology correlate with spreading rate (Macdonald 1982). Fast-spreading ridge axes such as the East Pacific Rise generally have shallow depths and relatively smooth morphologies, with very small extensional axial summit troughs (except where these are completely buried by the latest eruption in the neovolcanic rift zone). Slow spreading ridges such as the Mid-Atlantic Ridge generally have much deeper, rougher, and higher-amplitude axial valleys (Fig. 4), except near hotspots such as Iceland where magma supply is unusually large and even slow-spreading ridges have shallow axes with fast-spreading morphology.

The asthenosphere typically melts to become mid-ocean ridge basalt in a magma chamber under the ridge axis.

Seafloor Spreading, Fig. 2 Eltanin-19 magnetic anomaly profile (*top*) from Pitman and Heirtzler (1966), shown compared with its mirror image (*middle*) and magnetic anomaly model calculated from the magnetic reversal timescale (*bottom*), assuming seafloor spreading at a constant 44 km/Myr. (From Vine 1966. Reprinted with permission from AAAS)

Some basalt is erupted onto the seafloor to form pillow basalts and lava flows, which are progressively covered by sediments as the lithosphere ages and moves away from the axis. Below the basalts are the sheeted dikes, the paths through which the lava moved from magma chambers to the surface, and below the dikes are the layered gabbros which cooled and crystallized in place (intrusives) rather than erupting at axial volcanoes (extrusives). This typical sequence of mantle ultramafics – gabbro – sheeted dikes – extrusive basalts – sediments is observed on the seafloor in tectonic windows where existing lithosphere is rifted apart, and also where slices of old ocean lithosphere are thrust into ophiolite mountain belts as in Oman and Cyprus (Karson 2002).

Vents Program website: <https://www.pmel.noaa.gov/pubs/outstand/bake2544/images/fig01a.gif> (Baker and German 2004))

Seafloor Spreading, Fig. 4 Ridge axis fault patterns and morphology as a function of spreading rate. (Modified from Macdonald 1982)

(Fig. 5). White and clear smokers occur at lower temperatures. The chemical reactions provide energy for an unusual kind of life that does not depend on photosynthesis but flourishes as chemosynthetic communities at many of these vents, rare deep-ocean oases in an otherwise extremely barren environment (Kelley et al. 2002).

Summary

Seafloor spreading was a critical step in the contentious scientific revolution from the previous static Earth paradigm to the now universally accepted plate tectonic paradigm. Today it refers to the processes creating new oceanic lithosphere where plates move apart. Seafloor spreading replaces the lithosphere destroyed by subduction and exerts important influences on Earth's chemical and biological evolution.

Hydrothermal Vents

As the new seafloor cools it contracts and cracks. Water goes down these cracks, is heated, reacts with the surrounding rocks, and comes back up as buoyant hydrothermal vents (Baker and German 2004). These occur at a range of chemistries and temperatures, up to $\sim 400^\circ\text{C}$ in black smokers, so-called because of the sulfide-rich plumes that precipitate suddenly when the superheated water is injected into the surrounding $\sim 2^\circ\text{C}$ seawater, forming sulfide chimneys

Sedimentary Basins

Magdalena Scheck-Wenderoth

Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences, Potsdam, Germany

RWTH Aachen University, Aachen, Germany

Definition

Sedimentary basins are regions of prolonged subsidence of the Earth's surface that provide the accommodation space for mineral and organic material (Allen and Allen 2013). These deposits – the sedimentary rocks – are the record of the past geological history including tectonic events, climatic conditions, changes in sea level, and other environmental modifications. In addition, sedimentary basins are long-lived, low-temperature geo-reactors in which the accumulated material experiences a variety of transformations (Bjorlykke 2010; Littke et al. 2008; Roure et al. 2009; Welte et al. 1997). As a result of these processes, basins contain our resources of fossil

fuels, groundwater, and inorganic commodities. Moreover, they are important reservoirs of heat and provide repositories for different socioeconomically relevant fluids such as CO₂, H₂, and CH₄.

Basin Types

Basins can be classified in terms of their plate-tectonic setting. The plate-tectonic Wilson cycle (Fig. 1) describes that the relative movements of plates on the sphere of the Earth result in a closed loop of *continental rifting* and breakup, ocean basin development, closure of oceans at subduction zones, and, in consequence of plate convergence, continental growth.

Basins thus can form as continental rifts that may either evolve into intracontinental basins or lead to continental breakup and ocean basin formation. New *oceanic lithosphere* (see entry ► “[Lithosphere, Oceanic](#)”) is produced along the mid-ocean ridges due to oceanic spreading. If oceanic lithosphere cools, it becomes denser and subsides in the oceanic basins that are bordered by passive continental margins. Of the latter “hot” or volcanic passive margins are distinguished from “cold” or nonvolcanic passive margins (White et al. 2003). If oceanic lithosphere cools beyond a specific threshold, it becomes too heavy to be sustained by the less dense asthenosphere and will finally descend back to the mantle at subduction zones. In these convergent settings, the descending plate is flexed downward and deep oceanic trenches develop above the down-going plate. Subduction may culminate in continent–continent collision if the oceanic lithosphere is entirely subducted and collisional fold and

thrust belts form. Loading by collision-related fold and thrust belts also causes a downward flexure of the lithosphere and foreland basins to form. The Wilson cycle may stop at any evolutionary step, because the causative forces cease to be effective. Accordingly, a continental rift not necessarily develops into an ocean basin, but may survive for hundreds of millions of years as an intracontinental basin (Heine et al. 2008; Littke et al. 2008; Cacace and Scheck-Wenderoth 2016). Finally, horizontal movements along strike-slip faults may also cause local extension and related pull-apart basins (Allen and Allen 2013; Gürbüz 2014; Petrunin and Sobolev 2008; Smit et al. 2010; Weber and DESERT Working Group 2009).

These different types of basins not only have a specific subsidence history (Xie and Heller 2009) but also a characteristic structure of the sediment fill as well as of the underlying crust and mantle lithosphere. This concerns the geometric configuration, the distribution of physical properties, and the resulting *isostatic* (see entry ► “[Isostasy](#)”) and thermal configuration. To assess the configuration of a basin, a wide spectrum of methods has to be integrated. Observations obtained from field measurements, from *deep seismic imaging* (see entry ► “[Deep Seismic Reflection and Refraction Profiling](#)”), and from wells drilled into the basin fill, potential field data, and *heat flow* (see entry ► “[Heat Flow Determinations, Continental](#)”) data, and new data sets from remote sensing need to be integrated with numerical models that simulate processes in basins at different scales.

Figure 2 shows exemplary crustal sections across the Norwegian passive margin and across the intracontinental Central European Basin System.

Basin-Forming Mechanisms

There are three main mechanisms leading to the formation of sedimentary basins (Allen and Allen 2005, 2013):

1. Extensional stresses causing the lithosphere to thin
2. Flexure of the lithosphere in response to vertical loading or compressive stresses
3. Viscous flow of the mantle causing positive or negative topography

All these mechanisms may act separately or in concert and may affect the lithosphere over a range of spatial and temporal scales.

Conceptual Models of Basin Formation

Conceptual models of basin formation (Fig. 3) attempt to integrate geophysical and geological observations describing

the geometry and the physical state of a basin into evolutionary schemes that explain basin evolution. These conceptual models also need to be consistent with data on the rheological behavior of rocks known from lab experiments as well as with data on the thermal and deformation history. All these conceptual models represent end-member scenarios and explain a large fraction of observed phenomena in specific basins.

In the concept of *passive rifting* (Fig. 3), the lithosphere is stretched in response to extensional tectonic stress. This may result in pure shear thinning (McKenzie 1978), in simple shear thinning (Wernicke 1981), or in a mixture of the two (Lister et al. 1986).

The *uniform stretching model* (McKenzie 1978) predicts a crustal and lithosphere thickness proportional to the stretching factor β where β is the ratio between initial lithosphere thickness and the stretched lithosphere thickness. Lithosphere thinning results in a passive rise of the isotherm at the thermal lithosphere–asthenosphere boundary LAB (Turcotte and Schubert 2002). This, in turn, causes additional thermal subsidence after the stress ceases to be effective, and cooling

Sedimentary Basins, Fig. 3 Conceptual models of basin formation

of the previously heated lithosphere causes a density increase. In this model, uniform and symmetric lithospheric thinning by β is accommodated by brittle faulting in the upper crust as well as by ductile flow in the lower crust and upper mantle. The uniform stretching model predicts a two-stage subsidence: (1) as a result of tectonic stretching, on a short timescale (10–20 my), and (2) as a result of thermal subsidence – on a longer timescale (50–100 my). Structurally, the uniform stretching model predicts syn-rift extensional faults in the upper crust with syn-rift sediments overlain by onlapping post-rift sediments of the thermal subsidence phase. The thermal history predicted by the uniform stretching model includes an initial heat peak due to the rise of the isotherm at the LAB to a shallower position (and thus an increase of the thermal gradient within the lithosphere) followed by continuous cooling during thermal re-equilibration.

Depth-dependent stretching (Sclater and Christie 1980) is a modification of the uniform stretching model and accounts for different stretching magnitudes in the upper brittle part of the crust by a factor β and in the deeper lithosphere by a factor γ . In the *asymmetric stretching models* (Lister et al. 1986; Wernicke 1981), crust- to lithosphere-scale listric faults accommodate large offsets in response to extensional stress and finally may lead to continental breakup with an “upper plate” margin developing from the hanging wall of the master detachment fault and a “lower plate” margin in the foot wall (Osmundsen and Ebbing 2008; Sibuet et al. 2007; Zuber et al. 1986). In particular, magma-poor margins like the Galicia-Newfoundland (Sibuet et al. 2007) are commonly explained by this mechanism.

In the concept of *active rifting*, basin initiation is caused by the impingement of a rising hot asthenospheric *mantle plume* (Allen and Allen 2005; Burov and Cloetingh 2009; Haxby et al. 1976; Turcotte and Schubert 2002). The concept of active rifting is in fact a special case of basins initiated by *dynamic topography*. The emplacement of the *mantle plume* (see entry ► “Mantle Plumes”) causes uplift and induces extensional stresses at the flanks of the uplifted area due to gravitational potential. The active rise of the isotherm may lead to surface uplift above the erosional level, and the eroded material may be removed from the system. Density increase in the lithosphere due to subsequent cooling causes surface subsidence and the formation of a sedimentary basin in the previously uplifted area. As the process is transient, the system would re-equilibrate after the thermal anomaly and the related dynamic topography stop to exist. For *isostatic* reasons, net subsidence will only occur if either igneous underplating of the crust has taken place (light crust replaced by dense underplate) or if material is removed from the system by erosion during uplift. Systematic work assessing the contribution of the three processes to subsidence (extension due to gravity potential, crustal underplating, and erosion-related mass loss) is still missing. The active rift

model predicts weak to missing syn-rift faulting, a syn-rift erosional unconformity, and a subsidence history corresponding predominantly to thermal subsidence. Actually, the active rift model predicts a subsidence history identical to a specific end-member case of (passive) depth-dependent stretching in which the mantle lithosphere is severely thinned, whereas the crust is not. However, the active rift model predicts a colder heat flow scenario than the passive rift model, as the thermal gradient is not disturbed by an initial thinning of the lithosphere.

According to the concept of dynamic topography, basins can also be initiated in response to downward flow of high-density material in the convective mantle, a process causing *negative dynamic topography*. This mechanism could be related to detached subduction slabs sinking into the asthenospheric mantle and is discussed as an explanation for the subsidence of intracontinental basins that subside over several hundreds of millions of years at a very slow rate (Allen and Allen 2005; Heine et al. 2008; Ritzmann and Faleide 2009).

Two main conceptual models exist for *flexural basins* that form as response of the flexural rigidity of the lithosphere (Watts 2001) to external loads: (1) downward flexure of the lithosphere due to vertical loading (Zhang and Bott 2000) and (2) formation of crustal- to lithosphere-scale folds in response to horizontal compressive stress, a process also called *lithosphere buckling* (Burov and Cloetingh 2009; Burov and Diament 1992; Cloetingh and Burov 2010). Both concepts predict a lack of syn-rift extensional faulting, a cold thermal scenario, and subsidence lasting only as long as the stress is effective (either vertical as load or horizontal as tectonic stress). Due to structural similarity, lithosphere buckling in response to far-field compressive tectonic stress (Burov and Cloetingh 2009; Burov and Diament 1992) can be mistaken as an expression of active rifting if the analyzed region is too small to capture the full wavelength of the buckling. Again, the different predicted subsidence and thermal histories can help to distinguish the two.

Vertical loading by sediments enhances subsidence in basins of all geodynamic settings (Watts 2001). It has recently been proposed that mineral phase transitions may also play a role for subsidence history in different tectonic settings (Kaus et al. 2005).

Geodynamic modelling studies (Braun and van der Beek 2004; Brune 2018; Buck 1991; Buitier 2014; Cacace and Scheck-Wenderoth 2016; Cloetingh et al. 1998; Huismans et al. 2005; Huismans and Beaumont 2008; Kusznir and Ziegler 1992; Lavier et al. 1999; Le Pourhiet et al. 2018; Pascal and Cloetingh 2002; Pérez-Gussinyé et al. 2006; Royden and Keen 1980; Sclater and Christie 1980; Simon et al. 2009; van Wijk 2005; Wijns et al. 2005; Zuber et al. 1986) indicate that the nature of rheological coupling between the crust and the lithospheric mantle, local strain weakening and strengthening, and the rate of extension are the dominant factors controlling not only the subsidence evolution of basins

but also if they develop in a symmetric or asymmetric style and in a narrow or wide rift mode. Recent progress toward 3D thermodynamic models illustrates that some concepts for basin formation and evolution need to be reconsidered (Burov and Gerya 2014; Le Pourhiet et al. 2018).

The Configuration of the Sediment Fill

The sediment fill can vary in thickness between a few to up to 20 km and is analyzed using stratigraphic methods (Allen and Allen 2005; Catuneanu 2006; Einsele et al. 1991; Vail et al. 1991) to assess the nature of sediments (sand, silt, shale, carbonates, evaporites), the depositional environment (continental or marine), and the climatic conditions prevailing during the time of deposition. Subsidence and deposition may alternate with nondeposition due to sea level fall or tectonic surface uplift and lead to stratigraphic gaps separating different sequences (Fig. 2). In addition, the rate of subsidence and sedimentation as well as of uplift and erosion may change with time. Stratigraphic gaps and changes in depositional conditions are expressed as unconformities separating sedimentary sequences, the analysis of which is required to understand the history of a basin.

Progressive sedimentation and subsidence goes along with changes in physical properties of the deposited sediments. The two most prominent changes are (1) an increase in temperature and (2) a decrease in porosity with increasing burial depth. The initially high porosity of each layer decreases as the load of the covering deposits increases and fluids filling the initial pores are expelled. Also, chemical compaction may lead to a loss in porosity. With decreasing porosity, physical properties like density, seismic velocity, or thermal conductivity increase.

Stratigraphic analysis is performed in field studies if the fill of a basin is accessible in outcrops due to post-depositional uplift. Most of the sedimentary basins, however, extend by their very nature (areas of enduring subsidence) into the subsurface and to large depths. Accordingly, subsurface analytical methods are required to assess their configuration. The most important of these methods is *seismic imaging*. *Seismic reflections* (see entry ► [“Deep Seismic Reflection and Refraction Profiling”](#)) originate from the contrast in impedance at discontinuities in the subsurface that can represent stratigraphic boundaries and unconformities or changes in attributes of a specific layer. The reflection seismic technique provides a picture of these interfaces in a two-way travel time that is constrained by wells. Wells provide information on the absolute depth position of stratigraphic horizons and enable the conversion of seismic travel times to depth. Furthermore, wells yield data on the thermal gradient with depth as well as on changes in lithology and petrophysical properties. Properties such as

composition, compaction, porosity, permeability, density, thermal and hydraulic conductivity, *radiogenic heat production* (see entry ► [“Radiogenic Heat Production of Rocks”](#)), and content and maturation of organic matter are measured using ► [“Geophysical Well Logging”](#) methods.

Apart from recording changes in relative sea level or climatic conditions, the configuration of the sediment fill may be influenced by deformation (Kley et al. 2008). Accordingly, sediments can be faulted, folded in response to tectonic forces, or deformed due to halokinetic movements (Hudec and Jackson 2007; Scheck-Wenderoth et al. 2008; Vendeville and Jackson 1992). This deformation can take place pre-, syn-, or postdepositionally, each of which is expressed by characteristic structural styles.

In particular, basin initiation in extensional plate-tectonic conditions is typically associated with normal faulting in the upper crust leading to a thinning of the lithosphere and to the accumulation of syn-rift deposits. After the tectonic stresses have declined, basins experience a phase of post-rift thermal subsidence and may even experience late basin inversion in response to compressive stress (Cooper and Williams 1989; Mazur et al. 2005; Sandiford 1999) (Fig. 2).

Finally, there is a feedback between surface processes and deep mechanisms in the sense that *isostatic* loading by sediments will increase total subsidence and erosion of basin flanks will cause flexural rebound (Braun 2005; Braun et al. 2008; Braun and van der Beek 2004; Garcia-Castellanos 2002; Kounov et al. 2007; Simoes et al. 2010; Van der Beek 2007; Willenbring and von Blanckenburg 2010).

The Configuration of the Crust Beneath Sedimentary Basins

The different mechanisms responsible for the thinning of the lithosphere leave characteristic traces that can be detected with geophysical observations, which, however, are not always leading to unique interpretations. The most prominent attribute of the crust beneath sedimentary basins is that it is thinned compared to neighboring regions. Deep seismic data imaging of the preserved thickness of the crust helps to determine the amount of the stretching factor β as the ratio between the initial crustal thickness as often preserved outside the basin margins and the crustal thickness beneath the basin. Crustal thinning can vary considerably across a basin with values of β largest in the area of strongest thinning. The average initial thickness of the crust may reach up to 50 km in cratonic areas, around 30 km in Phanerozoic continental domains, and less than 10 km below oceans.

As the crystalline crust is characterized by a higher density and higher velocities of seismic waves than the sediments, the interface between the two can be detected. Accordingly,

the *interpretation of gravity anomalies* (see entry ► “[Gravity Anomalies, Interpretation](#)”) and the analysis of the observed variation of seismic velocities are key to evaluate the crustal structure. Refraction seismic techniques are used to detect variations in seismic p-wave velocities at depth, whereas reflection seismic methods are useful to evaluate the changes in reflectivity of the deeper crust.

Seismic p-wave velocities (V_p) increase to values >6 km/s in the upper crystalline crust and can range up to 7.4 km/s (Christensen and Mooney 1995) depending on the composition of the crust. There is a negative correlation between the quartz content of crystalline rocks and seismic p-wave velocity as well as density. Silicic (quartz-rich) rocks are characterized by smaller velocities and lower densities than mafic rocks (Table 1). Seismic shear wave velocities are also higher for crystalline than for sedimentary rocks but are also dependent of additional parameters (Christensen and Mooney 1995). Accordingly, the V_p/V_s ratio is an additional parameter helping to interpret crustal structure (Afonso et al. 2010; Mjelde et al. 2003). As also the magnetic properties are different for mafic (Fe-rich) and silicic (Fe-poor) rocks, the *interpretation of magnetic anomalies* is an additional technique for the evaluation of the crustal structure beneath basins.

At the crust–mantle boundary (Moho), often a characteristic reflection and a sudden increase of seismic p-wave

velocity to values >8 km/s are observed in deep seismic data marking the transition to the lithospheric mantle (Bauer et al. 2000; DEKORP-BASIN Research Group 1999; Fowler 1996; Hirsch et al. 2009; Levander et al. 2006; Meissner and DEKORP Research Group 1991; Thybo and Nielsen 2009; Turcotte and Schubert 2002; Weber and DESERT Working Group 2009). This is related to the change in composition from various crustal rocks to the mantle consisting mainly of peridotite.

As less dense sediments replace a denser crystalline crust, sedimentary basins should be characterized by a negative Bouguer anomaly with highest amplitude in the basin center after re-equilibration of the isotherm. Many basins, however, are characterized by a long-wavelength negative Bouguer anomaly with positive anomalies superimposed. This observation, together with strong variations in the crustal velocity structure beneath sedimentary basins, challenges the classical concepts of crustal thinning and related Moho uplift in that they commonly occur in concert with a flat Moho (Thybo and Nielsen 2009).

Crustal bodies with seismic velocities >7 km/s, generally referred to as “high-velocity bodies,” are observed in the lower crust beneath many intracontinental rift structures, for example, the Baikal and the Kenya Rifts (Thybo and Nielsen 2009); beneath intracontinental basins, for example, in the

Sedimentary Basins, Table 1 Overview on physical properties of rocks relevant to sedimentary basins: *seismic properties* (After Christensen and Mooney 1995), *thermal properties*. (After Cermak and

Rybach 1982; Fernández et al. 2005; Förster and Förster 2000; Ritter et al. 2004; Scheck-Wenderoth and Maystrenko 2008)

Danish Basin (Nielsen and Thybo 2006); and beneath extended passive margins, for example, at the conjugate margins of the North and South Atlantic (Bauer et al. 2000; Contrucci et al. 2004; Faleide et al. 2008; Franke et al. 2007; Hirsch et al. 2009; Mjelde et al. 2002, 2005; Sibuet et al. 2007). Gravity analysis indicates that these bodies are also characterized by higher densities than the average crust (Fernández et al. 2005, 2010; Franke et al. 2007; Hirsch et al. 2009; Maystrenko and Scheck-Wenderoth 2009; Osmundsen and Ebbing 2008).

Differential thinning with depth (Huisman et al. 2005; Huisman and Beaumont 2008; Kuszniir and Ziegler 1992; Lavier et al. 1999; Lavier and Steckler 1997; Pascal and Cloetingh 2002; Sclater and Christie 1980; Steckler and Watts 1978), emplacement of magmatic material in the crust during the thinning process, and magmatic underplating (Thybo and Nielsen 2009; Burg and Gerya 2008) are some possible processes during basin formation and evolution that can be responsible for the actual configuration of the crust beneath a specific basin. The relative contributions of the processes vary strongly for different basins, and, accordingly, their relative importance in general terms is still under debate.

Moreover, structural inheritance may have a fundamental role in defining the crustal and lithosphere structure. Successive suturing of different plates in Earth history may result in a mosaic of crustal domains with contrasting physical properties, possibly also including lower crustal bodies predating the rifting process (Ebbing et al. 2009; Faleide et al. 2008; Plomerová and Babuska 2010; Scheck-Wenderoth and Lamarche 2005; van Wijk 2005; Vauchez et al. 1998; Sippel et al. 2017). In basins developing on such a substrate, such older rheological discontinuities may be reactivated to localize deformation in areas of reduced strength, thus also facilitating discontinuous stretching with depth.

The Configuration of the Mantle Lithosphere

Much less is known on the configuration of the mantle lithosphere below sedimentary basins due to the limited amount of direct observations. Though reflections and lateral variations in seismic wave velocities in the lithospheric mantle have been observed in deep seismic data, the energy used in active seismic experiments is generally not sufficient to reach depth intervals below the Moho. Also, the gravity signal from the lithospheric mantle is difficult to isolate from the cumulative signal of the entire upper mantle. Recent development in the acquisition and evaluation of passive *seismological* data (Dalton and Faul 2010; Fichtner et al. 2018; Fishwick 2010; Geissler et al. 2010; Heintz and Kennett 2005; Hieronymus and Goes 2010; Plomerová and Babuska 2010; Priestley and

McKenzie 2013; Priestley et al. 2006; Ritzmann and Faleide 2009; Rychert and Shearer 2009; Schaeffer and Lebedev 2013; Zhang and Lay 1996); electromagnetic and *magnetotelluric* methods (see entries ► [“Magnetotelluric Interpretation”](#) and ► [“Magnetotelluric Data Processing”](#)) (Jones et al. 2010), together with remote sensing gravity observation (Kaban et al. 2003; Schotman et al. 2009); as well as geochemical data (O'Reilly and Griffin 2010; Trumbull et al. 2002; Wang 2010; Kovács et al. 2018) and thermal studies (Artemieva 2009; Hasterok and Chapman 2007; Hieronymus and Goes 2010; Schaeffer et al. 2016; Lucazeau 2019) indicates that the lithospheric mantle is less homogenous than previously thought. Apart from strong differences in thickness, also considerable lateral variations in surface *heat flow* (see entry ► [“Heat Flow Determinations, Continental”](#)) are observed, with a positive correlation between the two. The LAB may be located deeper than 250 km in cratonic areas, lies at around 100 km beneath Phanerozoic continental domains and old oceans, and is close to the seafloor at mid-ocean ridges.

Agreement is established that the LAB is a fundamental boundary in plate-tectonic theory that separates the rigid plates from ductile convecting material below the plates (Artemieva 2009; Eaton et al. 2009; Jones et al. 2010). Three broad definitions in terms of a mechanical boundary layer, a thermal boundary layer, and a chemical boundary layer are based on different types of data and partly in geometrical conflict. For the evolution of sedimentary basins, the depth of the thermal LAB is especially relevant as it determines the thermal and mechanical state of the lithosphere subjected to any of the basin-forming mechanisms. Systematic mapping of lithosphere thickness beneath sedimentary basins is, however, still patchy and partly contradictory depending on the method used to derive it. The thermal LAB is interpreted as an isotherm of about 1,300 °C, and its depth corresponds to the depth where an average continental conductive geotherm intersects the mantle adiabat. This is corroborated by heat flow inversion studies in *continental lithosphere* (see entry ► [“Lithosphere, Continental”](#)) (Artemieva 2009), by combined thermal and gravity modeling (Fernández et al. 2005, 2010; Freymark et al. 2017; Hasterok and Chapman 2007; Hyndman et al. 2009; Maystrenko et al. 2013; Przybycin et al. 2015; Sippel et al. 2017; Scheck-Wenderoth and Maystrenko 2008) and by cooling models in *oceanic lithosphere* (see entry ► [“Lithosphere, Oceanic”](#)) (Crosby et al. 2006; McKenzie 1978; Sclater 2003; Stein and Stein 1992).

Isostatically, thinning of the lithospheric mantle results in net surface uplift as heavier lithospheric mantle is replaced by less dense asthenospheric material (active rift model). Only if the interaction with surface processes takes place (erosion), net subsidence takes place due to subsequent cooling of the asthenospheric material.

Heat Flow in Sedimentary Basins

The thermal field in sedimentary basins has been of primary interest in the exploration of fossil fuels (Welte et al. 1997) and gains increasing importance for the use of geothermal energy (Huenges 2010). Moreover, together with composition, temperature is a main controlling factor for the rheological behavior of the lithosphere and accordingly its deformation (Burov 2011; Violay et al. 2015a, b). The hotter the lithosphere, the weaker is its rheology and the easier it is thinned to form a sedimentary basin. Accordingly, the main controlling factors for the thermal state of a basin are its plate-tectonic setting and its evolutionary stage.

In terms of observables, surface *heat flow* measurements and temperatures measured in wells characterize the present-day thermal state of a basin, whereas the maturity of organic matter (Welte et al. 1997) and thermochronological data (Andriessen 1995; Braun 2005; Braun and van der Beek 2004; Kounov et al. 2007; Simoes et al. 2010; Van der Beek 2007; Willenbring and von Blanckenburg 2010) provide a record of the thermal history.

Different families of integrated process-oriented models attempt to reproduce these observables and indicate that several processes contribute to the heat flow in sedimentary basins. There is a first-order contrast in thermal properties between sedimentary and crystalline rocks, in that sediments are thermally less conductive and produce less radiogenic heat than crystalline crustal rocks (Table 1). The amount of heat entering the basin at the base of the sediment fill depends on the thickness and composition of the crystalline crust as well as on the depth of the thermal LAB. The mafic components of the crust and the lithospheric mantle are characterized by a high thermal conductivity but low *radiogenic heat production*. Accordingly, the shallower the LAB and the thicker and radiogenic the crystalline crust, the more heat arrives at the base of the sediments. Due to their higher porosities, the thermally low-conductive sediments act as a thermal blanket, causing heat storage in the basin (Cacace et al. 2010; Theissen and Rüpke 2009; Van Wees et al. 2009). In addition, the sediments contribute a modest but, in the sum, considerable amount of radiogenic heat to the system. Also within the sediment fill, the thermal properties may vary (Table 1) with the thermal conductivity of salt being two times larger than that of clastic sediments. The upper part of sedimentary basins may store paleoclimatic signals of previous glaciations as present-day permafrost down to more than 700 m depth attest (Majorowicz and Šafanda 2018; Szweczyk and Nawrocki 2011).

In response to the distribution of thermal properties, long-wavelength variations in temperatures in sedimentary basins (scale of hundreds of kilometers) are determined by the crustal structure and composition as well as by the thermal thickness of the lithosphere (Cacace et al. 2010; Hasterok and

Chapman 2007; Hyndman et al. 2009; Scheck-Wenderoth and Maystrenko 2008, 2013; Sclater 2003). In contrast, the short-wavelength pattern of temperature distribution (scale of kilometers and less) is controlled by the internal configuration of the sediment fill.

Heat transfer by conduction is assumed to dominate the transport of heat in the lithosphere in contrast to the *convecting mantle* (see entry ► “Mantle Convection”). Geological and geochemical data together with models of coupled fluid and heat transport (Scheck-Wenderoth et al. 2014) show that the thermal field in sedimentary basins is additionally influenced by heat transport due to moving pore fluids. Advective (fluid pressure-driven) heat transport can influence the thermal field of the sedimentary fill on the regional scale. In contrast, buoyancy-driven free convective heat transport and heat transport along faults is only locally important but needs consideration for exploration on the reservoir scale.

Summarizing, the heat flow in a specific basin may vary spatially, though some ranges can be given for different types of basins (Allen and Allen 2005, 2013). Typically, the surface *heat flow* in intracontinental basins varies between 40 and 70 mW/m², can be up to 150 mW/m² in active rifts or close to volcanic arcs, and can reach values higher than 180 mW/m² at mid-ocean ridges and oceanic rifts. In oceanic basins, surface *heat flow* decreases with increasing distance from the mid-ocean ridges according to the cooling of the lithosphere with age (Parsons and Sclater 1977; Stein and Stein 1992). While magma-poor passive margins are characterized by a rather low surface heat flow, the range of surface *heat flow* at magma-rich passive margins depends on the age of the adjacent oceanic lithosphere (Gholamrezaie et al. 2018). At young margins as in the 55-my-old North Atlantic, the surface heat flow is still controlled by the cooling of the oceanic lithosphere that is considerably thinner than the lithosphere of the continental margin. This step in the thermal LAB is consistent with observed heat flow values increasing from 45 mW/m² at the continental side to 80 mW/m² at the oceanic side of the margin (Ritter et al. 2004; Scheck-Wenderoth and Maystrenko 2008). At older passive margins as in the 130-my-old South Atlantic, an opposite trend is observed (Goutorbe and Bonneville 2008; Maystrenko et al. 2013) with about 45 mW/m² at the oceanic side of the margin to up 65 mW/m² at the continental side. As the oceanic lithosphere had sufficient time to cool and thicken, the depth of the thermal LAB is continuous and similar between the continental and the oceanic part of the system. Instead, the radiogenic heat contribution of the *continental crust* (see entry ► “Earth’s Structure, Core”) thickening toward the continent becomes the controlling factor for heat input from the lithosphere. Flexural basins are generally colder than extensional basins with average *heat flow* values around 40 mW/m² in oceanic trenches and foreland basins. The thermal signature of strike-slip basins is highly variable as it depends on the

attributes of the lithosphere on which they develop and if hydrothermal heat transport takes place along the fault zones.

Summary

The *geodynamics* of sedimentary basins results from the interaction of a variety of processes acting on different spatial and temporal scales. Geophysical and geological observations indicate that intra-plate stress and heat input from the asthenospheric mantle are first-order controlling factors. On the *continental lithosphere* (see entry ► “[Lithosphere, Continental](#)”), structural inheritance and its impact on rheology is a third major player controlling the development of sedimentary basins. Intra-plate stress determines if an extensional or a compressional basin is formed. Temperature dominantly controls the rheological behavior of the lithosphere in addition to composition. These two parameters determine if the lithosphere is thinned uniformly, depth dependently, and in a symmetric or asymmetric mode. The more layered the lithosphere rheology is, the more discontinuous and asymmetric the stretching process will be. In contrast, a lithosphere deforms in a uniform stretching mode if the crust is strongly coupled to the mantle and no significant vertical or horizontal rheology contrasts are present. In both cases, the magnitude and rates of effective stress as well as the magnitude of the heat anomaly determine if stretching takes place slow enough to allow for cooling related strain hardening or fast enough to result in continental breakup.

These deep factors interact continuously with surface processes such as deposition or erosion of sediments influenced by climatic conditions. Deposition leads to *isostatic* loading and enhanced subsidence, whereas erosion results in isostatic unloading and enhanced uplift.

Definition

Seismic data acquisition Generation of (artificial) seismic signals on land (on surface, or, buried) or in water, reception of the signals after their travel through the interior of the earth, and their (digital) recording for later analysis. Analysis of recorded seismic signals to filter (reduce/eliminate) unwanted components

Seismic data processing (noise) and create an image of the subsurface to enable geological interpretation and eventually to obtain an estimate of the distribution of material properties in the subsurface (inversion).

Introduction

Reflection seismics is akin to the “echo-in-the-well” experiment, it involves calculating the depth of the geological boundary from the two-way traveltimes (TWT) of the seismic signal and its speed.

Seismic data acquisition and processing aims mainly to obtain an image of the sedimentary basins in interior of the earth, using waves generated by “artificial” earthquakes. These images can then be used to identify locations favorable for accumulation of hydrocarbons (oil and gas), which may then be drilled to determine the ground truth – and eventually to exploit the resources. Since the first known reflection seismic experiment in 1921 near Oklahoma City, USA (Fig. 1.3, Sheriff and Geldart (1995)), reflection seismics has established itself as the most accurate technique to image the sedimentary basins for the exploration of hydrocarbons.

The phrase “seismic” instead of “seismological” in the following stresses the “man-made” nature of the waves used. Both seismics and seismology use the basic theory of wave-propagation through the earth, for which Aki and Richards (2002) is a good resource. Table 1 summarizes the important differences between the two approaches though; let us briefly look at two.

Frequency vs. period: Due to the spectral range of the signals involved, seismology traditionally uses period (s) to

describe the waves, whereas in seismics, frequency (Hz.) is used. Waves provide information about the medium through which they propagate at the scale of their wave-length, and use of higher frequencies in seismics (shorter wavelengths) leads therefore to a greater resolution (of the structure) compared to seismology.

Wave-propagation: Seismology – again historically – mostly uses refracted energy, whereas exploration seismics is often synonymous with reflection seismics, although refraction seismic exploration predates the latter.

It may be noted, however, that recently there has been a blurring of the boundaries between the two fields. This has been driven by progress both in the instrumentation (acquisition) and in theory (processing). Seismologists are increasingly using higher frequencies and reflected wavefields, and practitioners of reflection seismics are using lower frequencies and refracted phases – both with the aim to improve the imaging of their respective targets. Italicized items in Table 1 are thus changing with time.

A similar comment applies also to “noise.” Considered earlier to be a bane of imaging, it is being increasingly used in innovative ways to optimize acquisition and improve imaging; this aspect will be briefly dealt with later.

This essay will be mainly concerned with acquisition and processing of reflection seismic data. Note, however, that seismics is being increasingly applied to both shallower depths (high resolution seismics) and crustal-scale studies down to Moho and beyond (deep seismics), see ► [“Deep Seismic Reflection and Refraction Profiling”](#) for details of the latter. Seismic Data Acquisition and Processing is a broad subject, the treatment here will have to make choices based upon space constraints, etc. Some subtopics, for example, ► [“Seismic, Migration”](#) are, however, dealt with in separate essays in this volume. This essay has been updated for the 2nd

Seismic Data Acquisition and Processing, Table 1 Imaging the earth using natural/artificial earthquakes

Keyword	Seismics	Seismology
Wave source	Explosions, vibrations	Natural earthquakes
Energy penetration	Shallow	Deep
Max imaging depth	Base of crust	Whole earth
Location of source	Precisely known	Estimated postfacto
Time of occurrence	Precisely known	Estimated postfacto
Energy involved	Small-medium	Can be huge
<i>Wave propagation</i>	Mostly vertical	Mostly horizontal
<i>Frequencies mostly excited/used</i>	1–100 Hz	0.01–1 Hz.
Receivers	Geophones	Seismometers
Wave-field sampling	Dense	Sparse (getting better)
Data volume	Terrabytes	Gigabytes
Accuracy	Large	Small-medium
Main application	Oil and gas	Earth-structure
Other applications	Civil engg., crustal	Civil engg.
Investment	\$\$\$\$	\$\$

\$\$\$\$ Very → expensive; \$\$ → Expensive

edition by briefly indicating relevant advances and including references for the same. The adjective “classical” has been used at places to indicate possible recent changes of the subject/term under discussion.

The reader is assumed to be familiar with the basic theory of elasticity and wave-propagation and the related concepts of reflection, refraction, and scattering. The concept of rays will be frequently used – especially in illustrations – for convenience; real seismic signals are of course associated with wave-fronts. Similarly, the figures will depict a 2-D section of the 3-D earth.

There are many good resources available even for the narrower field of Reflection Seismic Data Acquisition and (Signal) Processing, for example, Vermeer (2002), Yilmaz (2001), Menke (1989), Liner (2004), and Sheriff and Geldart (1995); the last one also contains some historical background and material over refraction seismics. Recently, some resources have also been made available for downloading on the Internet, for example, Claerbout (1985a, b).

In this entry, all-capitals will be used to denote acronyms for jargons, of which there are quite a few (e.g., TWT above), and italicized phrases within double quotes will refer to articles elsewhere in this volume, for example, ► [“Propagation of Elastic Waves: Fundamentals”](#).

Seismic Data Acquisition

Before seismic signals can be processed, an artificial wavefield has to be generated using suitable *sources* at appropriate locations, measured by suitable *receivers* at other locations after getting reflected back from within the earth, and stored using *recorders*. Several technical and financial parameters have to be considered to obtain optimal data, for example, dense spatio-temporal sampling, power-supply, timing accuracy (GPS?), and – increasingly – HSE (Health–Safety–Environment) aspects. Design of a seismic survey (*geometry*) needs inputs from regional geology, exploration objectives, and logistical considerations.

At first confined to land, seismic surveys are now-a-days carried out mostly in marine environments in round-the-clock operations using large vessels and a lot of instrumentation; single-channel seismics has faded away in favor of multi-channel acquisition, allowing much more information to be obtained (see ► [“Single and Multichannel Seismics”](#)). Table 2 gives an overview of the equipment used under different field environments.

Several interesting theoretical- and practical-advances have been made recently in the field of seismic data acquisition and processing. These include *simultaneous* recording of wavefields *overlapping* in time and use of *noise as signal*. These will be briefly described towards the end of this entry.

Seismic Data Acquisition and Processing, Table 2 sources and receivers used in seismic surveys

Environment	Sources	Receivers
Land	Explosives/vibrators/ impact/noise	Geophones
Marine	Air/water-guns	Hydrophones/nodes
Water-bottom	Explosives/guns	Nodes/geo/hydro- phones
Onshore- offshore	Explosives/guns	Geo/hydro-phones

Seismic Sources

One needs a signal that is high in energy (amplitude) to ensure a good depth penetration and short in duration to ensure accurate determination and *separation* of the travel-times – a Dirac-Delta spike would be ideal, possessing perfect resolution, it is however a-causal. In practice, a sharp, compact, and *repeatable* signal is preferred. This quasi-idealized waveform, possessing finite temporal duration and frequency band-width (both with respect to the ambient noise), is called a *wavelet*. The source wavelet changes form as it travels through the earth due to several physical processes to be briefly discussed below – much of the later data processing aims to undo these changes.

Repeatability of the source wavelet – that is, that of its *amplitude* and *phase* content is an important pre-requisite for the later processing steps. Explosives were the initial choice for source on land, providing large energy (good depth penetration) but having non repeatable signal shape and negative environmental impact. Development of large, truck-mounted electro-mechanical vibrators have led since 1960s to their increasing use in land-seismics, with both the above disadvantages of impulsive sources reduced significantly.

In marine environment, compressed air is used – with explosion (*air gun*) or implosion (*water gun*) – to create the acoustic waves. The sources are towed by a ship together with the receivers (*single vessel seismic*) or by a separate ship (*two-ship seismics*).

There have also been experiments with shear-wave sources – both impact-type and vibratory. These – either alone or together with compressive sources – can provide extra information about the subsurface medium. For investigating shallower structures in engineering, environmental, and archeological applications, small impact-based sources, for example, weight-drops, rifles, and even portable vibrators are being frequently used and provide the required higher resolution.

Seismic Receivers

All land-seismic (and seismological) receivers (*geophones*, *seismometers*) are electro-mechanical devices that transform the relative motion of the medium in which they are embedded, into electrical voltages. Fidelity of this transformation –

both in *amplitude & phase* is important to ensure maximum information retention for later retrieval – a flat amplitude response, with no phase distortion within the band of frequencies that are of interest, would be ideal. The output of such devices can be made to be proportional to the displacement/velocity/acceleration associated with the causative motion. Dennison (1953) provides an overview of the physico-mathematical underpinnings of geophone design; see also ► [“Seismic Instrumentation”](#).

Originally, geophones were designed to move – and hence record information – only in the vertical direction. Later, the importance of recording and analyzing the entire three-dimensional elastic wavefield came to be realized. Multi-component receivers, enabling recording/analysis of both horizontal components, or all three spatial components of the ground movement are being increasingly used even in large scale surveys.

For use in water, small piezo-electric elements – hydrophones – are employed to record pressure variations – modern deployments typically consist of thousands of such elements being towed near the water surface by *streamers*, several kilometers long, which are liquid-filled plastic tubes, fitted with fins (for buoyancy), gps receivers (for location information), and fiber-optic cables (to transfer the data) to the ship.

Three-component receivers may be deployed together with hydrophones at the water bottom (4C), to record the wavefield across it, see ► [“Ocean Bottom Seismics”](#). Advances in this area have resulted in cable-free autonomous “nodes” – for both marine- and land-environments, for example, Dean et al. (2018). Besides saving cables and manpower (read: *cost*) for their deployment, they allow for complex acquisition geometries, large recording distances, and are also environmentally friendly.

Note that both sources and receivers may be deployed in *groups*, using specific patterns, which affect the generation and sampling of the wavefield due to their direction-dependent radiation/reception characteristics.

Seismic Recorder

The time-varying electrical signals output by the receivers represent *arrivals* back-scattered from different depths, all juxtaposed in time, and embedded within the ever present background noise and require storage for later processing. In the beginning, photographic films and later magnetic tapes were used for this purpose. The digital revolution starting in the 1960s, itself partly driven by the needs of seismic data-acquisition and processing, caused a complete shift to in situ digitization and digital storage. Similarly, the wires connecting the receivers to the recorder have been mostly replaced by fiber-optic cables or wireless. Modern 3-D seismic surveys record four-dimensional data – two each for sources and receivers; repeat surveys (*time-lapse seismics*) even add a fifth dimension.

Preserving the frequency, amplitude, and phase of the signal and the desired *dynamic range* are important considerations in designing the digitizing (*sampling*) unit. Digitization of this vast amount of data (wavefield) has traditionally been done honoring the *Nyquist Sampling Criterion*, which requires a uniform sampling rate of more than twice the highest frequency – or wavenumber – depending upon the domain (time/space) – present in the data. Sampling below the Nyquist rate produces artifacts (called aliases) in the digitized data at lower frequencies (or wavenumbers) and can eventually interfere with real signals that may be present there – see Claerbout (1985a) or Menke (1989) for details.

Theoretically, Nyquist rate sampling allows the reconstruction of the uniformly sampled wavefield using an infinite integral – which, clearly, is not practical. Hence, the signal received at each receiver location is usually over-sampled (e.g., at twice- or higher-Nyquist rate) to maintain high-fidelity while reconstructing the wavefield from the traces with a finite effort, without loss of information. Spatial sampling of the seismic wavefield is seldom regular and uniform and produces “gaps,” which need to be filled by interpolation; this will be briefly discussed in a later section.

Recently, the necessity of acquiring seismic data at- or above-the Nyquist criterion has come under critical review – especially in view of the resultant massive increase in the data volume. An interesting development in this field has been included towards the end of this entry.

As each *receiver (group)* corresponds to a different *channel* in the recorder, digitization in such systems (typically consisting of thousands of channels) must preserve the time-base, to enable comparison of the arrival-times between different *traces*. Also, the actual instant of the *shot* – t_0 – must be transferred from the source to the recorder and recorded; it is often used to start the recording process itself, as seismics is only interested in travel-times, that is, arrivals-times with respect to t_0 . The digitized data – uniformly sampled time-series – from each individual experiment (*shot*), consisting of multiple *traces* (output of receivers) is called a *seismic record*.

Acquisition Geometry

Assuming a *layer-cake* model (sedimentary beds parallel to the surface), early surveys deployed a number of sources and receivers along a straight line on the earth-surface to obtain a vertical cross-section of the geology below this line (2-D).

Figure 1 shows schematically the approach in such a survey and is – in spite of its simplifications – useful in understanding several basic ideas. All the five panels show the earth-surface at the top, and a reflecting boundary (*target*), parallel to it, at some depth. Numerals on the surface represent surveyed equi-distant flag-positions to denote locations. The top panel shows the first measurement, with the source at “0” and eight receivers at locations “1” thru “8”. Assuming a

Seismic Data Acquisition and Processing, Fig. 1

Schematics of seismic data acquisition by common-mid-point (CMP) profiling. Panels CSG_0 through CSG_3 represent common-source-gathers (CSG); CMP_4 is a common-mid-point gather for one common-depth-point (CDP). See text for details

homogeneous and isotropic medium, the paths predicted by Snell's law for a part of the source energy to first travel downwards to the target and then reflect upwards from it to reach the receivers are indicated by the oblique lines.

The signals output from the receivers are digitized in the recorder to yield a *seismic record*, that is, a collection of *seismic traces*. Such an ordered collection of seismic traces

is called a *gather*; having a common *source*, the record resulting from our first measurement is a *common source gather* (CSG_0), the suffix denoting source position.

Under the twin-idealizations of no background noise, and a spike-like source signal, each channel in the recorder (*seismic trace*) will consist of one single blip corresponding to the arrival time of the signal; in reality, the arrivals will have

random background oscillations due to noise, and one *wavelet* corresponding to the single reflection arrival. Assuming constant speed of propagation v and depth to the target H , it is trivial to show (e.g., Sheriff and Geldart 1995) that the travel-times to the receivers can be written as $t_x^2 = (x^2 + 4H^2)/v^2 = t_0^2 + x^2/v^2$, t_x being the arrival-time recorded by a receiver at a source-receiver *offset* of x . The travel-time curve for such a situation is thus a hyperbola – this simple relationship underlies much of seismic processing. t^2 plotted against x^2 thus yields a straight line, the slope being v^{-2} , that is, square of the *slowness* of the medium. Note that in seismics the *velocity*, which sensu-stricto is a vector, is almost always used to denote the local wave *speed* (a scalar), which is a property of the medium (rocks) ... we shall follow this usage.

Our aim is to find H , the depth to the target ($= t_0/2v$). We have thus to estimate t_0 from the rest of the reflection hyperbola. Note that the reflection points on the target for the different receivers are different.

Hence, in what has become almost universal practice, the measurement is repeated after shifting the whole set-up laterally along the measurement line, keeping all the relative distances the same. In panel 2 of Fig. 1, the source and the receivers have been shifted right by one unit; only a few ray-paths are shown for this gather (CSG_1). Similarly, gathers CSG_2 and CSG_3 are also measured and recorded. During these measurements, the same receiver locations recorded signals from different sources, so that a postmeasurement re-arrangement of the traces could also yield *common receiver gathers* (CRG), in our case we would obtain CRG_1 – CRG_{11} ; these are useful for certain processing situations.

The lowest panel of this figure shows a special kind of resorting, collecting the traces from the four *shots* with one *common reflection point* (CRP). Four traces corresponding to source/receiver combinations of 0/8, 1/7, 2/6, and 3/5 were selected respectively from the four gathers. For our simple geometry, the four ray-paths shown share two things – a *common mid-point* (CMP_4) between their respective source and receiver locations and the *common depth point* (CDP) at the target depth, the latter being the same as CRP. Such a gather is called a CMP-gather and indexed by the position of the CMP. The travel-time plot of the reflection arrivals in a CMP-gather is also a hyperbola.

The four ray-paths shown for the gather CMP_4 all have the same reflection point and thus contain information about the same subsurface geology. The arrival times of the reflection signal in the four traces are of course different, as the travel paths are different. If this difference is corrected for, then adding the four traces should increase the coherent signal (information regarding the CRP) with respect to the *random* noise. The improvement of S/N by adding N traces is given by

$$\frac{\sum(\text{N traces with identical signal})}{\sum(\text{N traces with random signal})} \approx \frac{N}{\sqrt{N}} = \sqrt{N}.$$

The improvement of the signal-to-noise (S/N) ratio is thus roughly proportional to the square-root of the number of traces added. This number (4 in our case) depends upon the survey geometry and is called the *fold* of the survey. Starting from fold 1 for $CMP_{0.5}$ (not shown), it gradually builds up to its nominal value (4 in this case) and again drops off at the other end of the survey.

Acquisition configuration can be specified by expressions describing the position of the source relative to the receivers viz. *end-on*, *split-spread*, *broad-side*, etc. Depending upon the geology and the noise regime, these configurations, as also varying *fold*, leave subtle but important *footprints* on the data.

In reality, the geology is of course not as in Fig. 1, and presence of structure (*dips*, *faults*, *folds*, etc.) is what makes hydrocarbon accumulation possible in the first place. Processing of 2-D data can remedy this situation – though only partially. Availability of more equipment and data-processing power led therefore to development of 3-D acquisition, with receivers laid out on the surface in a 2-D pattern, and sources also positioned in a different 2-D pattern, thus causing a better illumination of the subsurface by the seismic waves. Here too, the basic concept of adding *fold* number of traces in a CMP-gather holds sway – point-shaped CMPs and CDPs being replaced by finite *bins*, their sizes depending upon the survey design and objectives (see Vermeer 1990, 2002 for further insight into acquisition design).

In areas with structural complexity, the simplifying assumptions of CMP- processing break down, and the availability of computer power may make it possible – nay desirable – to process each trace of the recorded CSG separately, to try to obtain a better image (see also ► “[Seismic Imaging, Overview](#)” and ► “[Seismic, Migration](#)”).

Restricting the deployment to the surface of the earth implies – as we shall see later – a bias for horizontal structures; this was eventually removed by carrying out measurements inside bore-holes called VSP; see ► “[Vertical Seismic Profiling](#)” for details. Finally, better recording instrumentation coupled with the need to detect changes in the hydrocarbon reservoirs resulting from exploitation have given rise to *time lapse seismic* (4D), whereby repeat imaging of the same area carried out after several years of production is used to validate/improve production models for reservoirs.

Seismic Data Processing

Introduction

Reflection seismic data, acquired in the field, has to be taken through several processing steps, before it can be interpreted

in terms of the subsurface structure. The source signal, on its way down, and back up to the receivers is modified by many factors; the aim of processing is to *undo* (i.e., correct for) as many/much of these effects as possible, leaving only the effects due to the causative structure of interest (geology) to be interpreted.

Seismic data is a spatio-temporal sampling of the back-scattered seismic wavefield, an ordered collection of traces, and can be considered to be a 2/3-D data matrix along with some auxiliary information regarding location, etc. As indicated before, analysis of the recorded wavefield requires it to have been uniformly and properly sampled in all relevant dimensions. Field logistics, however, frequently causes the spatial dimension(s) of the wavefield to violate this criterion. The resulting data will then be irregularly sampled in that dimension and will need resampling. Gaps may exist even within areas of otherwise equidistant traces due to problems associated with some receiver locations (houses, factories, etc.).

Interpolating the recorded data to fill up these gaps to enable further processing requires theoretical underpinnings, for example, Gülünay (2003), Zwartjes and Sacchi (2007), and Liu and Fomel (2011). These are regularly employed to preprocess the seismic data before the real work (processing) can begin. It may be mentioned here that even after recovering uniformly sampled (spatial) wavefield obtained from an irregular acquisition geometry, the data may be aliased for coherent noise, for example, groundroll and multiples; see below for a brief explanation of these terms and ► “Seismic Noise” for details.

Recently there have been some interesting advances in this field, which economize by intentionally undercutting the Nyquist criterion during acquisition before recovering the wavefield by suitable preprocessing – these will be briefly mentioned at the end of this entry. Presently, the spatial dimension too will be assumed to have been uniformly- and properly sampled.

The traces themselves are an ordered collection of uniformly sampled amplitude values (*time-series*), with relevant information contained in their respective headers in (internationally) agreed formats. All processing steps aim to improve the spatio-temporal S/N ratio of the data by reducing the noise and/or by sharpening the wave-form (to improve the resolution).

Signal vs. Noise

Before proceeding further, it is useful to reflect on the terms *signal* & *noise*. That it is a matter of perspective is clear from this relative definition: *signal is useful noise and noise is useless signal*. In other words, someone’s noise is someone else’s signal, and vice versa. For example, the *ground-roll*, hated in reflection seismics, is useful in surface-wave

seismology and shallow-seismics. Amazingly, using noise for seismic imaging has now become a field of active research (see the section “Noise as a Seismic Source” for references).

In classical reflection seismics, signal is synonymous with *primary reflection*. *Primaries*, as these are often referred to, represent seismic energy reflected only once during its travel from source to receiver. Everything else, present in the traces, is taken to be *noise*. This includes multiply-reflected energy (*multiples*), diffractions (caused by *sharp* structures in the subsurface, for example, faults, pinch-outs), refracted arrivals, surface-waves (*ground-roll*). Nongeological noise sources include nature (wind, waves, animals) and man (traffic, drilling, industry, etc.). From processing point of view, noise could be coherent (ground-roll, water-pump, multiples), or, incoherent, each needing a different strategy. See ► “Seismic Noise” for details.

Kinematics of the Seismic Signal (Primaries)

Starting with some simple (but inaccurate) assumptions, for example, horizontal layering, constant speed, useful structural information can be extracted – a large data volume contributing to the robustness of the processing algorithms (also see ► “Seismic, Migration”). In this section, we focus on the travel-times of the waves (visualized as *rays*), see also additional information in ► “Seismic Ray Theory”.

NMO

The travel-time for a primary-reflection from a horizontal reflector, shown earlier to be hyperbolic, can be rewritten as:

$$t_x - t_0 = \frac{\sqrt{x^2 + 4H^2} - 2H}{v}. \quad (1)$$

The quantity on the left is the difference (see Fig. 2) between the oblique reflection-time at source-receiver offset (distance) x and the vertical TWT and leads to the relation:

$$\Delta t_x = \frac{2H}{v} \left(\sqrt{1 + \frac{x^2}{4H^2}} - 1 \right) = t_0 \left(\sqrt{1 + \frac{x^2}{4H^2}} - 1 \right). \quad (2)$$

Expanding the expression under square-root, and recognizing that in most seismic measurements offset $\ll$ target-depth, we obtain the approximate relation 3, which could be improved by retaining additional higher order terms.

$$\Delta t_x \approx \frac{x^2}{4vH} = \frac{x^2}{2v^2 t_0} \quad (3)$$

$\Delta t_x (= t_x - t_0)$ is called the *normal moveout* (NMO) associated with the reflection travel-time. NMO can be used to

align the primary reflection in all traces at t_0 (TWT) by removing the effect of source-receiver distance (offset), that is, by *flattening the reflector*. NMO, an important concept in seismics, is used both to first identify *primaries* and later to align them for imaging the reflector. Note that to use 3 we need to know x (source-receiver offset), v (speed), and H (target depth); in practice, x is known and iteration is used to obtain optimal values for v and H .

Dipping Bed

For a dipping reflector (Fig. 2, below), travel-time for the primary reflection is still hyperbolic, given by

$$v^2 t_0^2 = x^2 + 4H^2 + 4Hx \sin \theta. \quad (4)$$

The minimum of the hyperbola is now shifted *updip*; the quantity $t_{+x} - t_{-x}$ is a measure of the asymmetry and can be used to estimate the dip.

Seismic Data Acquisition and Processing, Fig. 2 NMO of a primary reflector; horizontal (above), dipping (below). See text for details

Many Reflectors: Layer-Cake

Dix (1955) considered the case of many reflectors parallel to the surface – a good starting model for sedimentary sequences – and showed, that here too, the travel-time curve can be approximated at short offsets by a hyperbola:

$$t_x^2 \approx t_0^2 + \frac{x^2}{v_{rms}^2}, \text{ with } v_{rms} = \sqrt{\frac{\sum v_i^2 \Delta t_i}{\sum \Delta t_i}}. \quad (5)$$

The homogeneous velocity v ($= v_{nmo}$) is now replaced by v_{rms} (root-mean-square velocity), which depends upon the velocities of the layers v_i and the vertical transit times t_i through them. V_{rms} plays a role similar to v_{nmo} in flattening the primaries in the multilayer case. Individual layer-velocities may then be computed from the Dix' equation:

$$v_n = \sqrt{\frac{v_{rmsn}^2 t_n - v_{rmsn-1}^2 t_{n-1}}{t_n - t_{n-1}}}. \quad (6)$$

Velocities in Seismics

In seismics different terms are used to denote “velocity” depending upon the context. Table 3 lists a few, along with brief explanations, some of these will be elaborated later.

NMO Stretch

After NMO correction, a time-interval Δt_x , say corresponding to a period of the wavelet recorded on a trace at an offset x , becomes Δt_0 ; the wavelet is thus distorted (*stretched*). The expression $100 (\Delta t_0 - \Delta t_x) / \Delta t_x$ is a percentage measure of this stretch – 0% implying no distortion. In practice, a threshold percentage is specified to exclude parts of data – relatively large offsets and small arrival times – from being NMO-corrected (and taking part in further processing).

Semblance: A Measure of Signal Alignment

To apply optimal NMO correction, a quantitative measure of alignment of amplitudes, across several traces, is useful. Such a measure of similarity between n (amplitude) values, called *semblance*, is defined by

Seismic Data Acquisition and Processing, Table 3 Jargons associated with the term velocity in seismics

Jargon	Brief description
v_{int}	Speed in a geological interval (assumed constant)
v_{av}	Average speed between two points along a ray path
v_{app}	Apparent speed measured by receivers in field ($= dx/dt$)
v_{nmo}	Speed used for NMO-correction (strictly, only for one layer)
v_{rms}	Dix' root-mean-square NMO velocity for layer-cake situation
v_{stk}	best velocity to stack CMP gathers
v_{mig}	best velocity to migrate the seismic data

$$S = \frac{(\sum_n val)^2}{n \sum_n val^2}, \quad \text{and } S_{\text{gate}} = \frac{\sum_{\text{gate}} (\sum_n val)^2}{\sum_{\text{gate}} (\sum_n val^2)}. \quad (7)$$

Note that semblance is a dimensionless number between 1 (perfect match) and 0 (perfect mismatch). The second form uses a time gate along the traces, generally having the width of the dominant period of the signal, for increased robustness. Semblance is used extensively in modern *reflection velocity analysis*, to evaluate the goodness of alignments of primary reflections along move-out curves computed for a range of trial velocities (Fig. 3).

Velocity: Processing Point of View

Wave-speed (called velocity in seismics) in the medium is the missing link needed to convert the travel-time information to depths required for structural interpretation – and eventually drilling. Note that *velocity* is needed to find the structure (geology), but structure is needed to find the velocity. This catch-22 situation is solved iteratively – shown schematically in Fig. 4.

Velocity is a macroscopic (wave-length-scale average) property of the rock depending upon the density and elastic properties of the minerals making up the lithology (see ► “Seismic Properties of Rocks”). In rocks of interest in seismics (*sandstone, shale, limestone*), velocity is not a good indicator of lithology, with considerable overlap in

values, with some exceptions, for example, salt, anhydrite (relatively higher velocity). Presence of *porosity and pore-fluids (water, oil, gas)* are the most important factors for this overlap and are in turn caused by the *burial history* of the rocks. Wave-propagation in fluid-filled porous media is described by Biot-Gassman theory, see Lee (2008) for references and recent developments.

Propagation velocity (the missing link) can be estimated by direct measurements (see, e.g., Sheriff and Geldart 1995 for details), which have shortcomings though (see Table 4). The velocity used for processing seismic reflection data is usually determined iteratively from the data itself and will be described later.

Amplitude Changes along the Propagation Path

Several factors cause the amplitude of the seismic waves to change as they travel from source to receiver. These can be corrected for, so as not to mask the weaker changes (signals) of interest.

Geometrical Spreading

Conservation of energy requires a continuous reduction of amplitude, as a seismic wave-front spreads through a medium – hence the term *geometrical spreading*. The loss depends upon the mode of spreading and the distance travelled (r). For primaries (body-waves), amplitude ($\propto \sqrt{\text{energy}}$) decreases $\propto r^{-1}$, whereas for ground-roll (surface-wave), the decrease is $\propto r^{-1/2}$, the latter shows why ground-rolls, with their (relatively) large amplitudes, are a big problem in seismics.

Absorption

The propagating wave continuously loses energy due to absorption too, which is a physical property of the medium, and can be described by several equivalent parameters, for example, *absorption coefficient, damping factor*, the most common being the *quality factor* of the material, $Q = 2\pi/[\text{fractional energy lost per cycle}]$. It is a dimensionless quantity, with a value of 0 implying perfect absorption and ∞ implying perfect elasticity. Absorption, with Q considered to be frequency-independent within the band-width of interest in seismics, causes relatively greater attenuation of higher frequencies – leading to a change in the waveform during propagation. See ► “Seismic Viscoelastic Attenuation” for more details.

Energy Partitioning at Interfaces

Boundaries of geological heterogeneities (layering, faults, etc.) also cause changes in the amplitude of the wavelet; such

Seismic Data Acquisition and Processing, Fig. 3 Schematic drawing showing calculation of multichannel semblance. Curved bold line represents the move-out curve for a trial velocity, and the two surrounding lines represent the boundaries of the time-gate; see text for details

Seismic Data Acquisition and Processing, Fig. 4 Iteratively solving for both structure and velocity in seismics

Seismic Data Acquisition and Processing, Table 4 Direct determination of seismic velocities and their shortcomings

Method	Shortcoming
Uphole-time	Useful only for the weathering layer
Check-shots, well-shoot	Limited depth-range, destructive
VSP	Available late in exploration, expensive
Sonic log	Available late, noisy (high-frequency)
Lab measurements	Limited availability

changes are, indeed, of prime interest in seismics. As in optics, the interaction between the wave-fronts and the geological structure depends upon their relative dimensions, that is, their radii of curvature – with specular reflections and point-scattering building the two end-members, both of which are encountered in seismics. Another concept from optics, *diffraction*, is useful to understand the complexity of the interaction between the wave-front and the medium. See ► “[Seismic Diffraction](#)”, ► “[Seismic Waves, Scattering](#)”, and ► “[Energy Partitioning of Seismic Waves](#)” for additional details.

Waveforms: Convolution, Deconvolution

Factors modifying the source signal along the path of the seismic wave may be divided as: near-source (*ns*), that is, weathering layer, earth (*e*), that is, the target geology, near-receiver (*nr*), receiver (*r*) and recorder (*rec*), with the output trace (*o*) as the final result. Each of these, denoted in Eq. 8 below by the expression in parentheses, affects (*filters*) the source wavelet (*s*). In a series of papers/reports (Robinson 2005; Treitel 2005), the MIT geophysical analysis group (GAG) laid the foundation of the *digital revolution* in seismic data processing, by examining the nature of these filters and developing methods to undo their effects. These resulted in major advances in *time-series analysis and digital filtering* (Robinson and Treitel 1964) and a critical evaluation of the (statistical) nature of earth’s reflectivity (*target geology*).

Convolutional Model of the Seismic Trace

As the source – and recorded – signals are both time-series (uniformly sampled, ordered collection of amplitudes), it is useful to represent all the other elements mentioned in the above-paragraph also as such. For a column of vertically layered reflectivity, such a time series would correspond to values equal to *RCs* placed at times converted from depths using velocities. Now, making the crucial assumption that all these filter elements are linear systems, the recorded trace can be expressed as:

$$o(t) = s(t) * ns(t) * e(t) * nr(t) * r(t) * rec(t) + n(t). \quad (8)$$

In Eq. 8, $*$ (*star*) is the convolution operator, well-known in the theory of linear systems; $n(t)$ represents some additive noise which does not follow this model, hopefully, it is mostly removed early in the processing. The time-series that transform $s(t)$ into $o(t)$ can also be interpreted as the *impulse*

response of the corresponding elements, for example, $r(t)$ is the response of the receiver to a sudden spike signal. Using *Fourier-Transforms* to change the time-series into their *spectra*, and remembering that convolution in time-domain corresponds to multiplication in frequency domain, one obtains:

$$O(\omega) = S(\omega) \cdot NS(\omega) \cdot E(\omega) \cdot NR(\omega) \cdot R(\omega) \cdot REC(\omega), \quad (9)$$

where the noise term has been neglected (see Sheriff and Geldart 1995 for introduction to linear operators and Fourier theory). Equation 9 clearly shows the *filtering* effect of the different elements, each one modifying the spectrum of the incoming signal by modifying/removing a part of its frequencies. Our aim, in seismic data processing, is to extract $e(t)$, the geological structure from the recorded signal $o(t)$.

Deconvolution as Inverse Filtering

Undoing the act of the filterings implied in Eqs. 8 and 9 is called *deconvolution* (decon), or, *inverse filtering*. Equation 9 can be rewritten as $O(\omega) = E(\omega) \cdot REST(\omega)$, where $REST(\omega)$ groups together all the elements on the right besides the geology. Then, $E(\omega)$, or $e(t)$, can be *estimated* from

$$E(\omega) \cong O(\omega) / REST(\omega), \quad \text{or,} \quad (10)$$

$$e(t) \cong o(t) * rest(t)^{-1}.$$

The approximation sign, for both forms of Eq. 10 – in frequency-domain (first), or, in time-domain (second) – is necessary, even in the *noise-free* case. Spectral division needs precautions to avoid zero-division in parts of the spectrum, where frequencies have been weakened/removed. Fortunately, addition of *noise* helps, since signals of interest in seismics exist – by definition – only above the ambient noise level. See Liner (2004), Sheriff and Geldart (1995) and Yilmaz (2001) for the stabilizing role of *spectral whitening* in decon.

Wavelet Processing

Wavelets: Let’s take a closer look at *seismic wavelet*, introduced in the section about “[Seismic Sources](#),” as a signal of finite frequency band-width and temporal duration. Using standard concepts from time-series analysis (Sheriff and Geldart 1995; Yilmaz 2001), simple examples of wavelets are:

$$a : (3, -2, 1), \quad b : (2, 3, -1) \quad \text{and} \quad c : (-1, 2, 3),$$

the numbers representing uniformly sampled amplitudes starting from $t = 0$. Remembering that squares of the amplitudes in a wave(let) are measures of energy, we see that these three wavelets, while looking very different, have the same total energy. Depending upon the energy build-up, wavelet *a* is called *minimum-delay* (energy is front loaded), *b* is *mixed-delay*, and *c* is *maximum delay*; physical (causal) wavelets are

minimum delay, although in the example, a is not strictly causal, due to the instantaneous build-up of energy at $t = 0$. In frequency domain, the expressions minimum/mixed/maximum-phase are used instead.

Wavelet estimation: *Auto-correlation* of the wavelets a - c are all symmetrical about $t = 0$, that is, have no phase information, for example, $\varphi_{bb} = (-2, 3, 14, 3, -2)$; these are Fourier Transforms of the respective power-spectra. In seismics, an estimate of the power spectrum is often available from the data. The question then arises whether an estimate of the wavelet may be obtained from it – an outline follows. Using Z -transform notation, one can write the wavelet, say c , and its auto-correlation as polynomials:

$$C(Z) = -1 + 2Z + 3Z^2, \text{ and,} \\ \Phi_{cc}(Z) = -3Z^{-2} + 4Z^{-1} + 14 + 4Z - 3Z^2,$$

Z being the *unit-delay* operator, its powers denoting time-shifts with respect to $t = 0$. According to the fundamental theorem of algebra, a polynomial of degree n in Z must have n roots, that is, it can be expressed as a product of n factors of the form: $(Z - Z_1)(Z - Z_2) \dots (Z - Z_n)$, each factor representing a basic wavelet (*doublet*). Half the doublets of an auto-correlation polynomial are minimum-delay; their product represents the Z -transform of the unique minimum-delay causative wavelet. See Yilmaz (2001) and Sheriff and Geldart (1995) for details, assumptions, critical remarks, and alternate approaches (e.g., *homomorphic deconvolution*) to deconvolution of time-series.

Wavelet manipulation: Much of seismic processing is involved with manipulating the wavelet (deconvolution in a general sense). While very powerful, it contains potential for pitfalls, if applied without a proper understanding of the suitability of the particular technique, as each decon step also causes artifacts.

Spiking decon aims to sharpen the shape of the signal, to improve temporal resolution – and interpretation. Ideally, it involves convolving the wavelet with its inverse operator, to yield a spike, that is, perfect resolution.

Zero-phasing converts the signal to one with zero-phase; the result is a symmetrical signal (a-causal) and is primarily useful for interpretation if the peak can be made to coincide with the reflecting boundary.

Any-phasing is used in merging seismic datasets of different vintages and with differing source wavelets.

General shaping groups methods to convert the signal to any desired shape optimally – using some statistical criteria.

Depending upon whether a model is available for decon, the methods could also be divided in *deterministic*, that is, model-based and *statistical*.

Deterministic Deconvolution

Vibroiseis processing: Vibrators (see the section on “[Seismic Sources](#)”) use a repeatable source signal, called *sweep*. It is a

time-limited (typically, 10–20s long) signal with the frequency continuously varying between given start- and end-values and comes in many flavors, for example, up-, down-, linear-, nonlinear-sweeps. Neglecting other terms, one could write from Eqs. 8 and 9: $o(t) = s(t) * e(t)$. The recorded signal is thus the convolution of *earth reflectivity* with the sweep signal. We could remove its effect (deconvolve) by *cross-correlating* the observed signal with the sweep (which we know precisely), a process, which is equivalent to convolving with its time-reversed version, and get

$$s(-t) * o(t) = s(-t) * s(t) * e(t) \approx \delta(t) * e(t) \approx e(t). \quad (11)$$

Due to the sweep-signal being time-limited, its auto-correlation is not a Delta-spike (ideal), but is a symmetrical (zero-phase) signal called *Klauder wavelet*. The result is thus not quite the desired earth reflectivity (although it has the correct phase) and needs further processing for improvement (see Yilmaz 2001; Liner 2004; Sheriff and Geldart 1995).

De-ghosting: The effect of large RC s in the shallow subsurface has been mentioned earlier. Figure 5 (above) shows one such situation; here the source is placed below the weathering layer, for better energy transmission towards the deeper target (ray going directly downwards). A part of the

Seismic Data Acquisition and Processing, Fig. 5 deterministic deconvolution applied to ghost (above) and reverberation (below). The near vertical ray-paths are shown obliquely for better visualization, see text for details

wave-energy also travels upwards and gets reflected down from the base of the weathering layer (ray going first up, and then down). In certain cases, the $RC_{weathering}$ could be quite large and negative. The energy reflected downwards follows with a short delay behind the direct wave and is called a *ghost*; the observed record is thus corrupted by that caused by a delayed ghost. Removing the latter from the recorded trace is called *deghosting* and is an example of model-based decon. Assuming the TWT between the source and the base of the weathering to be n samples ($= n\Delta t$), one can write: $o(t) = s(t) - Rs(t - n\Delta t)$, or, using Z-transforms,

$$O(Z) = S(Z) - RS(Z) \quad Z^n = S(Z)(1 - RZ^n).$$

$(1 - RZ^n)$ is, clearly, the Z-transform of the ghost-operator. Hence,

$$S(Z) = R(Z)(1 - RZ^n)^{-1}, \quad \text{or,} \quad s(t) = o(t) + s(t - n).$$

The last form above implies recursive filtering in the time-domain to achieve deghosting. Alternately, expanding $(1 - RZ^n)^{-1}$, the inverse-filter operator in time-domain can be written as

$$g(t)^{-1} = (1, 0, 0, \dots + R, 0, 0, \dots + R^2, 0, 0, \dots)$$

De-reverberation The lower part of Fig. 5 shows another situation, where strong reflectivity associated with the water-bottom causes long trains of high-amplitude *reverberation* of signals in the water-layer. The ray-paths shown schematically are: one primary reflection from the target, *two* multiples reflected once in the water layer, and *three* multiples reflected twice; there could be many more, posing a serious problem in marine seismics. Depending upon the depth of water, certain frequencies will, as a result, experience severe distortion (enhancement or suppression). In the simplified case of a water-column with a TWT equal to the sampling interval, and remembering that the negative reflectivity causes phase-change, the total operator (signal + reverberation) can be written as:

$$\begin{aligned} w(t) &= (1, -2R, +3R, \dots) \rightarrow W(Z) \\ &= 1 - 2RZ + 3R^2Z^2 - \dots = (1 + RZ)^{-2}. \end{aligned}$$

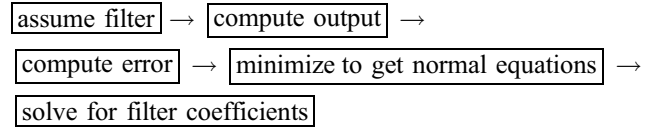

It follows that the deconvolution in this case can be achieved by the operator

$$W(Z)^{-1} = (1 + RZ)^2, \quad \text{or,} \quad w(t)^{-1} = (1, 2R, R^2).$$

This elegant operator is called the Backus filter (see Backus 1959).

Statistical Deconvolution

In the absence of a deterministic model, one could attempt to change the signal wavelet to any desired shape, by designing filters that are optimal in a statistical sense. Based upon work in information theory by Norbert Wiener and others, the applications in seismics were pioneered by the MIT-GAG group, for example, Robinson (1967). Schematically, the basic approach is:

If errors are assumed to be Gaussian, and l_2 norms are used, the operators obtained are called Wiener filters. Such *optimum filters* are used widely, for example, in

- Zero-lag spiking – to increase resolution
- Zero-phasing – to ease interpretation
- Prediction Filtering – to remove multiples which are predictable, the remnant being the prediction error, corresponding to the deeper signal

Wiener optimum filter The normal equations for the filter-coefficients f are given by the matrix equation shown in Eq. 12 in its compact form

$$\phi_{input,input} * f = \phi_{input,output}, \quad (12)$$

which relates the auto-correlation of the recorded (*input*) wavelet to its cross-correlation with the desired (*output*) wavelet. For the derivation of Eq. 12, and a detailed treatment of statistical deconvolution, see, for example, Yilmaz (2001) or Sheriff and Geldart (1995) – an example is shown below to illustrate the approach.

Spiking filter If the wavelets are all n -sample long, the Matrix Eq. 12 can be expanded as

$$\begin{pmatrix} \phi_{i,i}(0) & \phi_{i,i}(1) & \dots & \phi_{i,i}(n-1) \\ \phi_{i,i}(1) & \phi_{i,i}(0) & \dots & \phi_{i,i}(n-2) \\ \phi_{i,i}(n-1) & \phi_{i,i}(n-2) & \dots & \phi_{i,i}(0) \end{pmatrix} \begin{pmatrix} f_0 \\ f_1 \\ \vdots \\ f_{n-1} \end{pmatrix} = \begin{pmatrix} \phi_{i,d}(0) \\ \phi_{i,d}(1) \\ \vdots \\ \phi_{i,d}(n-1) \end{pmatrix} \quad (13)$$

The auto-correlation matrix $\phi_{i,i}$ in Eq. 12, with the same element in each diagonal descending from left to right, is a

Toeplitz matrix; f is a column vector with the filter-coefficients to be determined and $\phi_{i,o}$ is a column-vector with elements from the cross-correlation matrix. Equations with Toeplitz matrices can be efficiently solved by a procedure called *Levinson recursion*.

Wiener filter: a simple example Given the input wavelet $i_t = (1, -1/2)$, let us find the optimum two-element Wiener-operator to transform it to the desired wavelet $d_t = (1, 0)$, that is, a zero-delay unit-spike. We get, $\varphi_{i,i} = (5/4, -1/2)$, and, $\varphi_{i,d} = (1, 0)$. Equation 13 then becomes

$$\begin{pmatrix} 5/4 & -1/2 \\ -1/2 & 5/4 \end{pmatrix} \begin{pmatrix} f_0 \\ f_1 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \end{pmatrix},$$

$$\text{yielding } f_{\text{Wiener}} = \left(\frac{20}{21}, \frac{20}{21} \right).$$

Applying this filter to the input, we obtain the output $(20/21, -2/21, -4/21)$, which compared to the desired output, gives a squared-error of $1/21$. The ideal filter for this decon is the *inverse filter* for the input wavelet. Writing $I(Z) = 1 - Z/2$ for the Z-transform of the input, the Z-transform of the inverse-filter (which will convert the input to an ideal unit-spike) is $(1 - Z/2)^{-1} = 1 + Z/2 + Z^2/4 + \dots$, which is an infinitely long operator! For an honest comparison of its performance with that of the Wiener-filter, we apply its first two terms to the input, getting the filtered version as $(1, 0, -1/4)$; although looking better at the first glance, its squared error is $1/16$, that is, larger than that of the Wiener-filter! It can be shown that the Wiener filter is the *best* two-element filter for this problem.

Suppose the input wavelet is $(-1/2, 1)$, that is, not minimum delay, which we want to transform to a zero-delay spike. Normal equations now give the Wiener-filter as $(-10/21, -4/21)$, with the output $(5/21, -8/21, -4/21)$ and the squared error as $6/21$. Inverse filter is now $(-2, -4, -8, \dots)$, which is extremely unstable! Its first two filter-elements give the output $(1, 0, -4)$ with 16 as error! Wiener filter performs here worse than in the first case, because it was trying to convert a maximum-delay wavelet to a minimum-delay spike, but it still does better than the (finite) inverse filter. In this case, if a maximum delay spike $(0, 1)$ was desired, Wiener-filter coefficients would be $(16/21, -2/21)$, giving a filtered output of $(-8/21, 17/21, -2/21)$ with a squared error $4/21$, which is better than that for a zero-lag spike output. Table 5 summarizes the results.

Seismic Data Acquisition and Processing, Table 5 Performance of Wiener- and Inverse-filters

Input wavelet	Desired wavelet	2-point Wiener		2-point inverse	
		Filter	Error	Filter	Error
$(1, -0.5)$	$(1, 0)$	$(20/21, 8/21)$	$1/21$	$(1, 0.5)$	$1/16$
$(-1/2, 1)$	$(1, 0)$	$(-10/21, -4/21)$	$6/21$	$(-2, -4)$	16
$(-1/2, 1)$	$(0, 1)$	$(16/21, -2/21)$	$4/21$		

The Processing Flow: Putting it all Together

Most of the processing *modules (filters)* operate on the data (time-series) sequentially, the entire process resembling a *flow*, though there are a few stand-alone modules too. The operations could be on individual traces (*single-channel*), or on a gather of traces (*multichannel*). Schematically, a seismic processing flow looks like:

Modules have been developed for carrying out specific tasks within the flow, for example, static correction, band-pass filtering, stacking, migration. Usually, there is a choice of modules (algorithms) available for a specific step – each with slightly different characteristics (and artifacts) – and the proper selection of the modules for a flow needs both expertise and experience. This point is illustrated in the Fig. 6, which shows six *different* results of processing the same data.

An overview of commonly applied *corrections* (processing module) is shown in Fig. 7. Space constraints will permit us to briefly describe only selected items from this list, which itself is not exhaustive; see Yilmaz (2001) for a more detailed treatment, and ► “[Seismic Imaging, Overview](#)” for additional information. Note that some modules may be applied more than once in the flow, and also, that parts of the flow may be iteratively repeated, till a reasonable result is obtained. The latter shows the importance of quality control (Q/C), by means of visual-display and other (quantitative) tools. The decision as to whether the processing of a dataset is finished depends often on the geological objectives, technical possibilities, and managerial constraints of time and money.

Preprocessing

Editing of seismic traces is an important first step, in view of the largely automated processing sequences later. *Geometry assignment* is also an essential step at this stage and attaches acquisition information to the traces, for example, source- and receiver-coordinates. Each seismic trace is assigned a header, to store such and other information to enable efficient inter-process communication.

Prestack Processing

Static corrections These are time-invariant corrections applied to the traces, due to, for example, elevation differences, and involve up-, or, down-shifting the entire trace in time; an example of their dramatic effect can be seen in Fig. 8. The static effects due to slow lateral changes (long wavelength statics) are particularly difficult to model and can cause imaging problems. *Residual statics* involves *small* time-shifts applied late in the flow to improve the result; it uses the powerful concept of *surface-consistency* to try to correct for near-surface errors that were not modeled properly in the earlier stages. Its implementation by Rothman (1985)

Seismic Data Acquisition and Processing, Fig. 6 Seismic Data Processing has no perfect answer. Seismic cross-sections produced from the same data processed by six different contractors. (Figure from Yilmaz 2001, courtesy SEG and the author)

heralded the use of nonlinear optimization (*simulated annealing, genetic algorithm*) in seismics.

Amplitude corrections Loss of amplitude due to *geometrical spreading* and *absorption* can be corrected for using the theory described earlier; the latter needs a Q-model, in the absence of which empirical relationships based on the total travel path/time are used. A part of the record may be removed

from processing due to the presence of noise, or suspected nonprimaries; depending upon the part of the data-volume removed, one then talks about *top-mute*, *bottom-mute*, or a *generalized mute*. Similarly, a *balancing* (amplitude equalization) may be applied to several adjacent traces to compensate, in an ad hoc manner, for local variations, for example, bad receiver coupling.

Seismic Data Acquisition and Processing, Fig. 7

Components of seismic processing flow

Pre-processing

QC: edit bad traces – assign field-geometry – resample – notch-filter

Pre-stack processing

statics: elevation – datum – residual

amplitude: spreading – Q-compensation – mute – balance

filtering: band-pass – f-k – f-x – τ -p – median – notch

deconvolution: deterministic – predictive – statistical

velocity analysis: CMP sort – const. velocity stack – semblance analysis

stack: NMO correction – DMO correction – CMP stack – AGC – display

Post-stack processing

migration velocity analysis – migration – time-to-depth – display

No-stack processing

migration velocity analysis – prestack depth migration – display

Special processing

True Amplitude (AVO, DHI) – VSP – Anisotropy – image rays

Filtering, sharpness, taper Any process that removes/reduces a part of the suspected *noise* from the data is a *filter*. Frequency-filters (high-cut, low-cut, band-pass) are the simplest examples. Data $f(t)$ is transformed using Fourier theory to its spectrum $F(\omega) = A(\omega) \exp^{-i\omega t}$ in the frequency domain, the amplitudes mainly corresponding to noise are zeroed-out, and the data is transformed back to the time-domain. Development of algorithms for fast and efficient Fourier transform of time-series (FFT) have caused large scale application of digital filters.

Multichannel data enables double-transformation of $f(x, t)$ to $F(\omega, k)$, making filtering possible based upon slopes (apparent velocities) in the ω - k plane; this is particularly effective in eliminating, for example, slow travelling ground-roll (large amplitude surface waves), which often mask the primaries. An example of such filtering is shown in Fig. 9. *Notch* filters are used to remove a narrow band of frequencies, for example, a 50 Hz noise from overhead transmission line. τ -p transforms are useful in filtering multiples, and in untangling far-offset data for velocity analysis, these use the Radon domain for the decomposition (Phinney et al. 1981). A few general comments apply to all filters:

- Filtering is effective only to the extent of signal-noise separation in the transformed domain.
- For any filtering, there is a trade-off between sharp cut-offs in the transform-domain and oscillatory artifacts in time-domain – and vice versa. A compromise solution to this unavoidable problem is to apply *tapers* to smoothen the cut-off and thus minimize edge-effects.

Deconvolution This important aspect has been dealt with in some detail in an earlier section.

Stacking velocity analysis This is almost always carried out in the CMP-domain, after *re-sorting* the data. The aim is to determine the velocity model, that is, $v_{rms}(TWT)$, to be used for computing the best move-out correction for the CMP-gathers. For a suite of velocity models, hyperbolic move-out curves are computed for the range of TWTs of interest; semblances are then computed to determine how well the arrivals in the gather line-up along these curves and displayed in a contour plot in the v_{trial} -TWT domain, allowing interactive picking of an improved velocity model (Fig. 8). The process is repeated at as many CMPs as possible – sometimes grouping neighboring CMPs together for averaging, velocity being a macroscopic property. The result is a laterally varying

Seismic Data Acquisition and Processing, Fig. 8 Stacking velocity analysis using semblance (color contours). Semblance values are shown for a dataset for a range of trial velocities (horizontal- axis) and enable interactive velocity picking as a function of TWT (vertical- axis). The

right panel shows a dramatic improvement in resolution as a result of proper static correction. (Figure from Yilmaz 2001, courtesy SEG and the author)

model of v_{rms} . Equation (6) can now be used to infer interval velocities.

CMP-stack Once a reasonable velocity function has been determined, each trace in the CMP-gather (say, CMP_4 in Fig. 1) is shifted in time by subtracting the corresponding move-out corrections. The move-out corrected traces in the CMP-gather are then added (*stacked*) together to produce one trace. This process, *CMP-stack*, reduces random noise – which does not line-up, while strengthening the reflection signal – which does, and thus improves S/N ratio of the data. Note that stacking reduces the data volume too – by a factor of *fold*! Much of the power of the seismic imaging derives from this simple step, which enhances the *primary* reflections (those only once reflected) at the expense of everything else.

Zero-offset traces/sections The stack traces are also called *zero-offset* traces, the move-out correction having made the source and receiver coincident. A collection of stack traces is a stack- or zero-offset section and represents the first (albeit approximate) 2-D cross-section of the subsurface. For display purposes, CMP-stack sections may be subjected to *automatic gain control* (AGC), an extremely nonlinear time-variant amplitude scaling, to balance weaker/deeper signals and stronger/shallower ones.

Poststack Processing: Positioning Properly

The CMP-stack has one big drawback, and dips were neglected throughout, which is what we are really after. This results in many artifacts in the section, for example, crossing

Seismic Data Acquisition and Processing, Fig. 9 Use of two-dimensional Fourier Transform as an apparent-velocity filter for four marine-seismic records brings out (weaker) reflections. (Figure from Yilmaz 2001, courtesy SEG and the author)

Seismic Data Acquisition and Processing, Fig. 10 Effect of dip in positioning the reflector

layering, diffraction tails. Anticlinal structures are somewhat flattened, and synclinal structures could give rise to *bow-ties*.

Migration Fig. 10 shows the problem schematically in the CMP-domain, for the case of a trace recorded from source S at receiver R from a reflector with a dip θ . After conventional prestack processing, the zero-offset trace would be plotted on the t axis below the mid-point M . This is clearly an error, as the zero-offset ray for M should be incident normally on the reflector – at N , this correction is called *migration* (Yilmaz 2001; Sheriff and Geldart 1995).

Migration steepens and shortens energy alignments and moves these up- dip, clarifying the tangled image. Figure 11 shows an example of a successful migration. For further details, please see ► “[Seismic, Migration](#)”.

DMO Fig. 10 shows yet another error to be considered – the actual reflection point for the source-receiver combination S – R is P , and not N . Even worse, for the different S – R pairs

making-up the CMP-gather with mid-point M , the reflection points are all different, that is, are *smeared* along the reflector, the amount of smear being dip-dependent. The process used to correct for this dip-dependent part of the move-out correction is called *DMO*. In practice, this step is applied before migration as indicated in Fig. 7; Figure 10 shows the sequence:

- Reflection time is NMO corrected and plotted *below* M .
- NMO corrected time is DMO corrected and plotted below M' , the *true* zero-offset point.
- NMO + DMO corrected time is MIGRATED and plotted at P , the *reflection point*.

Time-to-depth conversion For final structural interpretation, the TWTs in the seismic section (stacked, or, migrated) need to be converted to depths, with velocity again playing the key role. For a homogeneous medium, this is just a rescaling of the vertical axis; with the velocity varying smoothly only in vertical direction (e.g., for flat sedimentary sequences), a non-uniform stretch of the vertical axis may suffice. Laterally varying velocities present depth-conversion problems though, increasing with the strength of the heterogeneity; ray-bending now needs to be taken into consideration.

No-Stack Processing: Imaging Complex Structures

In the presence of strong lateral velocity variations (e.g., below salt structures), the conceptual model used to process CMP-gathers breaks down. Removing the simplifying assumptions makes the imaging physically more reasonable, albeit at the cost of substantially increased computational effort.

Seismic Data Acquisition and Processing, Fig. 11 Migration positions energy from dipping structures properly. Here bow-tie like artifacts in the top part of panel (a) are imaged back into causative synclinal

structures in panel (b). The artifacts persisting in the bottom of panel (b) probably point to lack of interest in imaging deeper structures in this case. (Figure from Yilmaz 2001, courtesy SEG and the author)

Prestack depth migration and Migration velocity analysis

Simply put, *prestack depth migration* involves tracing the seismic energy from the source to the receiver for every recorded trace, with the philosophy that every seismic trace should be computable *if the structure and the velocity model were both known*. A detailed velocity model is essential for the success of PSDM; often a simplified model is assumed and iteratively improved using *migration velocity analysis* (MVA). For details/issues regarding 2-D vs. 3-D, time- vs. depth- and post-stack vs. prestack migration, see ► “Seismic, Migration” and Yilmaz (2001).

Special Processing

True amplitude – AVO, DHI Observed variations of the *RC* with respect to angle of incidence may be interpreted in terms of changes in lithology across the reflecting boundary (*amplitude* versus *offset*, or, *AVO*) and may even indicate the nature of the pore-fluids. Such *direct hydrocarbon indicators* (DHI) include *bright-spots*, *flat-spots*, *polarity-reversals*, etc. (see Yilmaz 2001; Sheriff and Geldart 1995). A prerequisite for such analyses is *true amplitude processing*, avoiding modules that remove differential amplitude information, for example, balancing, stacking, AGC.

Converted waves Using multicomponent receivers, it is possible to identify waves that have been converted at the reflection boundary and hence possess asymmetrical up- and down-ray-paths. Proper processing of such data, with CCP (*common conversion point*) replacing CDP, provides a better constraint for imaging.

VSP & Cross-well tomography Bore-holes can be used for placing receivers (and sources), resulting in significant noise-reduction. The first processing step now is to separate up- and down-going wavefields, for details, see ► “Vertical Seismic Profiling”.

Anisotropy Many seismic media are *anisotropic*, a common example being shales, which exhibit faster speeds parallel to the layering than across it, and require modification of procedures for proper imaging, for example, the move-out curve would no more be hyperbolic. This field is proving important for reservoir studies too, see Helbig and Thomsen (2005) for an overview and also ► “Magnetic Anisotropy”.

Some Recent Developments

Recording overlapping wavefields Several efforts have been initiated recently to gather more (denser) data without significantly adding to the recording time. Commonly referred to as *simultaneous/continuous sources*, these use rapidly firing sources, for example, airguns/vibrators in marine surveys, and record wavefields overlapping in time (*blending*), which are later separated using various flavors of *deblending*. This results in a considerable increase in spatial bandwidth due to much closer spacing of the sources. Not having to repeatedly reshoot the lines later from the intermediate source locations also leads to significant savings of time (read: *costs*) besides improving data quality by reducing/eliminating unavoidable location errors. Another variation of this approach is “simultaneously” recording sources from different azimuths for both land- and marine-surveys.

Blending/deblending in seismic acquisition mentioned above involves coding/decoding different parts of the recorded wavefield in a manner enabling their later separation. The subject is well known in communications theory; the “Cocktail Party Effect” uses differential characteristics of the desired signal (voice of a single person at a distance) to make it understandable from out of a cacophony of many others including some (loud) near ones (Cherry (1953)).

The related but different issue of intentionally recording overlapping signals in seismics is not new (Garotta 1983), although it is currently undergoing rapid development – both in theoretical and practical aspects (Beasley 2008). Carrying the idea farther, an interesting case has been reported, wherein wavefields generated by individual elements of the airgun firing at rapid but randomized intervals are being continually recorded (Hegna et al. 2019).

Simultaneous sources could be a game changer in the field of seismics due to its positive impact on several fronts – faster, cheaper, safer, and better, for example, Nakayama et al. (2019).

Randomly undersampling the wavefield The importance of properly sampling the seismic wavefield in both temporal and spatial dimensions has been stressed before, as the first step for deriving accurate structural information regarding the subsurface. Sampling in the time domain is usually not a problem albeit at the cost of the increased data volume (by the factor) associated with oversampling with respect to the Nyquist criterion.

Proper sampling in the spatial domain à la Nyquist, however, is a different story and is seldom achieved in a modern acquisition setting, owing partly to the scale of operations – the necessary preprocessing step of interpolation of traces to fill-up the “gaps” has already been mentioned.

The necessity – or otherwise – to adhere to the Nyquist criterion while sampling analog signals has been studied also by signal processing engineers. Recent work in information theory has shown that signals can indeed be recovered even from (severely) undersampled data under certain circumstances. If the signal of interest exhibits a certain structure in a transformed domain, it can be sampled below the Nyquist criterion and recovered in that domain – fortunately, this characteristic is shown by reflection seismic data too.

One of the earliest contributions in this field, specifically for the case of spatial undersampling in reflection seismics, was by Bednar (1996). In it, the possibility of *randomly* sampling the wavefield spatially was discussed and was hinted to be more efficient and economical than uniform undersampling. This is perhaps not surprising, given that imaging reflectors is essentially summing up (integration) of energy along certain specified trajectories (see ► “[Seismic, Migration](#)”), and efficient evaluation of integrals by summing values at random points is known in applied mathematics.

In practice, *random* undersampling of the signal is supposed to perform superior to *regular* undersampling as it will convert *aliased* energy (due to undersampling) into incoherent noise, which can then be easily filtered out. Hennenfent and Herrmann (2008) showed *jittery* undersampling (with respect to the Nyquist criterion) to perform even better, as it also enables control of the omnipresent gaps that need to be filled by interpolation for later reconstruction. Herrmann (2010) discusses this idea of randomized undersampling

further. Developed from the technique of *compressive sampling*, commonly used in modern electronics, e.g., digital camera and magnetic resonance imaging, it is shown to lead to a significant reduction in data volume and hence to be able to master the “curse of dimensionality” – a phrase which points to the exponential increase in data volume with each added dimension of seismic acquisition. It is again shown to be particularly effective, if the signal is sparse in a suitable transform-domain.

Further studies about the applicability of this technique to related fields, for example, ► “[Seismic, Waveform Modeling and Tomography](#)” are subjects of active current research. One may dare to state that the Nyquist sampling criterion has at last been conquered – at least as far as seismics is concerned!

Noise as a seismic source As hinted in the first edition, it is now an exciting and established field of research under the general banner of *seismic interferometry & daylight imaging*. Starting from early conjectures (Claerbout 1968) and later breakthroughs (Fink 1993, 1997), there have been both theoretical and practical advances understanding its possibilities and limits. Although this topic belongs to some other essays in this volume (► “[Seismic, Ambient Noise Correlation](#)”, ► “[Seismic Noise](#)”), a very brief introduction follows. The basic idea is that “noise” – also in seismics – contains useful information, which can be extracted by – and this is somewhat surprising – some pretty straightforward processing. Noise recorded at two locations can be used to obtain relevant medium properties in the intervening medium. This approach can also be used to place virtual sources anywhere in the medium. For an introduction to this fascinating subject, see Curtis et al. (2006); Wapenaar and Snieder (2007); Wapenaar et al. (2010a, b); Snieder and Wapenaar (2010).

Imaging vis-a-vis Inversion Imaging tries to obtain useful (drillable) structural information using large data-redundancy and simple conceptual models, whereas inversion aims at getting values for the physical parameters of the medium, using more involved theory, see ► “[Seismic Imaging, Overview](#)”. Buske et al. (2009) give a good introduction to the two approaches, whereas Weglein et al. (2009) discuss some critical underlying questions. Till recently, resolution in seismic imaging suffered from an information-gap as pointed out by Claerbout (1985b): velocity information was being obtained by kinematic analyses for apparent frequencies below ca. 2 Hz and reflectivity was being derived for frequencies above ca. 10 Hz. Recent improvements in tomographic velocity analysis and broadband data acquisition have resulted in increasingly narrowing this gap, which results in improved resolution (Nichols 2012). As shown in the Fig. 12, there is now even an information overlap between the results obtained from these two processing techniques. This, in turn, gives rise to interesting questions regarding the consistency of the high- and low-frequency results that have finally to be combined.

Seismic Data Acquisition and Processing, Fig. 12 Sketch showing the improvement in resolution in reflection seismics. In black, the famous sketch by Claerbout (1985b), showing the gap between information (accuracy) from velocity analysis and reflectivity. Advances in

tomography (red) and broadband acquisition (blue) have changed the situation essentially to that of an informational overlap. (Figure from Lambare et al. (2014), courtesy EAGE and the author)

Full wave-form inversion Obtaining the visco-elastic properties of the medium so as to be able to reproduce each seismic/seismological trace *completely* remains the ultimate goal of inversion of seismic/seismological data (see ► “Seismic, Waveform Modeling and Tomography”). This subject is currently the subject of major theoretical and applied research, the latter also profiting from considerable increase in available computational power. In the beginning, efforts were limited to achieving a reasonable match between a selected part (phase) of the observed waveform and the computed synthetic. Given improvements in acquisition, theory, and the computer power, progress is being made to reproduce larger parts of the entire wavetrain – a complete reproduction may though be never achievable. For a quick introduction to this topic, including underlying problems, and related developments in exploration geophysics, see Virieux and Operto (2009); Virieux et al. (2017); Brittan and Jones (2019). Note that *perfect inversion implies perfect imaging – and vice versa!*

Summary

The simple *echo-in-the-well* experiment mentioned at the start needs many physico-mathematical supports to analyze data obtained from the earth’s subsurface. Starting at data acquisition, these acquisition/processing modules yielding the final image resemble a pipeline (flow). Several of these have been explained briefly; for others, cross-references elsewhere in this volume have been provided.

Seismic Diffraction

Enru Liu

China University of Mining and Technology, Xuzhou, China

Definition

- Diffraction** Redistribution in space of the intensity of waves resulting from the presence of an object. It is also referred as the penetration of wave energy into areas forbidden by geometrical optics, e.g., the bending of wave energy around obstacles without obeying Snell's law as explained in Huygens' principle (generation of secondary sources).
- Diffraction wave-field** An event observed on seismic data produced by diffracted energy, resulting at the termination of reflectors (as at faults and other abrupt changes in seismic impedance), and it is characterized on seismic records and sections by a distinctive alignment.
- Diffraction tomography** An inverse technique that is used in seismic exploration to reconstruct the physical properties under investigation using wave-equation propagation.

Introduction

When a wave (elastic wave, electromagnetic wave, or sound wave) meets an object, particle, or obstacle, it is diffracted due to scattering of energy of the propagating wave (Fig. 1). However, in the literature, the terms of diffraction and scattering are often used interchangeably, and it can be sometimes confusing. Scattering and diffraction are two physical phenomena that any kind of waves can experience, but they are not the same thing. Scattering is understood in terms of particles, and behaves similarly for waves. Scattering is effectively bouncing off something. For waves, it is being absorbed and then almost immediately released in another direction. Scattering occurs because an object gets in the way of the wave. The part of the wave that strikes the object

Seismic Diffraction, Fig. 1 Problem configuration: a scattering object S bounded by the curve L with outward normal n . Upon an incidence of u_0 located at source, the total wave-field received at receiver is the superposition of the incident wave-field u_0 and the scattered wave-field u_s .

must either pass through (e.g., light through glass), be absorbed (sunburn), or be scattered (light bouncing off the wall, so we can see the wall). Diffraction is due to part of a wave being removed. It is an action taken by the part of the wave that does not strike an object. Here is an example of diffraction: Imagine a straight wave traveling forward along the surface of water. If you block the left half of the wave, the right half will not just keep moving forward, and it will expand toward the left, toward where the blocked wave would have been. A wave seems to continuously regenerate itself, always pushing forward on itself. When a section is removed, parts of the wave get pushed into the empty spot. This, in some ways, correlates to your pushing a wide row of blocks. If many people push on a few blocks each, a straight line can be maintained. If one person tries to do so, the blocks in front will tend to spread out.

In a sense, diffraction and scattering refer to a wave being redirected as a result of interacting with objects. However, a more precise definition used in optics distinguishes these two. In optics, scattering generally implies interaction of waves (or photons) with spatially uncoordinated (unordered) atoms, i.e., wave being scattered off the particles and surfaces. This means that if one looks at a picture of the scattered radiation, one would see a spatially continuous footprint. Diffraction, on the other hand, occurs when the object or part of the object is made up of ordered atoms. These atoms, being neatly arranged, “scatter” the waves or photons in a coordinated way, i.e., in specific directions, giving rise to what we can see on a film as bright spots rather. In other words, diffraction is a special type of scattering that leads to large-scale interference effects. Usually this is because the surface causing the scattering has some overall organization, such as a ruled diffraction grating or the knife-edge of a slit.

Although scattering and diffraction are not logically separate, the treatments tend to be separated, with diffraction being associated with departures from geometrical optics caused by the finite wavelength of the waves. Thus, diffraction traditionally involves apertures or obstacles whose dimensions are large compared to a wavelength. To lowest approximation the interaction of waves is described by ray tracing (geometrical optics). The next approximation involves the diffraction of the waves around the obstacles or through the apertures with a consequent spreading of the waves. Simple arguments show that the angle of diffraction of the waves are confined to the region $\theta \leq \lambda/a$ where λ is the wavelength and a is linear dimension of the aperture or obstacle (approximations considered work well if $\lambda/a \leq 1$). Note that diffraction may cause the localization of seismic waves – a phenomenon that is similar to the localization of lights in crystal (Larose et al. 2004). This phenomenon is caused by the focusing and defocusing of energy when seismic wave propagates through media with distributions of periodical or random distribution of scattering bodies.

In order to gain some perspective on these two extremely complex phenomena (diffraction and scattering), various theories and models have been developed in physics, and the limitations and validity of these theories are controlled by two ratios: object dimension a to wavelength (a/λ) and path-length L to wavelength $\lambda(L/\lambda)$. In contrast to other branches of physics, in geophysics path-length is also important as we are interested both in near field as well as far field (and often near and far fields are treated differently). We also often use the dimensionless parameters ka and kL (where $k = \omega/\lambda$ is the wave number, ω is frequency).

Diffraction Theories

Application of any diffraction model can be divided into two separate tasks. First, one must obtain the fields exiting a diffracting object (i.e., the near fields, or the boundary field values), or a reasonable approximation thereof. The second step involves propagating those fields to the desired observation point. These are distinct and separate parts of the diffraction models. Most texts do not make this separation clear. Instead, the boundary value assumptions and subsequent propagation into the far field are lumped together into one theoretical treatment. If the resulting diffraction pattern is at all inaccurate, it is difficult to determine how much of that error is due to incorrect boundary fields and how much is the result of the propagation calculation. Because of this, it is often difficult to know which model is appropriate for a particular problem.

There are a number of different models to compute diffraction wave-field due to wave scattering, including the Huygens’ Principle, the Rayleigh-Sommerfeld theory, the

Kirchhoff's diffraction theory, Taylor series perturbation theory or the high-order Born approximation, Rytov phase approximation, and a model referred to as angular spectrum of plane waves. The well-known Fraunhofer and Fresnel approximations, as they appear in most introductory texts, are derived from the Kirchhoff model. Several other methods are also available for treating diffraction problems: discrete wave-number techniques; generalized ray techniques; and various numerical methods (finite difference methods; finite element method; and boundary integral or element methods). Each of these theoretical methods and models is based on some assumptions and has its strengths and weaknesses, and each can be satisfactorily employed for some ranges of problems. The choice of an appropriate model is based on what is known about a specific problem.

If there are several objects or particles, the scattering from one object will induce further scattered fields from all the other objects, which will induce further scattered fields, from all the other objects, and so on. This process is called multiple scattering. Not all theories are applicable to multiple scattering problems (in physics, this is called many-body problem). The Kirchhoff approximation ignores multiple scatterings between any two surface points. In general, it has been considered valid for the large-scale objects. Perturbation theory based on the Taylor series expansion, also sometimes called the high-order Born approximation, is valid for the small-scale objects whose dimensions are less than a wavelength (or objects whose physical properties are not too different from background solids). The Rytov phase approximation to large-scale object is not subject to the stringent restrictions that apply to the Kirchhoff approximation. Studies have shown that the Rytov approximation improves the Kirchhoff approximation in both amplitude and phase. To some degrees, the high-order Born series approximation can account for multiple scattering between closely-spaced objects. For instance, the second-order Born approximation might be sufficient to guarantee the accuracy for general rough surfaces without infinite gradients and extremely large surface heights. In contrast to other branch of field, e.g., optics, in seismology two kinds of waves exist, compressional and shear waves. These two waves can convert to each other when one meets an object. When multiple objects exist, the conversion and interaction between different wave types due to multiple scattering can be very complex. Therefore, care must be taken when one uses any diffraction theory to solve specific geophysical problems.

Geometrical Theory of Diffraction

The geometrical theory of diffraction (GTD) is an extension of geometrical optics that accounts for wave diffraction by edges. It was introduced in 1953 by Keller (the most

commonly cited reference was published by Keller in 1962). The geometrical theory of diffraction was devised to eliminate many of the problems associated with geometrical optics. The strongest diffracted fields arise from edges, but ones of lesser strength originate from point discontinuities (tips and corners). The total field $u = (u_1, u_2, u_3)$ at an observation point $\vec{x}$ is decomposed into geometrical optic rays (the incident or reference field) u_i^0 and diffracted components u_i^d

$$u_i(\vec{x}) = u_i^0(\vec{x}) + u_i^d(\vec{x}). \quad (1)$$

The behavior of the diffracted field is based on the following postulates of GTD:

1. Wavefronts are locally plane waves.
2. Diffracted rays emerge radially from an edge.
3. Rays travel in straight lines in a homogeneous medium.
4. Polarization is constant along a ray in an isotropic medium.
5. The diffracted field strength is inversely proportional to the cross sectional area of the flux tube.
6. The diffracted field is linearly related to the incident field at the diffraction point by a diffraction coefficient (see Achenbach et al. 1982, for various analytic solutions).

GTD is a high frequency method for solving wave scattering problems from large-scale discontinuities or discontinuities in more than one dimension at the same point, and it uses ray diffraction to determine diffraction coefficients for each diffracting object-source combination. These coefficients are then used to calculate the field strength and phase for each direction away from the diffracting point. These fields are then added to the incident fields and reflected fields to obtain a total solution. Multiple scattering wave-fields cannot be easily computed using GTD.

Kirchhoff Approximation

In the Kirchhoff representation of diffracted wave-fields, the i th component of diffracted wave-field u_i is computed using

$$u_i^d(\vec{x}) = - \int_{\Sigma} [u_k(\vec{x})] c_{kjpq}^0 \left[\frac{\partial G_i^p(\vec{x}, \vec{X})}{\partial x_q} \right] n_j dS_{\vec{x}}, \quad (2)$$

where n_j is the j th component of the normal n to the surface of scattering object, $\vec{X}$ is a point on the face of the scattering object, $[u_k]$ is the k th displacement discontinuity across the object in the direction of n (object normal), and c_{kjpq}^0 is the elastic tensor of the background, which are often assumed to be isotropic. Equation 2 provides a means of evaluating the diffracted field so long as the displacement discontinuity $[u]$

on the object can be estimated accurately. Since the amplitudes and phases of $[u]$ are unknown, in the Kirchhoff approximation, these are taken to be the same as if the object were infinitely long, that is, the effect of the boundary is ignored (see Douglas and Hudson 1990; Liu et al. 1997). Therefore, the Kirchhoff approximation is a high frequency approximation, which is only applicable to diffraction from objects whose dimension is larger than the wavelength.

Perturbation Theory: Born and Rytov Approximation

The diffracted wave-field in Eq. 1 can be written as an infinite series of the Taylor series expansion and is derived by assuming that the physical property of scattering objects is written as a perturbation of background media. The Born approximation consists of taking the incident field in place of the total field as the driving field at each point in the scatterer. It is the perturbation method applied to scattering by an extended body. It is accurate if the scattered field is small, compared to the incident field, in the scatterer. It is only valid for weak scattering or when the obstacles are small compared to both the wavelength and the spacing between the objects. Clearly, it has serious limitations when dealing with large-scale objects. The simplest approximation, called single scattering or the first-order Born approximation, is to ignore the multiply scattered field between objects. This approximation has been widely used in geophysics (Hudson and Heritage 1981; Wu 1982, 1989).

The Rytov approximation linearly perturbs the phase of a wave-field with respect to model parameters such as velocity whereas the Born approximation perturbs the amplitude. When the Green's functions for point sources are replaced by Eikonal approximations, the Rytov perturbed wave-field becomes a scaled, differentiated, time-delayed version of the reference or incident wave-field.

Numerical Methods Used to Compute Diffraction Wavefield

Various numerical methods can also be used to compute diffracted wave-fields, particularly now, when highperformance computers are widely available. In geophysics, finite difference methods have been used widely in the study of scattering of elastic waves by crustal heterogeneities with continuous variation of physical properties and they have also been used to model scattering by thin cracks and large fractures (see Coutant 1989; Fehler and Aki 1978; Coates and Schoenberg 1995; Vlastos et al. 2003, 2007). Elastodynamic boundary integral equation or boundary element method has also been widely used to compute wave-fields from discrete inclusions with various spatial distributions as well as rough-surface topographic variations

(see Bouchon 1987; Pointer et al. 1998; Liu and Zhang 2001; Sanchez-Sesma and Campillo 1991, 1993).

An Example of Seismic Diffraction from a Single Fracture

Some practical applications of diffraction theories in seismology include scattering from cavities; topographic variation, fractures, cracks (Fig. 2). Here we give three examples to demonstrate the application of various theories in tackling diffraction problems. An example is given here for diffraction from a single fracture as computed using the finite difference method (Vlastos et al. 2003, 2007). The model geometry is shown in Fig. 2. The source, receivers, and fracture are situated in an ideal elastic full space ($V_p = 3300$ m/s, $V_s = 1800$ m/s, density $\rho = 2.2$ g/m³). The receiver array at which vertical and horizontal particle displacements are recorded is horizontal and 340 m above the fracture. The fracture is 300 m long. The source is located at the center of the receiver array. The source type is a vertical force. The source signal is a Ricker wavelet with a peak frequency of 25 Hz and a pulse initial time of 0.1 s. Figure 3 also shows the different kinds of waves generated by the interaction of the waves generated by the source and the fracture. The source generates both P and S waves. When they reach the fracture boundary those waves are reflected and we have PPr, PSr, SPr, and SSr waves. We calculate the theoretical ray travel-times and overlap them on the synthetic seismograms. Figure 3a, b

Seismic Diffraction, Fig. 2 Schematic representation showing diffraction from a fracture, and representation of the ray paths of the different kind of waves generated by the source that interact with the fracture

Seismic Diffraction, Fig. 3 Comparison between the theoretical ray travel-times and the synthetic seismograms generated by the modeling method: (a) the horizontal (x) and (b) the vertical (z) components

show the horizontal (x) and the vertical (z) components, respectively, of the synthetic seismograms together with the theoretical ray travel-times. As we can see from both figures, we have very good agreement between the theoretical ray travel-times and the synthetic seismograms. All types of waves are accurately represented in the synthetic seismograms. Owing to the type of source that we implement, we have strong arrivals at short offsets on the horizontal component and strong arrivals at long offsets on the vertical component. In addition to that, the diffracted waves from the tips of the fracture and the PPr and PPd waves are not visible in the horizontal component, but they are very clearly demonstrated in the vertical component and follow the theoretical travel-times. This is expected because the source causes vertical displacements on the medium, so very close to the source and very far away from it, the horizontal displacement is negligible. Another aspect of the comparison between the theoretical and the modeled data is that they give us further insight into the waveform patterns. For instance, we can see in both Fig. 3a, b that in the areas of superposition between the reflected waves from the fractures and the diffracted waves from the tips we have maximum amplitude in the wave-field, as a result of constructive interference. This gives us valuable information concerning the medium we are examining.

Diffraction Tomography

Seismic tomography is emerging as an imaging method for determining subsurface structure. When the viewangle

coverage is limited and the scale of the medium inhomogeneities is comparable with the wavelength, as is often true in geophysical applications, the performance of ordinary ray tomography becomes poor. Other tomographic methods are needed to improve the imaging process, e.g., diffraction tomography. It has been widely used in surface reflection profiling (SRP), vertical seismic profiling (VSP), and cross-hole measurements. Theoretical formulations are derived by Wu and Toksoz (1987) for two-dimensional geometry in terms of line sources along a source line and line receivers along a receiver line. The theory for diffraction tomography is based on the Born or Rytov approximation. Multisource holography, which is similar to Kirchhoff-type migration, often gives distorted images of the object. This distortion causes long tails of the image in the case of SRP and a strong noise belt in the case of VSP and is due to incomplete and nonuniform coverage of the object spectrum. The filtering operation of diffraction tomography helps in correcting the nonuniform coverage (including duplication) of the object spectrum in the reconstruction process and therefore reduces the distortions. On the other hand, multisource holography is better suited for imaging sharp boundaries with large acoustic impedance contrasts since diffraction tomography is restricted, to weak inhomogeneities. In addition, multisource holography has the flexibility to be used with an arbitrary number of sources (including a single source). Its sampling interval is not restricted by the Nyquist frequency. Numerical examples show that combined data sets (such as surface reflection data combined with VSP data or cross-hole data combined with surface data) improve the image quality.

Summary

Diffraction refers to the spatial distribution of the intensity of seismic waves resulting from the presence of an object (e.g., a hill- or valley-like topographic feature on the surface, or a fracture, cavity, or cave in the subsurface). It is also referred as the penetration of wave energy into areas forbidden by geometrical optics, e.g., the bending of wave energy around obstacles without obeying Snell's law as explained in Huygens' principle (as secondary sources). In the geophysical literature, the words of diffraction and scattering are often used interchangeably and it can be confusing. Diffraction and scattering are two different physical phenomena, but they are related to each other. Several analytic diffraction theories have been developed, e.g., geometrical theory of diffraction and Kirchhoff diffraction theory. More recently, numerical methods, such as finite difference and boundary element or boundary integral methods, are becoming increasingly used by geophysicists to simulate wave diffractions by complex variation of Earth's topography or subsurface cavities (cavities), fractures, irregular layers, etc. Geophysicists now often use the diffracted wave-field to reconstruct the subsurface physical properties (diffraction tomography) to solve the so-called inverse diffraction problem.

Seismic Discontinuities in the Transition Zone

Lev P. Vinnik

Institute of Physics of the Earth, Moscow, Russia

Definition

The transition zone (TZ) is the mantle layer bounded by the 410- and 660-km seismic boundaries. The high P-wave and S-wave velocity gradients within the TZ are caused by a series of polymorphic phase transitions, the depths (pressures) of which are controlled by temperature and composition. Structure of the TZ plays an important role in the heat/mass transfer between the upper and the lower mantle.

Mineral Physics Data on the Phase Transitions in the TZ

The most frequently used model of mantle composition is pyrolite which contains ~60% of olivine (Mg,Fe)₂SiO₄. At a depth of ~410 km olivine (α) transforms to wadsleyite (β , modified spinel). The Clapeyron slope of this transition is positive (4.0 MPa/K, Katsura et al. 2004); the increase of the S-wave velocity is ~12%. At a depth of ~550 km wadsleyite transforms to ringwoodite (γ , silicate spinel). At a depth of ~660 km ringwoodite transforms to a mixture of

perovskite (Mg,Fe)SiO₃ and magnesiowüstite (Mg,Fe)O. The S velocity contrast of this transition is comparable to that of the α/β transition. The post-spinel transition is sharp and has a negative Clapeyron slope of -2.8 MPa/K (e.g., Hirose 2002). This value is disputed and more recent estimates are in a range from -0.4 to -1 MPa/K (Ohtani and Sakai 2008).

The other components of pyrolite are pyroxenes and garnet. These components experience in the TZ more gradual transformations: the pyroxenes dissolve into garnet (majorite) and majorite transforms to perovskite near the bottom of the TZ. The Clapeyron slope of the post-majorite transition is 1.3 MPa/K (Hirose 2002). The post-spinel and post-majorite phase boundaries intersect at $1,700$ – $1,800$ °C, and the corresponding seismic discontinuity may be an effect of both transitions. At the temperatures less than $1,700$ °C the discontinuity is formed mainly by the post-spinel transition, while at the higher temperatures the post-majorite transition becomes dominant (Hirose 2002).

Seismic Methods

The models of composition and temperature of the TZ are constrained by seismic data. An increase of the seismic velocity with depth is mirrored by the increase of the apparent velocity of the P and S seismic arrivals with distance. Details can be obtained from the analysis of the related loop (triplication) in the travel times and modeling the related waveforms with synthetic seismograms.

The triplications corresponding to discontinuities in the TZ are observed at epicentral distances between $\sim 1,700$ and $\sim 3,200$ km, whereas properties of the mantle may change significantly on a scale of a few hundred kilometers. Observations of reflected and mode-converted phases of distant earthquakes provide better lateral resolution. In the neighboring field of exploration seismology, accurate mapping of discontinuities is based on observations of reflected phases. These signals are small relative to noise, and the detection is performed by using receiver arrays and stacking the recordings of different sensors with move-out time corrections. In seismology adequate receiver arrays still are few, especially in the oceans. The idea of receiver function approach in seismology is to replace receiver arrays by seismic-source arrays that can be very large and dense. The differences in the waveforms of individual earthquakes that are recorded at the same station are eliminated by appropriate frequency filtering (deconvolution).

P-wave receiver functions (PRFs) present the oldest and most usable variety of receiver functions. This technique is based mainly on observations of Ps (converted from P to S) phases. The delay of the Ps phase relative to P depends on the depth of the discontinuity and velocities along the wave-propagation paths. The amplitude of the Ps phase is

proportional to the S velocity contrast at the discontinuity. The detection of small seismic phases in PRFs is accompanied by measurements of their slowness. In a laterally homogeneous Earth, Ps phases from the TZ discontinuities differ by slowness from lithospheric reverberations that arrive in the same time window, and this difference helps to separate the signals from noise. The best results can be obtained by combining source and receiver arrays. Unfortunately, practical detection of the TZ seismic phases in noise is often based on relaxed criteria. Some of the widely cited results are obtained from noisy receiver functions which show a continuous train of positive “swells” and negative “troughs.” This interference pattern may be mistaken for a sequence of separate seismic arrivals.

S-wave receiver functions (SRFs) are complementary to PRFs and deal with the Sp phases converted from S to P. Multiple scattering at shallow discontinuities, which presents the major source of noise in PRFs, is practically absent in SRFs, because the Sp phases from large depths arrive much earlier than the scattered phases from shallow discontinuities. Another useful method is based on observations of ScS reverberations. Detection of the phases reflected from TZ discontinuities in this method is in principle similar to that employed in receiver functions and this technique can be viewed as a variety of receiver function techniques. A shortcoming of this method is its low (in comparison to PRFs and SRFs) lateral resolution. Precursors to the seismic phases SS (SH component), PP, and P'P' (SH, P, and P' waves reflected from the Earth's surface between the source and the receiver) include phases reflected from TZ discontinuities. These phases can be detected by using the receiver function approach. Lateral resolution of the SS-precursor technique (a few thousand kilometers) is by an order of magnitude lower than of P410s and P660s phases in PRFs, but the SS precursors are useful in the studies of the TZ on a global scale.

Topography and Sharpness of TZ Discontinuities

The amplitudes of seismic phases converted or reflected from the TZ discontinuities at 410- and 660-km depths vary laterally but on the average are approximately two times lower than predicted for olivine. This relationship implies that the actual composition of the TZ is broadly similar to pyrolite which contains $\sim 60\%$ of olivine.

In the literature there are numerous reports on observations of reflected phases from a discontinuity at a depth around 520 km (e.g., Flanagan and Shearer 1998). The most popular interpretation relates this discontinuity to the phase transition from wadsleyite to ringwoodite. However, the theoretical amplitudes of reflected and converted phases from the 520-km discontinuity in pyrolite should be several times lower than the observed ones and, for this reason, practically

unobservable. There are indications of a low S-wave velocity in a depth range from 450 to 500 km in the vicinities of several hotspots. Hence the seismically detectable 520-km discontinuity in hotspot regions may in reality present the base of this low-velocity layer (e.g., Vinnik et al. 2012).

The width of the 410-km discontinuity has been estimated by seismic studies since about 1993. The estimates range from 4 km to 35 km. According to Katsura et al. (2004) the width of the olivine-wadsleyite transition is from 7 to 13 km. The largest width is possible in regions of rapid mantle flow. The smallest value is characteristic of stagnant mantle with a slow vertical movement. The width of 4 km and less has no accepted explanation.

There are many observations of short-period P waves reflected from the 660-km discontinuity, which indicate that this discontinuity is sharp. However, the spectra of P660s converted phase are shifted to longer periods relative to P with implication that the 660-km boundary is a few tens of kilometers wide. This complexity may be explained with a model of two phase transitions (post-spinel and post-majorite) of different width in about the same depth range.

Analysis of PRFs demonstrates that the large, in a range of a few seconds, lateral variations of travel times of the TZ seismic phases are caused mainly by lateral heterogeneity of the upper mantle outside the TZ. These variations are similar for P660s and P410s seismic phases and can be removed by taking the difference between the P660s and P410s arrival times at the same station. Lateral variations of this difference are sensitive to changes in the TZ thickness. The data on the P660s-P410s differential times suggest that the depths to the 410- and 660-km discontinuities usually vary in a range of not more than a few kilometers or a fraction of a second in time almost everywhere, except in the anomalously hot and cold regions: hotspots and subduction zones, respectively. These normal depths of the major boundaries practically coincide with those in the IASP91 model (410 and 660 km), and correspond to the normal TZ thickness of 250 km.

The results for hotspots, most of which are located in oceans, are controversial. The related data are highly variable in quality. Therefore, instead of relying on statistics, I prefer to single out the results for Iceland, which is one of the most thoroughly investigated hotspots. The network of seismograph stations in Iceland is large, and there are several independent tomographic studies of this region. Seismic tomography and receiver functions reveal beneath Iceland a narrow columnar low-velocity body extending into the TZ, in which the 410-km discontinuity is depressed by ~ 15 km, while the 660-km discontinuity is flat. The conclusion on the flat 660-km boundary is by Du et al. (2006). The depressed 410-km discontinuity suggests that the TZ temperature is elevated by ~ 150 °C. The flat 660 km discontinuity means that either the temperature at this depth is close to normal or,

as suggested by high-pressure data (Hirose 2002), a sensitivity of depth of the transition to temperature is low.

This model is disputed by Jenkins et al. (2016) who propose that the 660-km boundary is depressed like the 410-km boundary. This depression implies that the Clapeyron slope at a depth of 660 km is positive. The positive slope is possible if the 660-km discontinuity is related with the phase transition in garnet. It should be noted that the dual interpretation of the data on topography of the 660-km discontinuity beneath Iceland depends on some poorly resolved details. The seismic data for another hotspot in the Atlantic (Cape Verde, Vinnik et al. 2012) provide clear evidence of a depression on the 410-km discontinuity and uplift of the 660-km discontinuity of comparable amplitude. Note that for the ray paths outside the columnar body beneath Iceland, the time difference between the P660s and P410s seismic phases is close to the standard time with implication that the TZ of the normal oceanic mantle has the same 250-km thickness as beneath the continents.

Broadly similar results are obtained for several other hotspots. For example, similar measurements at several stations in the region of the South Pacific superswell (Suetsugu et al. 2007) show that beneath one station the thickness of the TZ is 216 ± 19 km. The anomalous region cannot be larger than a few hundred kilometers. The average for all other stations is 248 ± 5 km, very close to the standard value of 250 km. By comparison, the SS-precursor data portray in the South Pacific a large (several thousand kilometers) region, where the TZ thickness is reduced to ~ 230 km (e.g., Flanagan and Shearer 1998). A similar region is found in the Atlantic. These data, if accepted at face value, imply that the TZ beneath oceans differs from that beneath continents, and the TZ beneath the hotspots is the normal oceanic TZ, contrary to the receiver function data. Substantial discrepancies between the results of the two methods exist in continental regions where numerous seismograph stations provide good-quality data.

Subduction zones demonstrate another kind of complexity. Temperature in subducted slabs is anomalously low and the equilibrium depth of the olivine-wadsleyite phase transition should be ~ 100 km less than in ambient mantle. However, the 410-km discontinuity in most of the presently active subduction zones apparently cannot be detected with either PRFs or other methods, most likely because the olivine-wadsleyite phase transformation is kinetically hindered and a wedge-shaped zone of olivine may persist at depths greatly exceeding 410 km. The signals from the 410-km discontinuity that are sometimes obtained in seismic studies of these regions are most likely formed outside the cold subducted lithosphere. Observations of short-period phases converted from S to P near the hypocenters of deep earthquakes show that the 660-km discontinuity in subducted slabs varies in depth but sometimes is depressed by up to ~ 50 km. This may be

explained by the negative Clapeyron slope of the post-spinel transition and a low temperature of the subducted slab. The temperature anomalies may be up to -600°C .

Seismic observations sometimes reveal a low S-wave velocity layer over the 660-km discontinuity. This feature can be explained by accumulation of oceanic crust in subduction zones above the 660-km discontinuity.

Robust evidence for an elevated differential time P660s-P410s and a depression of the 660-km discontinuity is provided by PRFs in the Alps where the active phase of Cenozoic subduction is over, but remnants of the oceanic lithosphere are present in the TZ. Similar anomalies are either found or can be expected in other regions of the Alpine belt.

The Issue of Water in the TZ

The cited results of mineral physics were obtained for the dry TZ. Many researchers examined solubility of water in minerals of the TZ (see, e.g., Ohtani and Sakai 2008). Hydration means modification of structures of the TZ minerals by incorporation of hydroxyl (OH). It appears that wadsleyite and ringwoodite may incorporate up to ~ 2.0 wt% of water, and the TZ is thought to be the main reservoir of water in Earth (e.g., Karato 2011). Pressure of the olivine-wadsleyite transition decreases by hydration by up to about 1 GPa (~ 30 km in depth), whereas the pressure of the post-spinel transition increases. The width of the two-phase loop between olivine and wadsleyite increases with increasing water content, and may reach a few tens of kilometers in depth relative to several kilometers for dry conditions. Hydration of 1 wt% lowers S velocity by 1–2%, whereas P velocities remain practically the same.

The predicted anomalies in the depth (30 km) and thickness (a few tens of kilometers) of the 410-km discontinuity are sufficiently large to be detected by PRFs. These predictions stimulated attempts to detect the effects of water in seismic data. So far the results are controversial. Karato (2011) stressed striking incompatibility between the results of different studies and concluded that frequently used seismological observations are more sensitive to the temperature and major element chemistry than to water content. The estimates of the Clapeyron slope for the post-spinel transition (between -0.4 and -1.3 MPa/K) in the dry TZ may explain only part of the observed topography on the 660-km discontinuity, but the discrepancy can be reduced in the wet TZ (Litasov et al. 2005).

A low S velocity layer atop the 410-km discontinuity may present another possible effect of hydration of the TZ. Owing to the large water solubility, the TZ may have higher water concentration than water storage capacity of the upper mantle. Then upwelling mantle material entering the upper mantle from the TZ may undergo dehydration melting.

Evidence of the low-velocity layer atop the 410-km discontinuity is obtained in PRFs and SRFs at a number of locations that include Antarctica, Africa, Siberia, North America, China, and Arabian Peninsula. Most locations of this layer seem to be associated with Cenozoic and Mesozoic mantle upwellings.

Summary

Seismic observations of the major TZ discontinuities near 410- and 660-km depths on a global scale are broadly consistent with the pyrolite mantle model. The 410-km discontinuity is related to the olivine-wadsleyite phase transition with a positive Clapeyron slope. The 660-km discontinuity is related to the post-spinel transition in the olivine component and post-majorite transition in the other components, with a negative and positive Clapeyron slope, respectively. In the normal mantle, the depths of the discontinuities are stable and in good agreement with the IASP91 model, where the thickness of the TZ is 250 km. Anomalous topography of the TZ discontinuities is related to hot and cold regions (hotspots and subduction zones, respectively). The anomalies beneath oceans are related mainly to hotspots, where the 410-km discontinuity is depressed by ~ 20 km. The corresponding temperature anomalies are up to $\sim 200^{\circ}\text{C}$. Beneath continents, except Africa and Antarctica, the anomalies are related mainly to Cenozoic subduction zones, where the 660-km discontinuity can be depressed by up to ~ 50 km. The related temperature anomalies are in a range of several hundred degrees Celsius. In spite of high water solubility in wadsleyite and ringwoodite, credible observations of seismic effects of hydration in the TZ are few. The thin low-S-velocity layer atop the 410-km discontinuity, found at a number of locations, is the exception. The low velocity can be an effect of a hydrous melt. On a regional scale the TZ may contain less well-understood complexities such as the 520-km discontinuity or a low S velocity layer between 450- and 500-km depths.

Seismic Hazard

Andrzej Kijko

Natural Hazard Centre, Africa, University of Pretoria, Pretoria, Republic of South Africa

Definition

Seismic hazard	Any physical phenomenon associated with an earthquake (e.g., ground motion, ground failure, liquefaction, and tsunami) and its effects on land, man-made structures, and socioeconomic systems that have the potential to produce a loss. The terms are used also without regard to a loss to indicate the probable level of ground shaking occurring at a given point within a certain period of time.
Seismic hazard analysis	Quantification of the ground motion expected at a particular site or selection of sites.

Deterministic seismic hazard analysis	Quantification of a single or relatively small number of individual earthquake scenarios.
Probabilistic seismic hazard analysis	Quantification of the rate (or probability) that a specified level of ground motion will be exceeded at least once at a site (or a map of sites) given all possible earthquakes during the specified exposure time.
Ground motion model (known also as ground motion prediction equation)	A mathematical equation that provides a means of predicting the level of ground shaking and its associated uncertainty at any given site or location, based on earthquake magnitude, source-to-site distance, local soil conditions, and focal mechanism.

Introduction

Estimating the ground motion that could occur at a particular site is crucial in the design of both vital structures, such as nuclear power plants, bridges, and dams, and ordinary structures, such as houses and commercial buildings. The process of assessing future earthquake ground motion parameters is called seismic hazard assessment or seismic hazard analysis. Seismologists and earthquake engineers distinguish between seismic hazard and seismic risk, although the two phrases have the same meaning in everyday usage. Seismic hazard is used to characterize the severity of the ground motion at a site regardless of the consequences, whereas risk refers exclusively to the consequences to humans and infrastructure from the occurrence of the hazard. Therefore, even a strong earthquake could have negligible risk potential if it occurred in sparsely populated and undeveloped areas. In contrast, a relatively weak seismic event in a highly developed and densely populated location poses a high risk owing to the possible loss of life and extensive infrastructure damage.

Seismic hazard analysis is performed *deterministically* when a particular earthquake scenario is considered and *probabilistically* when the likelihood or frequency of specified earthquake size and location are evaluated.

Deterministic seismic hazard analysis (DSHA) involves an initial assessment of the maximum possible earthquake magnitude $m_{\max}$ for each of the seismic sources, such as active faults or seismic source zones (SSHAC 1997). The maximum earthquake magnitude for a particular seismic source is often referred to as the maximum credible earthquake (MCE). An area with a radius of up to 450 km around the site of interest can be investigated. Assuming that each of these earthquakes will occur at the minimum possible distance from the site, the ground motion is calculated using approximate attenuation equations, known as the ground motion model (GMM).

However, this straightforward and intuitive procedure is overshadowed by the complexity and uncertainty in selecting the appropriate earthquake scenario. This creates the need for an alternative, *probabilistic* methodology free from selecting an earthquake occurrence scenario. Probabilistic seismic hazard analysis (PSHA) quantifies the rate (or probability) of exceeding various ground motion levels at a site (or a map of sites) from all earthquakes of all possible magnitudes and at all significant distances from the site of interest. Therefore, deterministic earthquake scenarios are special cases of the probabilistic approach. Depending on the scope of the project, DSHA and PSHA could be complementary, i.e., providing additional insights into the seismic hazard. The current study discusses PSHA.

In principle, any natural hazard caused by seismic activity can be described and quantified by the formalism of PSHA. As the damage caused by ground shaking quite often results in the largest economic losses, this presentation of the basic concepts of PSHA is illustrated by quantifying the likelihood of ground shaking generated by earthquakes.

The classic (Cornell 1968; McGuire 2004) procedure, known as the Cornell–McGuire procedure for PSHA, includes four steps (Fig. 1).

Step 1. Identification and parameterization of the *seismic sources* (also known as *source zones*, *seismogenic zones*, or *seismic zones*) that can affect the relevant site. These can be represented as area, fault, or point sources. Area sources are often used when a specific fault cannot be identified. In classic PSHA, uniform distribution of seismicity is assigned to each seismic source, implying that earthquakes are equally likely

to occur at any point within the source zone. Combining earthquake occurrence distributions with the source geometry results in the space, time, and magnitude distributions of earthquake occurrences. Seismic source models can be interpreted as a list of potential scenarios, each with associated earthquake magnitude, location, and seismic activity rate.

Step 2. Specification of the temporal and magnitude distributions of seismicity for each seismic source. The Cornell–McGuire approach assumes that earthquake occurrence in time is random and follows the Poissonian process. This implies that earthquake occurrences in time are statistically independent and occur at a constant rate, i.e., the occurrence of future earthquakes does not depend on the occurrence of past earthquakes. The model of earthquake magnitude recurrence used most often is the Gutenberg–Richter frequency–magnitude relation

$$\log(n) = a - bm, \quad (1)$$

where n is the number of earthquakes with a magnitude of m and a and b are parameters. It is assumed that earthquake magnitude m belongs to the domain $\langle m_{\min}, m_{\max} \rangle$, where $m_{\min}$ is the level of completeness of the earthquake catalogue and magnitude $m_{\max}$ is the upper limit of the earthquake magnitude for a given seismic source. Parameter a is the measure of the level of seismicity, whereas parameter b describes the ratio between the number of small and large events. The Gutenberg–Richter relations can be interpreted either as a cumulative relationship where n is the number of

Seismic Hazard, Fig. 1 Four steps of PSHA

events with magnitude equal or larger than m or as a density law, i.e., n is the number of earthquakes in a specific, small magnitude interval around m . Under these assumptions, the seismicity of each seismic source is described by four parameters, i.e., the (annual) rate of seismicity λ , which is equal to the parameter of the Poissonian distribution, the lower and upper limits of earthquake magnitude $m_{\min}$ and $m_{\max}$, and the b -value of the Gutenberg–Richter relation.

Step 3. The relevant parameters in PSHA include peak ground acceleration, peak ground velocity, peak ground displacement, spectral acceleration, macroseismic intensity, strong ground motion duration, and the like. Most ground motion models available today are empirical and depend on the earthquake magnitude, source-to-site distance, type of faulting, and local site conditions. Therefore, the third step, i.e., choosing an appropriate ground motion model, is crucial, as, quite often, it is a major contributor to the formal uncertainty in the estimated PSHA.

Step 4. Calculations of the ultimate result of PSHA in terms of a *seismic hazard curve*, i.e., the annual probability of exceeding a specified ground motion parameter at least once. An alternative definition of the hazard curve is the frequency of exceedance vs ground motion amplitude. This calculation integrates the uncertainties in the earthquake location, earthquake magnitude, and ground motion model into the probability that the relevant ground motion parameter will be exceeded at the specified site during the specified time interval.

Cornell–McGuire PSHA Methodology

Conceptually, the computation of a seismic hazard curve is fairly simple (Kramer 1996). Assuming that seismic hazard is characterized by ground motion parameter Y , the probability of exceeding a specified value y , $P[Y \geq y]$, is calculated for an earthquake of particular magnitude located at a possible source and then multiplied by the probability that such a particular earthquake will occur. The computations are repeated and summed for the entire range of possible magnitudes and earthquake locations. The resulting probability $P[Y \geq y]$ is calculated by utilizing the total probability theorem

$$P[Y \geq y] = \sum P[Y \geq y|E_i]P[E_i] \quad (2)$$

where

$$P[Y \geq y|E_i] = \int \cdots \int P[Y \geq y|x_1, x_2, x_3, \dots] \times f_i(x_1)f_i(x_2|x_1)f_i(x_3|x_1, x_2) \cdots dx_3 dx_2 dx_1 \quad (3)$$

$P[Y \geq y|E_i]$ denotes the probability of ground motion parameter $Y \geq y$ at the relevant site when an earthquake

occurs within seismic source i . The variables x_i ($i = 1, 2, \dots$) are uncertainty parameters that influence Y . In the classic approach, developed by Cornell (1968) and later extended to accommodate ground motion uncertainty, the parameters of ground motion are earthquake magnitude M and earthquake distance R . Functions $f(\cdot)$ are probability density functions (PDFs) of parameters x_i . Assuming that $x_1 \equiv M$ and $x_2 \equiv R$, the probability of exceedance (3) takes the form:

$$P[Y \geq y|E_i] = \int_{m_0}^{m_{\max}} \int_{R|M} P[Y \geq y|m, r] f_M(m) f_{R|M}(r|m) dr dm, \quad (4)$$

where $P[Y \geq y|m, r]$ denotes the conditional probability that the chosen ground motion level y is exceeded for a given magnitude and distance, $f_M(m)$ is the probability density function (PDF) of earthquake magnitude, and $f_{R|M}(r|m)$ is the conditional PDF of the distance from the earthquake for a given magnitude. The conditional PDF of the distance $f_{R|M}(r|m)$ arises in specific instances, such as a seismic source being represented by a fault rupture. As the earthquake magnitude depends on the length of the fault rupture, the distance to the rupture and the resulting magnitude are correlated. In Eq. (4) the magnitude m_0 is chosen on the basis of the minimum magnitude that will cause damage or loss. In most PSHA, the m_0 is set in the range of 4.0–5.0.

The standard choice for the probability $P[Y \geq y|m, r]$ is a normal, complementary, cumulative distribution function (CDF), based on the assumption that the ground motion parameter y is a log-normal random variable, $\ln(y) = g(m, r) + \varepsilon$, where ε is a random error. The mean value of $\ln(y)$ and its standard deviation are known and are defined as $\overline{\ln(y)}$ and $\sigma_{\ln(y)}$, respectively. In most engineering applications of PSHA, it is assumed that earthquake magnitudes follow the Gutenberg–Richter relation (1), which implies that $f_M(m)$ is a negative exponential distribution, shifted from zero to level of completeness $m_{\min}$, and truncated from the top by $m_{\max}$

$$f_M(m) = \frac{\beta \exp[-\beta(m - m_{\min})]}{1 - \exp[-\beta(m_{\max} - m_{\min})]} \quad (5)$$

In Eq. (5), $\beta = b \ln 10$, where b is the parameter of the Gutenberg–Richter frequency–magnitude relation (1). It should be noted that the truncation of the classic Gutenberg–Richter frequency–magnitude relation is obligatory to ensure that the seismic energy released by the seismogenic process is finite.

If n_S seismic sources $\{E_i, i = 1, \dots, n_S\}$ can be distinguished in the vicinity of the relevant site, each with an annual average rate of earthquake occurrence λ_i , the total average annual rate of events with a site ground motion level y or more takes the form

$$\lambda(y) = \sum_{i=1}^{n_s} \lambda_i P[Y \geq y | E_i], \quad (6)$$

After assuming that in every seismic source, earthquake occurrences in time follow a Poissonian distribution, the probability that y , a specified level of ground motion at a given site, will be exceeded at least once within any time interval t is

$$P[Y > y; t] = 1 - \exp[-\lambda(y)t]. \quad (7)$$

For $t = 1$ year, the plot $P[Y > y; t]$ vs ground motion parameter y is the *hazard curve* – the ultimate product of PSHA (Fig. 2). For small probabilities, less than 0.05,

$$\begin{aligned} P[Y > y; t = 1] &= 1 - \exp[-\lambda] \\ &\cong 1 - \left(1 - \lambda + \frac{1}{2}\lambda^2 - \dots\right) \cong \lambda, \end{aligned} \quad (8)$$

which means that the probability (7) is approximately equal to $\lambda(y)$. This shows that PSHA can be characterized interchangeably by the annual probability (7) or by the rate of seismicity (6). Often, practitioners prefer to describe seismic hazard in terms of frequency rather than probability. Frequencies have a clear physical meaning and, following Eq. (6), they are additive. Therefore, frequencies facilitate assessing the individual hazard contribution from each seismic source/area and support the optimal design decision and choice of alternative sites for structure location.

In the Cornell–McGuire procedure for PSHA, it is assumed that the earthquakes in the catalogue are independent events. As clusters of seismicity, or foreshocks and

aftershocks, violate this assumption, these dependent events are removed from the catalogue before computing PSHA. However, removing such dependent events is one of the most controversial practices in current PSHA.

Estimation of Seismic Source Parameters

Following the Cornell–McGuire PSHA procedure, each seismic source is characterized by four parameters:

- Level of completeness of the seismic data, $m_{\min}$.
- The annual rate of seismic activity λ , corresponding to the magnitude $m_{\min}$
- B -value of the Gutenberg–Richter frequency–magnitude relation
- The upper limit of earthquake magnitude $m_{\max}$

Estimation of $m_{\min}$. The level of completeness of the seismic event catalogue, $m_{\min}$, can be estimated in at least two different ways.

The first approach is based on information provided by the seismic event catalogue, where $m_{\min}$ is determined from the deviation of the empirical and assumed earthquake magnitude distribution model. In most instances, the model is based on the Gutenberg–Richter relation (1). Occasionally, $m_{\min}$ is estimated from a comparison of the day-to-night ratio of events. Despite being used widely, the approach based on the seismic event catalogue has several weak points. One of these is the prerequisite knowledge of the spatial and temporal earthquake occurrence model.

The second approach utilizes information on the detection capabilities and signal-to-noise ratio of the seismic stations that record seismic events. The approach is free from assumptions that seismic events are statistically independent and that they form a stationary process. Choosing the most appropriate procedure for estimating $m_{\min}$ depends on several factors, such as knowledge of the time history and evolution of the seismic network and data collection and processing.

Estimation of the rate of seismic activity λ and the b -value of Gutenberg–Richter. The maximum likelihood procedure is the conventional approach to estimate the seismic source recurrence parameters λ and b . If successive earthquakes are independent in time, the number of earthquakes with magnitude equal to or exceeding a level of completeness $m_{\min}$ follows the Poissonian distribution, with the parameter equal to the annual rate of seismic activity λ . The maximum likelihood estimator of λ is then equal to n/t , where n is the number of events occurring within time interval t .

For specified $m_{\max}$, the maximum likelihood estimator of the b -value of the Gutenberg–Richter relation can be obtained from the recursive solution of the equation:

Seismic Hazard, Fig. 2 Example of a peak ground acceleration (PGA) seismic hazard curve and its confidence intervals

$$1/\beta = \bar{m} - m_{\min} + \frac{(m_{\max} - m_{\min}) \exp[-\beta(m_{\max} - m_{\min})]}{1 - \exp[-\beta(m_{\max} - m_{\min})]}, \quad (9)$$

where $\beta = b \ln 10$ and $\bar{m}$ is the sample mean of earthquake magnitude. If the range of earthquake magnitudes $\langle m_{\max} - m_{\min} \rangle$ exceeds two magnitude units, the solution of Eq. (9) can be approximated by the well-known Aki–Utsu estimator

$$\beta = 1/(\bar{m} - m_{\min}). \quad (10)$$

In most instances, estimating λ and the b -value by the above simple formulas cannot be performed because seismic event catalogues are incomplete. Generally, seismic event catalogues contain three types of data, namely, prehistoric (paleo-) events, the incomplete largest historical events that usually occurred over a period of a few hundred years, and the instrumental data, recorded over the last 100 years. The completeness of instrumental data often varies with time (Fig. 3).

Obviously, combining and utilizing all three types of data would be the optimal procedure to apply in such an instance. Additionally, such a procedure should accommodate information on highly uncertain sizes (magnitudes/focal intensities) of paleo- and historical earthquakes and unavoidable uncertainties associated with the applied earthquake occurrence models. The procedure developed by Smit et al. (2019) extends the well-known approach developed by Weichert (1980), which does not allow for the paleo- and historic part of the catalogue.

Estimation of $m_{\max}$. The maximum magnitude $m_{\max}$ is defined as the upper limit of magnitude for a given seismic source. Often, the magnitude of the largest possible earthquake or maximum credible earthquake is synonymous with the upper limit of earthquake magnitude. This terminology assumes a sharp cutoff earthquake magnitude distribution at a maximum magnitude $m_{\max}$.

As a rule, $m_{\max}$ is crucial in PSHA, particularly in assessing long return periods, although, currently, there is no generally

accepted method for estimating $m_{\max}$. It is estimated by combining several factors, based on two types of information, namely, the seismicity of the area and the geological, geophysical, and structural information of the seismic source. Using The seismological information focuses on the maximum observed earthquake magnitude within a seismic source and the statistical analysis of the available seismic event catalogue. The geological and geophysical information is used to identify distinctive tectonic features, which control the value of $m_{\max}$.

Current assessments of $m_{\max}$ are divided between deterministic and probabilistic procedures, based on the nature of the tools applied.

Deterministic procedures. The deterministic procedure most often applied is based on the tectonic features of the investigated area, revealed by empirical relationships between magnitude and various parameters, such as the fault rupture length, rupture dimension, or slip rate. Relationships differ for different seismic areas and different types of faults. Despite empirical relationships between magnitudes and fault rupture parameters being used extensively in PSHA (particularly for assessing the maximum possible magnitude generated by fault-type seismic sources), the weak point of the approach is the requirement to specify the highly uncertain length of a future rupture. An alternative approach to determining earthquake recurrence on singular faults with a segment-specific slip rate is the so-called cascade model, where segment rupture is defined by the individual cascade-characteristic rupture dimension.

Another deterministic procedure that has strong intuitive appeal is based on records of the largest historical or paleo-earthquakes. This approach is particularly applicable to areas of low seismicity, where large events have long return periods. In the absence of any tectonic and geological indications, it is assumed that the maximum possible earthquake magnitude is equal to the largest magnitude observed $m_{\max}^{\text{obs}}$, plus an increment. Typically, the increment varies from $1/4$ to 1 magnitude unit.

Another deterministic procedure for $m_{\max}$ evaluation, particularly for area-type seismic sources, is based on extrapolation of the Gutenberg–Richter frequency–magnitude relation

Seismic Hazard, Fig. 3 Illustration of a typical seismic event catalogue. Prehistoric (paleo-) data suffer from uncertainty related to the time of occurrence and the event size. The historic part of the catalogue contains only the largest events, the size of which is also highly

uncertain. The third part of the catalogue contains complete data, with different levels of completeness. T_g denotes gaps in the catalogue where records are absent or the seismic networks were out of operation. (After Smit et al. 2019)

when the frequency–magnitude curve is truncated at the specified value of the annual probability of exceedance (e.g., 0.001). However, currently, the procedures based on such extrapolation are not used often, and they are replaced by procedures based on the physical parameters of fault rupture.

The value of $m_{\max}$ can be estimated also from tectonic and geological features, such as the strain rate or the rate of seismic moment release. Similar approaches have also been applied in evaluating the maximum possible magnitude of anthropogenic seismicity, particularly that generated by fluid injection or deep mining. However, mostly, the uncertainty of $m_{\max}$ as determined by any deterministic procedure is large, often reaching a value of one unit on the Richter scale.

Probabilistic procedures. The first probabilistic procedure for maximum regional magnitude was developed in the late 1960s and is based on the formalism of the extreme values of random variables. Statistical tools required for the estimation of the end point of distribution functions have only been used recently (Kijko 2004, and references therein).

Available statistical tools for estimating $m_{\max}$ vary significantly. Selecting the most suitable procedure depends on the assumptions of the statistical distribution model and/or the information available on past seismicity. Some of the procedures can be applied in extreme cases when no information is available on the nature of the earthquake magnitude distribution. Some of the procedures can also be used when the earthquake catalogue is incomplete, i.e., when only a limited number of the largest magnitudes are known. Two estimators are presented here. Broadly speaking, the first estimator is straightforward and simple in application, whereas the second requires a more computational effort but provides more accurate results. It is assumed that both the analytical form and the parameters of the distribution functions of earthquake magnitude are known.

Based on the distribution of the largest among n observations, and on the condition that the largest observed magnitude $m_{\max}^{\text{obs}}$ is equal to the largest magnitude to be expected, the “simple” estimate of $m_{\max}$ is of the form (Pisarenko et al. 1996)

$$\hat{m}_{\max} = m_{\max}^{\text{obs}} + \frac{1}{nf_M(m_{\max}^{\text{obs}})}, \quad (11)$$

where $f_M(m_{\max}^{\text{obs}})$ is the PDF of the earthquake magnitude distribution. If applied to the Gutenberg–Richter relation with PDF (5), it takes the simple form

$$\hat{m}_{\max} = m_{\max}^{\text{obs}} + \frac{1 - \exp[-\beta(m_{\max}^{\text{obs}} - m_{\min})]}{n\beta \exp[-\beta(m_{\max}^{\text{obs}} - m_{\min})]}. \quad (12)$$

The second (“advanced”) procedure often used in assessing $m_{\max}$ is based on the formalism derived by Cooke (1979)

$$\hat{m}_{\max} = m_{\max}^{\text{obs}} + \int_{m_{\min}}^{m_{\max}^{\text{obs}}} [F_M(m)]^n dm, \quad (13)$$

where $F_M(m)$ denotes the CDF of random variable m . If applied to the Gutenberg–Richter frequency–magnitude relation (1), the respective CDF is

$$F_M(m) = \begin{cases} 0 & m < m_{\min} \\ \frac{1 - \exp(-\beta(m - m_{\min}))}{1 - \exp(-\beta(m_{\max} - m_{\min}))} & m_{\min} \leq m \leq m_{\max} \\ 1 & m \geq m_{\max} \end{cases}, \quad (14)$$

and the $m_{\max}$ estimator (13) takes the form

$$\hat{m}_{\max} = m_{\max}^{\text{obs}} + \frac{E_1(n_2) - E_1(n_1)}{\beta \exp(-n_2)} + m_{\min} \exp(-n), \quad (15)$$

where $n_1 = n/(1 - \exp[-\beta(m_{\max}^{\text{obs}} - m_{\min})])$, $n_2 = n_1 \exp[-\beta(m_{\max}^{\text{obs}} - m_{\min})]$, and $E_1(\cdot)$ denotes an exponential integral function.

Despite these probabilistic procedures providing powerful tools for evaluating $m_{\max}$, they have a significant weak point, namely, most of the catalogues of tectonic origin events are too short and provide insufficient information for reliable estimations of $m_{\max}$. Therefore, the Bayesian extension of statistical procedures, allowing the inclusion of alternative and independent information, such as local geological conditions, tectonic environment, geophysical data, paleo-events, a similarity with another seismic area, and the like, is superior to the procedures based only on knowledge of the seismicity of the area.

Finally, the recent trend in $m_{\max}$ assessment must be mentioned. As most of the current techniques provide quite uncertain point estimates of $m_{\max}$, several researchers suggest using instead the assessment of the confidence level of the maximum magnitude to be observed in the future time interval T . However, many engineering applications require knowledge of the point estimates of $m_{\max}$. Therefore, the formalism of the quantile assessment T -maximum cannot be used.

Numerical Computation of PSHA

Excepting a number of special cases, the hazard curve cannot be computed analytically. For the most realistic distributions, the integrations can only be evaluated numerically. The common practice is to divide the possible ranges of magnitude and distance into n_M and n_R intervals, respectively. The average annual rate (6) is then estimated as

$$\lambda(Y > y) \cong \sum_{i=1}^{n_S} \sum_{j=1}^{n_M} \sum_{k=1}^{n_R} \lambda_i P[Y > y | m_j, r_k] f_{M_j}(m_j) f_{R_k}(r_k) \Delta m \Delta r, \quad (16)$$

where $m_j = m_{\min} + (j - 0.5)(m_{\max} - m_{\min})/n_M$, $r_k = r_{\min} + (k - 0.5)(r_{\max} - r_{\min})/n_R$, $\Delta m = (m_{\max} - m_{\min})/n_M$, and $\Delta r = (r_{\max} - r_{\min})/n_R$.

Applying the procedure to a grid of points will result in a map of PSHA, on which the contours of the expected ground motion parameter during the specified time interval can be mapped.

An example of applying the above formalism is shown in Fig. 4. This figure shows the worldwide distribution of seismic hazard expressed in terms of the PGA, with a 10% probability of being exceeded at least once in 50 years. The maps were created in the framework of the Global Earthquake Model (GEM) project.

Deaggregation of Seismic Hazard

By definition, the PSHA aggregates ground motion contributions from earthquake magnitudes and distances of significance to a site of engineering interest. Therefore, the PSHA results are not representative of a single earthquake. However, an integral part of the design procedure of any critical structure is examining the most relevant earthquake acceleration time series, which are generated by earthquakes at specific magnitudes and distances. Such earthquakes are called “controlling earthquakes,” and they are used to determine the shapes of the response spectral acceleration at the site.

Controlling earthquakes are characterized by mean magnitudes and distances derived from so-called deaggregation analysis (McGuire 2004). During the deaggregation procedure, the results of PSHA are separated to determine the dominant magnitudes and the distances that contribute to the hazard curve at a specified reference probability.

Controlling earthquakes are calculated for different structural frequency vibrations, typically for the fundamental frequency of a structure. In the deaggregation process, the hazard for a reference probability of exceedance of specified ground motion is portioned into magnitude and distance bins. The relative contribution to the hazard for each bin is calculated. The bins with the largest relative contribution identify those earthquakes that contribute the most to the total seismic hazard.

Modifications of Cornell–McGuire PSHA Procedure and Alternative Models

Source-Free PSHA Procedures

The concept of seismic sources is the core element of the Cornell–McGuire PSHA. However, seismic sources or specific faults often cannot be identified and mapped, and the causes of seismicity are not understood. In such instances, the delineation of seismic sources is highly subjective and is a matter of an expert opinion. In addition, seismicity within the seismic sources is often not distributed uniformly, as is required by the classic Cornell–McGuire procedure. The difficulties in dealing with seismic sources have stimulated the development of alternative techniques, which are free from the delineation of seismic sources (Veneziano et al. 1984; Woo 1996; Molina et al. 2001).

The core of source-free procedures is calculation of the empirical distribution of the specified seismic hazard parameter, normalized for the duration of the seismic event catalogue. Alternatively, the nonparametric PSHA is based on

Seismic Hazard, Fig. 4 Example of the product of PSHA. Map of seismic hazard of the world. Peak ground acceleration expected at 10% probability of exceedance at least once in 50 years. The Global Earthquake Model (GEM) project

seismicity distributions, which are assessed by data-based kernel functions.

By their nature, nonparametric procedures function well in areas of high seismic activity and when the record of past seismicity is considerably complete. However, the nonparametric approach has significant weak points, as it provides an unreliable estimate of small probabilities for areas of low seismicity. Additionally, the procedure is not recommended for an area where the seismic event catalogues are incomplete. Moreover, in its present form, the procedure is not capable of using any additional geophysical or geological information to supplement the seismological data. Therefore, a procedure that accommodates the incompleteness of the seismic event catalogues and, at the same time, does not require the specification of seismic sources would be an ideal tool for analyzing and assessing the seismic hazard. Such a procedure, which can be classified as a *parametric-historic* procedure for PSHA, has been used successfully in several parts of the world (see, e.g., Giardini 1999). In some instances, during the computation process of seismic hazard, the Gutenberg–Richter frequency–magnitude relation is extended to account for the contribution of tectonic faults and characteristic earthquakes. The procedure accepts the potential contribution of seismicity from active faults and compensates for the incompleteness of seismic event catalogues. The final maps of seismic hazard are smoothed by a Gaussian-type kernel function. This conceptually simple and intuitive parametric–historic approach combines the best of the deductive and nonparametric historical procedures and, in many instances, is free from the disadvantages characteristic of each of the procedures.

Another approach to assessing seismic hazard is based on Monte Carlo simulations of long-term seismic catalogues. Despite this approach having several advantages and being straightforward and easy to apply, its role in PSHA is highly underestimated. The Monte Carlo-based procedure allows easy incorporation of alternative earthquake space–time–size occurrence models, such as Markovian, non-Poissonian, and non-Gutenberg–Richter frequency–magnitude relation. In addition, it allows for the assessment of uncertainties associated with the input data and model parameters. The potential disadvantage of the Monte Carlo-based procedure is the requirement for extensive computation power.

Alternative Earthquake Recurrence Models

Time-dependent models. In addition to the classical assumption that earthquake occurrence in time follows a Poissonian process, alternative approaches are used occasionally. These procedures attempt to assess the temporal or spatiotemporal dependence of seismicity. Time-dependent earthquake occurrence models specify the distribution of the time to the next earthquake, where this distribution depends on the magnitude of the most recent earthquake. In order to incorporate the memory of past events, non-Poissonian distributions or

Markov chains are applied. In this approach, the seismogenic zones that recently produced strong earthquakes become less hazardous than those that did not rupture in recent history.

Time-dependent models are also applied to quantify the occurrence of large earthquakes on segments of active faults. Kramer (1996) provides an overview of non-Poissonian models. Several time-dependent models play an important role in PSHA, of which the best-known are the two models by Shimazaki and Nakata (1980). These two models of earthquake occurrence, namely, a *time-predictable* and a *slip-predictable* model, are based on the correlation of seismic activity with earthquake-related coastal uplift in Japan.

The time-predictable model states that earthquakes occur when the accumulated stress on a fault reaches a critical level. However, the stress drops, and the magnitudes of subsequent earthquakes vary among seismic cycles. Therefore, assuming a constant fault slip rate, the time to the next earthquake can be estimated from the slip of the previous earthquake. The slip-predictable model is based on the assumption that irrespective of the initial stress on the fault, an earthquake occurrence always causes a reduction in stress to the same level. Therefore, the fault slip in the next earthquake can be estimated from the time since the previous earthquake (Shimazaki and Nakata 1980; Scholz 1990; Thenhaus and Campbell 2003).

The second group of time-dependent models is based less firmly on the physical considerations of earthquake occurrence, and these models attempt to describe intervals between the consecutive events by specified statistical distributions. At least two such models play a significant role in the current practice of PSHA, namely, the log-normal and Brownian passage time (BPT) renewal model.

Employing a log-normal model was justified by the discovery that normalized intervals between the consecutive large earthquakes in the Circum-Pacific region follow a log-normal distribution, with an almost constant standard deviation. Following this discovery, the log-normal model became a key component of time-dependent PSHA procedures.

More often applied nowadays than the log-normal model is the Brownian passage time (BPT) distribution. This model is described by two parameters, μ and σ , which, respectively, represent the mean time interval between the consecutive earthquakes and the standard deviation. The aperiodicity of earthquake occurrence, as described by the BPT model, is controlled by the variation coefficient $\alpha = \sigma/\mu$. For a small α , the aperiodicity of earthquake occurrence is small, and the shape of the distribution is almost symmetrical. For a large α , the shape of the distribution is similar to the log-normal model, i.e., skewed to the right and peaked at a smaller value than the mean. The straightforward control of aperiodicity of earthquake occurrence by parameter α makes the BPT model extremely attractive, and it has been used to model earthquake occurrence in many parts of the world.

Several comparisons between time-dependent and time-independent earthquake occurrence models have shown that the time-independent (Poissonian) model is applicable to most engineering applications of the PSHA. The exception is when the time interval from the occurrence of the last earthquake exceeds the mean time interval between consecutive events related to a seismic hazard dominated by a single seismic source with a significant component of characteristic earthquakes. However, in many instances, the information on strong seismic events provided by current earthquake databases is insufficient to distinguish between different models. Therefore, using non-Poissonian models is justified only if sufficient data are available.

Clearly, such time-dependent models can result in a more realistic PSHA, but many of them have not yet reached the level of development required by routine engineering applications.

Spatiotemporal models. Often, a sequence of foreshocks and a sequence of aftershocks after the main event can be observed. The fore- and aftershock sequences cannot be described by the homogenous Poissonian process, as their rate depends on time, the magnitude of the main event, and its location. Some areas are notorious for the generation of earthquake swarms. Frequently, individual tectonic faults interact with each other, and such seismic activity leads to earthquakes being clustered in both time and space.

The best-known spatiotemporal model of earthquake occurrence is ETAS (epidemic-type aftershock sequence) and its mutations. The core assumption of the ETAS model is that each earthquake, however small, triggers its own aftershocks (offspring) independently of the others. The probability distributions of location and magnitude of the triggered event are dependent on the magnitude and location of the triggering event. The rate of aftershock occurrence decays with time according to an inverse power law known as the modified Omori law. The magnitudes of all the events, including background events and their offspring, are independent random variables following the same probability distribution. An alternative spatiotemporal model is one in which each mainshock and its aftershocks are treated as spatially and temporally independent clusters. However, the mathematical formulation does not have a closed form, which restricts the usage of the model. An elegant, straightforward, and statistically consistent incorporation of foreshocks and aftershocks into standard PSHA is done by Iervolino et al. (2014). The proposed formalism provides a remedy to one of the most controversial current practices of PSHA, known as declustering (i.e., removal) of “dependent” events from the seismic event catalogue.

Alternative frequency–magnitude models. In the classic Cornell–McGuire procedure for PSHA assessment, it is assumed that earthquake magnitudes follow the Gutenberg–Richter relation truncated from the top by a seismic source

characteristic, the maximum possible earthquake magnitude m_{max} . The PDF of this distribution is given by Eq. (5).

Generally, the Gutenberg–Richter relation describes magnitude distributions within seismic source zones adequately; however, in some instances, it appears not to apply. In such an instance, the relationship (5) must be modified. In some places, particularly in areas known for paleo-earthquakes, seismic belts, and large faults, the Gutenberg–Richter relation underestimates the occurrence of large magnitude events. Consequently, the continuity of the distribution (5) breaks down. The distribution is adequate only for events up to a magnitude of 6.0–7.0. Larger events tend to occur within a relatively narrow range of magnitudes (7.5–8.0) but with a frequency higher than that predicted by the Gutenberg–Richter relation (5). These events are known as *characteristic earthquakes* (Youngs and Coppersmith 1985, Fig. 5). However, it must be noted that the characteristic earthquake model is not free from controversy. Some researchers believe that the frequency–magnitude Gutenberg–Richter relation satisfies the earthquake occurrence characteristics equally well as does the earthquake characteristic model. The discrepancy between the two models would disappear if a sufficiently long record of seismicity were available.

When a seismic hazard is caused by seismicity of anthropogenic origin, an alternative to the Gutenberg–Richter

Seismic Hazard, Fig. 5 Gutenberg–Richter characteristic earthquake magnitude distribution. The model combines the Gutenberg–Richter frequency–magnitude relation with a uniform distribution of characteristic earthquakes. The model predicts higher rates of exceedance at magnitudes near the characteristic earthquake magnitude. (After Youngs and Coppersmith 1985)

frequency–magnitude relation (1) is often required. For example, the magnitude distributions of tremors generated by mining activity are multimodal and change their shape in time (Gibowicz and Kijko 1994). Often, the only possible method that could lead to a satisfactory PSHA for mining or fracking areas is replacing the analytical, parametric frequency–magnitude distribution by its model-free, nonparametric counterpart.

Two additional modifications of the recurrence models are introduced regularly: one is when earthquake magnitudes are uncertain and the other when the seismic occurrence process comprises temporal trends, cycles, short-term oscillations, and purely random fluctuations. The effect of error in earthquake magnitude determination (particularly significant for historical events) can be minimized by the simple procedure of correcting the earthquake magnitudes in a catalogue (e.g., McGuire 2004). Modelling random fluctuations in earthquake occurrence is often done by introducing compound (mixed) distributions, in which the parameters of earthquake recurrence models are treated as random variables (Kijko et al. 2016).

Ground Motion Models

The assessment of seismic hazard at a site requires knowledge of the GMM, i.e., the prediction equation of strong-motion parameter as a function of distance, earthquake magnitude, faulting mechanism, and, often, the local site condition. The most common form of the GMM is

$$\ln(y) = \text{const} + g_1(m) + g_2(r) + g_3(\text{faulting system}) + g_4(\text{soil}) + \varepsilon. \quad (17)$$

In Eq. (17), y is the amplitude of the designated ground motion parameter. This parameter can be the peak ground acceleration (PGA), spectral acceleration, displacement, the Modified Mercalli (MM) Intensity, seismic record duration, and the like. Functions $g_1(m)$ and $g_2(r)$ are the function of earthquake magnitude and the function of the shortest earthquake distance from the site to the earthquake source, respectively. Function $g_3(\cdot)$ represents the faulting mechanism, $g_4(\cdot)$ describes the site effect, and ε is the random error with zero mean and standard deviation $\sigma_{\ln(y)}$. Assuming that $\ln(y)$ has a normal distribution, and following the properties of log-normal distribution, regression of (17) provides the mean value of $\ln(y)$, the exponent of which corresponds to the median value of y , $\bar{y}$. As the log-normal distribution is positively skewed, the mean value of y , $\bar{y}$, exceeds the median value $\bar{y}$ by a factor of $\exp\left(-0.5\sigma_{\ln(y)}^2\right)$. This indicates that the seismic hazard for a particular site is higher when expressed in terms of $\bar{y}$ when the hazard for the same site is expressed in terms of $\bar{y}$.

In general, GMMs are built in three distinct ways: (a) empirically, by application of observed ground motion characteristics; (b) by stochastic methods, which are based on the physical properties of the earthquake source and seismic wave travel path; and (c) by the hybrid empirical method.

Empirical methods are applied in areas of high seismicity in the presence of dense instrumental networks, where a significant number of ground motion records are available. Examples of such empirical GMMs are those developed as part of the Next Generation Attenuation Phase 2 (NGA-West2) project, managed by the Pacific Earthquake Engineering Research Center (PEER). Stochastic methods are used mainly in areas of low seismicity, where only a limited number of observations are available. The hybrid empirical method, like the stochastic method, is used to develop GMM for areas with limited ground motion records; however, the technique used is different. In the hybrid empirical method, the ground motion in the target area is predicted from the empirical GMM in the host region with the help of adjustment factors between the two regions. These factors consider the differences in earthquake source, wave propagation, and site response characteristics between the two regions.

The ground motion models remain a particularly important component of PSHA, as ground motion uncertainty is a major contributor to the uncertainty of the PSHA. An excellent discussion on all the aspects of the estimation, application, and role of GMMs in PSHA is provided by McGuire (2004).

Uncertainties in PSHA

Contemporary PSHA distinguishes between two types of uncertainty, namely, aleatory and epistemic.

Aleatory uncertainty derives from the randomness in nature and is inherent for any random phenomenon. It represents unique details of an earthquake, such as its source, path, and site, and cannot be known before the earthquake's occurrence. It is sometimes referred to as "randomness," "stochastic uncertainty," or "inherent variability" (SSHAC 1997). Typical examples of aleatory uncertainties are the number of future earthquakes in a specified area, parameters of future earthquakes as origin times, epicenter coordinates, depths and their magnitudes, size of the fault rupture, and associated stress drop. Additionally, the uncertainty of ground motion parameters at the given site is also aleatory by their nature. The aleatory uncertainties are characteristic of the current model and cannot be reduced by the incorporation of additional data. Aleatory uncertainties are included in the PSHA by means of integration over these uncertainties and are represented by the hazard curve.

Epistemic uncertainty is the uncertainty deriving from insufficient knowledge about the model or its parameters. In

the past, epistemic uncertainty was known as statistical or professional uncertainty (McGuire 2004). Examples of epistemic uncertainties are the boundaries of seismic sources, distributions of seismic source parameters (e.g., annual rate of seismic activity λ , b -value, and $m_{\max}$), or median value of the ground motion parameter, given the source properties. The model (in the broad sense of its meaning, as, e.g., a particular statistical distribution) can be inexact and, therefore, predicts values that differ from the observed values by a fixed, but unknown, amount. When uncertainties are associated with the numerical values of the parameters, they are also epistemic by nature. Epistemic uncertainty can be reduced by incorporating additional information or data. The epistemic distributions of model parameters can be updated using the Bayes' formalism. Epistemic uncertainties are included in the PSHA through the use of alternative hypothesis, different sets of parameters with different numerical values, different models, or a *logic tree*.

The major benefit of the separation of uncertainties into aleatory and epistemic is potential guidance in the preparation of input for PSHA and the interpretation of the results. However, the division of uncertainties into aleatory and epistemic is model dependent and, to a large extent, arbitrary, indefinite, and often confusing.

Logic Tree

The mathematical formalism of PSHA computation integrates over all the random (aleatory) uncertainties of a particular seismic hazard model. In many instances, however, because of the lack of information on the factors controlling the mechanism of the earthquake generation and wave propagation processes, the best choices for the elements of the seismic hazard model are not clear. The uncertainty could originate from the choice of alternative seismic sources and earthquake generation mechanisms, rupture type and directivity, competitive earthquake recurrence models and their parameters, particular site and its topography, settings of the recording instruments, and the chosen ground motion model. The standard approach to the explicit treatment of alternative hypotheses, models, and parameters is applying the *logic tree* formalism (Coppersmith and Youngs 1989). Although not without controversy, the logic tree formalism provides a convenient tool for the quantitative treatment of any alternatives. Each node of the logic tree (Fig. 6) represents uncertain assumptions, models, or parameters, and the branches extending from each node are the discrete uncertainty alternatives (McGuire 2004).

In logic tree analysis, each branch is weighted according to its probability of being correct. As a result, each end branch

Seismic Hazard,

Fig. 6 Example of a logic tree. The alternative hypothesis accounts for uncertainty in the ground motion attenuation relation, magnitude distribution model, and the assigned maximum magnitude $m_{\max}$

represents a hazard curve with an assigned weight, where the sum of weights of all the hazard curves is equal to 1.0. The derived hazard curves are used to compute the final (e.g., mean) hazard curve and its confidence intervals. Figure 6 shows an example of a logic tree, accounting for uncertainty in the ground motion attenuation model, magnitude distribution model, and assigned maximum magnitude $m_{\max}$.

It must be noted that the choice of the structure of the logic tree and its respective weights is critical and often extremely subjective.

Controversy

Although the PSHA procedure was formulated more than 50 years ago, controversy still surrounds it. Among others, the disagreements are related to (1) the requirement of declustering of the seismic event catalogue, (2) absence of the upper limit of ground motion parameters, (3) division of uncertainties between aleatory and epistemic, (4) correctness of the characteristic earthquakes model, and (5) accounting for epistemic uncertainty by applying the logic tree formalism.

Declustering, i.e., removing earthquakes that occur in clusters, such as foreshocks, aftershocks, and swarms, from the seismic catalogue (in order to create a catalogue of “independent” events) is probably the most controversial factor in current PSHA practice. The procedure violates the fundamental rule of physics taught to first-year students, i.e., “never twist data to suit theory; instead, design such theory, which suits the data.” However, declustering does the exact opposite. Declustering affects the estimation of the earthquake occurrence parameters (the magnitude activity rate and the b -value), and, thereby, it affects (usually underestimates) the true hazard and risk. Iervolino et al. (2014) show that in terms of the annual rate of exceedance of PGA, declustering leads to 30% underestimation of the true hazard.

Among others, Cornell and Winterstein (1988) contend that, in most instances, correct seismic hazard analysis can be performed without declustering. They show that the classic, time-independent (Poissonian) model is applicable even when the temporal clustering of earthquake occurrence is close to 30%. In addition, declustering can be avoided by replacing the Poissonian model (as well as the exponential Gutenberg–Richter magnitude distribution) with their compounded (mixed) counterparts.

Further criticism of the current PSHA procedure concerns the absence of the upper limit of the ground motion parameter in the hazard curve. The core of the classic Cornell–McGuire PSHA is the assumption that the logarithm of the ground motion parameter is distributed normally. As the domain of the normal distribution is unlimited from the right side, it results in a nonzero probability of unrealistically high values

for the ground motion parameter. Several solutions have been suggested; however, none of these is physically justifiable. The absence of the upper bound of the earthquake-generated ground motion parameter has been identified as the “missing piece” in current seismic hazard formalism. However, the problem of estimating the site-characteristic upper limit of PGA has been solved by Pavlenko (2017), who contends that, as a maxima of acceleration time series, PGA should follow an extreme value distribution, not the normal distribution. Based on extensive statistical tests of PGA records by K-NET and KiK-net networks, Pavlenko demonstrates that the distribution of $\ln(\text{PGA})$ converges to the generalized extreme value (GEV) distribution. Replacing the normal distribution in Eqs. (4) and (5) by the GEV distribution allows for the assessment of the upper bound value of PGA. Therefore, the GEV distribution provides a model that is physically justifiable and describes the scatter of the logarithm of PGA significantly better than does the currently used normal distribution, and its application provides the required upper bound of the seismic hazard curve.

Furthermore, criticism surrounds the division of uncertainties into aleatory and epistemic in the current PSHA procedure. As noted in section “[Uncertainties in PSHA](#),” the division remains an unresolved issue.

Different criticism is directed at the ergodic assumptions that underlie the formalism of the PSHA procedure. The ergodic process is a random process in which the distribution of a random variable in space is the same as the distribution of that variable at a single point when sampled as a function of time. It has been shown that the major contribution to PSHA uncertainty derives from the uncertainty of the ground motion model. The uncertainty of the ground motion parameter y is characterized by its standard deviation, $\sigma_{\ln(y)}$, which is calculated as the misfit between the observed and the predicted ground motions at several seismic stations for a small number of recorded earthquakes. Therefore, $\sigma_{\ln(y)}$ mainly characterizes the spatial and not the temporal uncertainty of ground motion at a single point. This violates the ergodic assumption of the PSHA procedure, leading to an overestimation of seismic hazard, particularly when the exposure times are longer than the earthquake return times.

Castanos and Lomnitz (2002) and Mulargia et al. (2017) have voiced equally strong criticism about the application of the logic tree formalism. They describe the application of the logic tree formalism as a misunderstanding in probability and statistics, as it is fundamentally wrong to admit “expert opinion as evidence on the same level as hard earthquake data.”

The science of seismic hazard assessment is, therefore, subject to much debate. Currently, PSHA represents a best-effort approach to quantify an issue of which not enough is known to provide definitive results and, as indicated by the numerous estimations, considerably more time and measurements will be needed before these issues can be resolved.

Further reading: Several excellent studies are available that describe all aspects of modern PSHA. Thenhaus and Campbell (2003) and McGuire (2004) present outstanding overviews covering theoretical, methodological, and procedural issues of modern PSHA. The most comprehensive treatment to date of all aspects of PSHA, including the treatment of aleatory and epistemic uncertainties, is provided by the SSHAC (1997) report. Seismic hazard from a geologist's perspective is described in a book by Yeats et al. (1997). Kramer (1996) provides an elegant, coherent, and understandable description of the mathematical aspects of both DSHA and PSHA. The information presented here benefited from all the sources quoted above, particularly the exceptional work by Kramer (1996).

Summary

The term seismic hazard refers to any physical phenomenon associated with an earthquake (e.g., ground motion, ground failure, liquefaction, and tsunami) and its effect on the land, infrastructure, and socioeconomic systems that, potentially, can produce a loss. The term is also used, without regard to any loss, to indicate the probable level of ground shaking occurring at a given point within a certain period of time. Seismic hazard analysis involves the quantification of the expected ground motion at particular sites. Seismic hazard analysis can be performed deterministically when a particular earthquake scenario is considered or probabilistically when the likelihood or frequency of a specified level of ground motion at a site during a specified exposure time is evaluated. In principle, any natural hazard caused by seismic activity can be described and quantified in terms of the probabilistic methodology. Classical probabilistic seismic hazard analysis includes four steps, which are (1) identification and parameterization of the seismic sources, (2) specification of temporal and magnitude distributions of earthquake occurrence, (3) calculation of ground motion prediction equations and their uncertainty, and (4) integration of uncertainties in earthquake location, earthquake magnitude, and ground motion prediction equations into the hazard curve.

An integral part of PSHA is the assessment of uncertainties. Contemporary PSHA distinguishes between two types of uncertainty, namely, aleatory and epistemic. Aleatory uncertainty stems from the randomness in nature and is the probabilistic uncertainty inherent in any random phenomenon. Aleatory uncertainties are characteristic of the currently used model and cannot be reduced by the incorporation of additional data. Epistemic uncertainty derives from insufficient knowledge about the model or its parameters. Epistemic uncertainty can be reduced by incorporating additional information or data. Aleatory uncertainties are included in the probabilistic seismic hazard analysis because of the integration over these uncertainties, and

they are represented by the hazard curve. In contrast, epistemic uncertainties are included through the use of alternative models, different sets of parameters with different numerical values, or a logic tree.

The PSHA procedure as known in its current form is not without controversy. The controversy arises from issues such as (1) the absence of the upper limit of the ground motion parameter, (2) division of uncertainties between aleatory and epistemic, and (3) the methodology itself, particularly the application of the logic tree formalism.

Seismic Imaging, Overview

Definition

Seismic imaging or tomography (tomo = slice and graph = picture) is a procedure for estimating the earth's rock parameters from seismic data. These rock parameters can be represented by the spatial distribution of, e.g., P-wave velocity, S-wave velocity, porosity, density, or anisotropic parameters. The result of inversion is graphically presented as a 2-D or 3-D grid of pixels, where each pixel contains the value of the model parameter of interest, which is P velocity in

Fig. 1g–h. Such tomograms are used to estimate the geometry and lithology of geologic layers, and can help exploration geophysicists and earthquake seismologists understand the evolution of the earth's interior.

There are five main types of seismic imaging: seismic migration, least squares migration, full waveform inversion (FWI), phase-like inversion, and migration velocity analysis. Four of these methods can be derived as special cases of finding the optimal model that minimizes a waveform or a phase-related misfit function. This entry will present these methods as they are applied to body wave events in seismic data, and overview the current best practices in waveform tomography.

Inversion Theory

There are four steps to inverting for the model $\mathbf{m}$ from seismic data $\mathbf{d}$. We will assume that the input data are either seismic traces, generated by man-made or earthquake sources, or some skeletonized part of the traces, such as first arrival traveltimes or the phase of an event at some frequency.

Step 1: $\mathbf{L}(\mathbf{m}) = \mathbf{d}$. Establish the mathematical relationship $\mathbf{L}(\mathbf{m}) = \mathbf{d}$ between the seismic data $\mathbf{d}$ and model $\mathbf{m}$.

$$\mathbf{d} = \mathbf{L}(\mathbf{m}), \quad (1)$$

where $\mathbf{L}$ represents the forward modeling operator for the actual model. Equations A1–A3 in Table 1 show the three steps in establishing a linearized version of Eq. 1 for the acoustic wave equation, where the extensions to the elastic (Mora 1987) and anisotropic (Barnes et al. 2008; Operto et al. 2009) wave equations are tedious but straightforward.

Step 2: Discretize $\mathbf{m}$, $\mathbf{d}$, and $\mathbf{L}$. Discretize the 3D earth model into a 3D grid of N physical parameters (e.g., unknown slowness in each cell) and assemble the unknowns into the $N \times 1$ vector $\mathbf{m}$. Discretize the seismic traces in both space and time (or frequency) into an $M \times 1$ vector $\mathbf{d}$ of data measurements. In this case, $\mathbf{L}$ reduces to a $M \times N$ matrix. The forward modeling for FWI requires knowledge of the source wavelet, which can be estimated in a variety of ways: stacking of the direct arrival at different near-offset hydrophones in marine data, iterative inversion of the source wavelet (Mora 1987; Zhou et al. 1997; Pratt 1999), or deconvolution of the shot gather with a time-windowed near-offset trace (Sheng, personal communication). The time window can be a few periods long centered about the direct arrival.

Step 3: Linearize $\mathbf{L}\delta\mathbf{m} \approx \delta\mathbf{d}$. Linearize the nonlinear relationship between the data and model. Expanding the i th data measurement $d_i(\mathbf{m})$ to first order in $\delta\mathbf{m}$ by a Taylor series about a first-guess model $\mathbf{m}_0$ (close to the true model) gives the linearized estimate:

Seismic Imaging, Overview,

Fig. 1 (a) Marmousi velocity model, (b) time-shifted and blended shot gathers, (c) zero-offset Kirchhoff migration image, (d) zero-offset least squares migration image after 30 iterations (courtesy of Naoshi Aoki), (e) reverse time migration (RTM) image, (f) least squares RTM image (Dai and Schuster 2009), (g) waveform tomogram after 50 iterations using the prestack gathers, and (h) waveform tomogram where the inputs are eight supergathers, each with 12 phase-encoded shot gathers (Zhan and Schuster in press); images are at different scales from one another

$$\begin{aligned}
 d_i(\mathbf{m}) &\approx d_i(\mathbf{m}_0) + \sum_j \frac{\delta d_i(\mathbf{m}_0)}{\delta m_j} \delta m_j \rightarrow \delta d_i(\mathbf{m}) \\
 &= \sum_j \overbrace{[\partial d_i(\mathbf{m}_0) / \partial m_j]}^{\text{wavepathfunction}} \delta m_j,
 \end{aligned} \tag{2}$$

or in matrix-vector notation

$$\delta \mathbf{d} = \mathbf{L} \delta \mathbf{m}. \tag{3}$$

Here, $\partial d_i(\mathbf{m}_0) / \partial m_j = \lim_{\Delta m_j \rightarrow 0} [d_i(\mathbf{m}_0 + \hat{\mathbf{j}} \Delta m_j) - d_i(\mathbf{m}_0)] / \Delta m_j$ is the Fréchet derivative with respect to the j th parameter; the data residual $\delta d_i = [d_i(\mathbf{m}) - d_i(\mathbf{m}_0)]$ is the difference between the i th components of the predicted data vector $\mathbf{d}(\mathbf{m}_0)$ and the observed data vector $\mathbf{d}(\mathbf{m})$; and $\hat{\mathbf{j}}$ is the j th unit

vector in the finite-dimensional model space. The model perturbation $\delta \mathbf{m} = \mathbf{m} - \mathbf{m}_0$ is the difference between the actual model $\mathbf{m}$ and the guessed model $\mathbf{m}_0$, and $\mathbf{L}$ is now interpreted as the Jacobian matrix. Its elements $[\mathbf{L}]_{ij} = \partial d_i(\mathbf{m}_0) / \partial m_j$ determine the sensitivity of the data to the perturbations in the model. For a windowed arrival, the Jacobian plots out in model space as a wavepath for a single source-receiver pair (Woodward 1992; Luo 1992; Dahlen et al. 2002; Marquering et al. 2002; Montelli et al. 2004; van der Hilst and de Hoop 2006; Xu and Xie 2009); and the velocity variations within its first Fresnel zone mostly influence the event of interest. Eq. A3 shows that the linearized equations take the form of the Born approximation (Stolt and Benson 1986) to the Lippmann-Schwinger equation, and its kernel is the Jacobian given by Eq. A4.

For a single source and a single receiver in a smoothly increasing velocity medium, Eq. A4 plots out as a curved

Seismic Imaging, Overview, Table 1 Symbols and specific formulas for inverting the Helmholtz equation for the perturbed slowness distribution $\delta s(\mathbf{x})$, where $\delta s(\mathbf{x})$ is assumed to be small compared to the background slowness model $s(\mathbf{x})$. The harmonic pressure field is denoted by $p(\mathbf{x}|\mathbf{s})$ for a source localized about $\mathbf{s}$, and the Green's function for the Helmholtz equation is given by $G(\mathbf{x}|\mathbf{s})$ for a point source at $\mathbf{s}$ and observer

at $\mathbf{x}$. The source wavelet spectrum is $W(\omega)$ at the angular frequency ω and the body force term localized about the point $\mathbf{s}$ is denoted by $f(\mathbf{x}|\mathbf{s})$. The predicted (observed) traveltime of an event received at $\mathbf{g}$ for a source at $\mathbf{s}$ is denoted as $\tau(\mathbf{g}|\mathbf{s})$ ($\tau(\mathbf{g}|\mathbf{s})^{\text{obs.}}$); and $\varepsilon = \|\mathbf{d} - \mathbf{d}^{\text{obs.}}\|^2$ is the misfit function for waveform inversion

Symbol	Mathematical formula
(A1) Helmholtz equation: $\mathbf{A}(\mathbf{d}, \mathbf{m}) = \mathbf{f}$	$(\nabla^2 + \omega^2 s(\mathbf{x}))p(\mathbf{x} \mathbf{s}) = f(\mathbf{x} \mathbf{s})$ $\mathbf{m} \rightarrow s(\mathbf{x}); \mathbf{d} \rightarrow p(\mathbf{x} \mathbf{s})$
(A2) linearized Helmholtz equation: $\delta \mathbf{A}(\mathbf{d}, \mathbf{m}) = 0$	$(\nabla^2 + \omega^2 s(\mathbf{x}))\delta p(\mathbf{x} \mathbf{s}) = -2\omega^2 s(\mathbf{x})\delta s(\mathbf{x})p(\mathbf{x} \mathbf{s})$ $\delta \mathbf{m} \rightarrow \delta s(\mathbf{x}); \delta \mathbf{d} \rightarrow \delta p(\mathbf{x} \mathbf{s})$

(A4) Jacobian or wavepath function: $\delta \mathbf{d}/\delta \mathbf{m}$	$\delta p(\mathbf{g} \mathbf{s})/\delta s(\mathbf{x}) = -2s(\mathbf{x})\omega^2 W(\omega)G(\mathbf{g} \mathbf{x})G(\mathbf{x} \mathbf{s})$
(A5) misfit gradient or reverse time migration or $\mathbf{L}^\dagger[\mathbf{L}\delta \mathbf{m} - \delta \mathbf{d}]$: $\delta \varepsilon/\delta \mathbf{m}$	$\delta \varepsilon/\delta s(\mathbf{x}) = \gamma \int G(\mathbf{g} \mathbf{x}) * \Delta d(\mathbf{g} \mathbf{s})G(\mathbf{x} \mathbf{s}) * dgds$ where $\gamma = -2\omega^2 s(\mathbf{x})W(\omega)$ and $\Delta d(\mathbf{g} \mathbf{s}) = p(\mathbf{g} \mathbf{s}) - p(\mathbf{g} \mathbf{s})^{\text{obs.}}$
(A6) least squares migration or linearized inversion: $\mathbf{m}^{(k)} - \delta \varepsilon/\delta \mathbf{m}$	$m(\mathbf{x})^{(k)} - \gamma \int G(\mathbf{g} \mathbf{x}) * \Delta d(\mathbf{g} \mathbf{s})^{(k)}G(\mathbf{x} \mathbf{s}) * dgds$
(A7) waveform inversion: $\mathbf{m}^{(k)} - \delta \varepsilon/\delta \mathbf{m}$	$m(\mathbf{x})^{(k)} - \gamma \int G^{(k)}(\mathbf{g} \mathbf{x}) * \Delta d(\mathbf{g} \mathbf{s})^{(k)}G^{(k)}(\mathbf{x} \mathbf{s}) * dgds$
(A8) wave equation traveltime inversion: $\mathbf{m}^{(k)} - \delta \varepsilon/\delta \mathbf{m}$	$m(\mathbf{x})^{(k)} - \gamma \int G^{(k)}(\mathbf{g} \mathbf{x}) * \Delta d(\mathbf{g} \mathbf{s})^{(k)}G^{(k)}(\mathbf{x} \mathbf{s}) * dgds$ where $\Delta d(\mathbf{g} \mathbf{s}) \approx p(\mathbf{g} \mathbf{s})^{\text{obs.}}(\tau(\mathbf{g} \mathbf{s}) - \tau(\mathbf{g} \mathbf{s})^{\text{obs.}})$

“fat” ray (trace a ray that connects the source and receiver and honors Snell’s law. Surround this ray with a “fat finite-frequency ray” such that the propagation of events from the source to receiver within the “fat” ray differs in traveltime by no more than 1/2 the period of the source wavelet. This fat ray region is that portion of the earth which mostly influences the traveltime of the event of interest) that connects the source and receiver points. This fat ray is denoted as a wavepath by Woodward (1992) and forms the basis of finite-frequency traveltime tomography. There seems to be a general (Montelli et al. 2004), but not a universal (van der Hilst and de Hoop 2006), agreement that finite-frequency tomography can be superior to that of ray-based tomography. As an example, earthquake seismologists use these wavepaths (renamed as banana-doughnuts) with finite-frequency tomography to invert earthquake traveltimes and surface wave data for deep mantle velocity variations attributed to, for example, ascending plumes of rocks (Dahlen et al. 2002; Marquering et al. 2002; Montelli et al. 2006).

Step 4: Solve $\mathbf{L}\delta \mathbf{m} = \delta \mathbf{d}$ by an iterative gradient method. Eq. 3 is typically an overdetermined, inconsistent, and poorly conditioned system of equations. Therefore, the solution we seek is the one that minimizes the sum of the data misfit $\|\mathbf{L}\mathbf{m} - \mathbf{d}\|_K^2$ and model penalty $\lambda^2 \|\mathbf{C}\mathbf{m}\|_W^2$ functions in the K and W norms (Clinthorne et al. 1993):

$$\varepsilon = \frac{1}{2} \|\mathbf{L}\delta \mathbf{m} - \delta \mathbf{d}\|_K^2 + \frac{\lambda^2}{2} \|\mathbf{C}\delta \mathbf{m}\|_W^2. \quad (4)$$

where $\|\mathbf{L}\delta \mathbf{m} - \delta \mathbf{d}\|_K^2 = (\mathbf{L}\delta \mathbf{m} - \delta \mathbf{d})^\dagger \mathbf{K}(\mathbf{L}\delta \mathbf{m} - \delta \mathbf{d})$ and $\mathbf{K}$ dimes taken as the inverse of the data covariance matrix (Tarantola 1987) that is real and symmetric. The penalty function (also known as the regularization term) is defined as $\|\delta \mathbf{C}\mathbf{m}\|_W^2 = (\mathbf{C}\mathbf{m})^\dagger \mathbf{W}(\mathbf{C}\mathbf{m})$, where the real symmetric matrix $\mathbf{W}$ might strongly weight certain regions in the model because they mostly influence the data. The matrix $\mathbf{C}$ might be a spatial second-derivative operator in one or several directions so as to encourage solutions with smoothly varying model parameters along selected directions.

A simplified steepest descent solution for the i th model parameter m_i is given by

$$m_i^{(k+1)} = m_i^{(k)} - \alpha \frac{\overbrace{\delta \varepsilon}^{\text{gradient Equation A5}}}{\delta m_i} \rightarrow \mathbf{m}^{(k+1)} \quad (5)$$

$$= \mathbf{m}^{(k)} - \underbrace{\alpha \mathbf{L}^\dagger \delta \mathbf{d}^{(k)}}_{\text{migration of data residual}},$$

where $\lambda = 0$; $\mathbf{K} = \mathbf{I}$; α is the step length; and preconditioning is used (Beydoun and Mendes 1989; Clinthorne et al. 1993; Causse et al. 1995) to accelerate convergence. A sequence of models is generated until the data residual falls below some acceptable level. In practice, a preconditioned conjugate gradient method (Mora 1987; Luo and Schuster 1991; Epanomeritakis et al. 2008), a Gauss-Newton Krylov solver (Erlangga and Hermann 2009), or a limited memory quasi-

Newton method (Pratt et al. 1998; Plessix 2006) for different implementations of the adjoint method (Plessix 2009) is implemented; and sometimes a direct matrix solver is used to find the Hessian inverse if the problem size is small enough (Pratt and Goulty 1991). Approximations to the Hessian by a systematic procedure can be found in Thierry et al. (1999). There is strong evidence (Cruse et al. 1990; Brossier et al. 2010) that using the L_1 norm, misfit function is noticeably more resistant to data noise than the L_2 norm misfit function, and the combination of the two is sometimes the best choice.

Five Types of Seismic Imaging Methods

Five types of seismic imaging methods and their resolution properties will be discussed (there are many seismic inversion methods, but the five types discussed here are often used in the geophysical community): migration (modest resolution of reflectivity), least squares migration (high resolution of reflectivity), full waveform inversion (high resolution of velocity), phase-like inversion (modest resolution of velocity), and migration velocity analysis (modest resolution of velocity). The high-resolution methods typically pay the price of increased computational cost and decreased robustness, compared to the moderate-resolution methods with relatively low cost and desirable robustness. For reflection migration and inversion, the spatial resolution limits are approximately defined by a generalized Radon transform analysis (Beylkin et al. 1985); and the resolution limits for ray-based transmission tomography (Williamson 1991) can be estimated by considering the width of the transmission Fresnel zone.

Migration is the first iterate solution of Eq. 5, and least squares migration, sometimes known as linearized inversion, is the final iterative solution where the operator $\mathbf{L}$ is not updated after each iteration; also, $\mathbf{m}(\mathbf{x})$ represents the reflectivity model at the position $\mathbf{x}$. In contrast to migration, the waveform inversion tomogram is the final iterative solution, where the velocity model $\mathbf{m}$ and $\mathbf{L}$ are updated after every iteration; waveform inversion falls under the class of non-linear optimization methods. It can be shown under certain assumptions that waveform inversion reduces to either wave equation traveltimes tomography (Luo and Schuster 1991) or ray-based tomography. These last two methods are classified as phase-like inversion methods. Unlike minimizing the data misfit function in Eq. 4, migration velocity analysis updates the velocity model to minimize a *model misfit function*, which is the normed difference between the predicted migration image and the actual migration image in the, e.g., common image gather. Convergence problems associated with local minima in the misfit function are reduced by emphasizing *flatness* in the CIG misfit function (Symes and Carazone 1991; Shen et al. 1993).

Migration

If the starting model is a smoothly varying velocity distribution that only generates the accurate first arrival, then the input data $\mathbf{d} - \mathbf{d}^{(0)}$ residual becomes the scattered data. In this case, the desired model is the reflectivity distribution, which is similar to the slowness perturbation function $\delta s(\mathbf{x})$, and the background velocity model is the inverse of slowness $s(\mathbf{x})$. If a finite-difference solution to the wave equation, for example, is used to calculate $G(\mathbf{x}|\mathbf{s})$ and $G(\mathbf{g}|\mathbf{x})$ in Eq. A5, then the first model update $\delta \mathbf{m}^{(1)}$ in Eq. 5 is known as the reverse time migration image (Whitmore 1983; McMechan 1983). If a oneway wave equation method is used to generate the Green's function, then the migration method is a phase-shift or FX-type algorithm (Stolt and Benson 1986; Claerbout 1992; Etgen et al. 2009). A diffraction-stack migration method results if the Green's function is replaced by its asymptotic approximation $G(\mathbf{x}|\mathbf{s}) = A(\mathbf{x}, \mathbf{s})e^{i\omega\tau_{xs}}$ (here, $A(\mathbf{x}, \mathbf{s})$ accounts for geometric spreading losses, and τ_{xs} is the first arrival time for a ray that connects the source at $\mathbf{s}$ with the observer at $\mathbf{x}$). A ray-tracing method can be used to compute these traveltimes for a sufficiently high frequency and smoothly varying medium [Bleistein et al. 2001]). An example of standard poststack migration is depicted in Fig. 1c, where the velocity model is shown in Fig. 1a. The migration image depicts the reflectivity distribution computed by a Kirchhoff migration method with an eikonal traveltimes solver.

Seismic migration is also used to migrate teleseismic body waves processed to form so-called receiver functions. Examples include Ryberg and Weber (2000), Sheehan et al. (2000), and also Bostock et al. (2001) who used a ray-Born inversion approach. More recently, Nowack et al. (2007) applied the Gaussian beam migration approach of Hill (2001) to the migration of teleseismic body waves. Despite its widespread use and its robustness, migration is considered to be a moderate-resolution method because it approximates the inverse Hessian matrix $[\mathbf{L}^\dagger \mathbf{L}]^{-1}$ by a diagonal matrix.

Least Squares Migration

If the background model $1/s(\mathbf{x})$ is not updated after each iteration (i.e., $\mathbf{L}$ in Eq. 5 is independent of the k index), then $\mathbf{m}^{(k+1)}$ for large k is known as the least squares migration image (Nemeth et al. 1999; Duquet et al. 2000). As in standard migration, the model to be iteratively updated is the reflectivity distribution and not the velocity model. The iterative least squares migration Eq. A6 is interpreted as a sequence of standard migrations, where the data residual is back projected into the earth model by the migration operator $\mathbf{L}^\dagger$. Least squares migration (LSM) is also known as linearized waveform inversion (Lailly 1984; Tarantola 1986, 1987; Jin et al. 1992; Lambaré et al. 1992) and is superior to standard migration by reducing migration artifacts caused by a poor acquisition geometry; it also can provide a spatial resolution that is more than twice (Nemeth et al. 1999; Yu

et al. 2006) that of standard migration if the migration velocity is sufficiently accurate. Its main drawbacks are that its effectiveness is very sensitive to the accuracy of the migration velocity model, and it can be more than an order of magnitude more expensive than standard migration. (Recent developments [Dai and Schuster 2009] in phase-encoded migration suggest a great reduction in the cost of LSM.) As an example, Fig. 1d depicts the LSM image obtained from zero offset (ZO) data, which is more accurate than the ZO standard migration image in Fig. 1c. Figure 1e–f depict the RTM and LSM RTM images obtained from the prestack shot gathers.

Full Waveform Inversion

If the background model is updated after each iteration, then Eq. A7 is known as nonlinear waveform inversion (Tarantola 1987; Mora 1987; Mora 1989; Song et al. 1995; and many others); a common designation for waveform inversion is FWI or full waveform inversion. Unlike LSM or standard migration, Eq. A7 for FWI iteratively updates the velocity and reflectivity models so that the final velocity image can be much improved in both resolution and accuracy. Its main drawbacks are a tendency to get stuck in local minima, it is computationally expensive compared to standard migration, and there might be more than one model that can explain the same data, i.e., a nonunique solution. For example, elastic isotropic modeling codes can sometimes generate predicted traces that adequately fit the observed data, but the estimated isotropic velocity model is inconsistent with the actual anisotropic rocks in the real earth.

Successful examples of waveform tomography images are shown in Fig. 1g–h and were obtained from the same shot gathers used for migration. The final tomogram shows the velocity distribution that is almost identical to that of the actual model. One of the keys to success in waveform inversion is that a good starting model is often required for an accurate result. This starting model can be obtained by migration velocity analysis (Stork 1992; Jousset et al. 2009), reflection traveltime tomography (Langan et al. 1985; Bishop et al. 1985; Nolet 1987; Zelt 2002), or refraction tomography (Pratt and Goult 1991; Luo and Schuster 1991; Min and Shin 2006; Sheng et al. 2006).

A major challenge to the success of waveform inversion is the limited offset range between sources and receivers and the lack of low-frequency information in the recorded data (Sirgue and Pratt 2004; Barnes et al. 2008; Boonyasiriwat et al. 2009; Kelly et al. 2009). Such deficiencies can prevent waveform inversion from reconstructing the low wave-number parts of the model, and sometimes prevent convergence to any type of reasonable model. Remedies being explored include the possibility of recording data at much lower frequencies with more capable recording devices, and

obtaining very wide-offset data. Other challenges address the validity of the acoustic approximation versus the reality that the recorded data are largely of elastic (Vigh et al. 2009) or viscoelastic nature (Causse et al. 1999; Askan 2006). Elastic inversion of elastic seismograms (Mora 1987; Mora 1989; Zhou et al. 1997; Brossier et al. 2009) have been presented, but the acoustic approximation can still provide useful results. One approach to viscoelastic inversion is to invert for the acoustic velocity first, then follow this with inversion for attenuation parameters (Kamei and Pratt 2008); another approach is to use a ray-based method to invert for the attenuation factor Q and then use this Q to correct for the attenuation in the data (Pratt et al. 2005; Sheng et al. 2007; Boonyasiriwat et al. 2009).

Wave Equation Traveltime Inversion

If the data residual $\delta d(\mathbf{g}|\mathbf{s})$ is replaced by the traveltime residual $\delta \tau(\mathbf{g}|\mathbf{s})$ weighted by the recorded trace $d(\mathbf{g}|\mathbf{s})^{\text{obs}}$, then this is known as wave equation traveltime (Luo and Schuster 1991) tomography (WT); it is a variant of Rytov inversion (Woodward 1992) and updates the velocity model by smearing weighted traveltime (not waveform) residuals over the associated wavepaths (Woodward 1992; Luo 1992). In the high-frequency limit, it reduces to ray-based traveltime tomography (RT). The advantage of WT over RT is that it does not require a high-frequency approximation and accounts for the band-limited nature of waves as they propagate through the earth. Shin et al. (2002, 2007) use a modified logarithm norm to invert for phase data, which bears a close relationship to the Rytov inversion method; and Effelsen (2009) compares phase inversion to traveltime tomography for inverting refraction events. Figure 2 illustrates how the above seismic imaging methods are related to one another.

The main disadvantage of WT is that it is at least an order of magnitude more expensive than RT because it requires a finite-difference solution of the wave equation rather than a ray-traced approximation. Earthquake seismologists often see wave equation traveltime as a major improvement in estimating the earth's velocity parameters from earthquake records (Dahlen et al. 2002; Marquering et al. 2002; Montelli et al. 2006; van der Hilst and de Hoop 2006).

Migration Velocity Analysis

The previous imaging methods can be described as estimating the earth model by predicting synthetic data that *best matches the observed data in the data domain*. In contrast, migration velocity analysis (MVA) finds the velocity model that *best flattens or focuses the migration sections in the image domain*; here, the image domain is the migration cube in the (x, y, z) indices and some other index s such as shot index, receiver index, source-receiver offset, (Yilmaz and Chambers 1984; Faye and Jeannot 1986; Al-Yahya 1989; Toldi 1989; Stork 1992; Lafond and Levander 1993), common angle

Seismic Imaging, Overview, Fig. 2 Three types of seismic imaging methods: phase inversion, least squares migration (LSM), and nonlinear waveform inversion. Note that LSM is a linearized inversion so that the modeling operator $\mathbf{L}$ does not get updated after each iteration. This compares to nonlinear waveform inversion which updates $\mathbf{L}$ after each iteration. The Lippmann-Schwinger-type and Woodward-Roca-type integrals are displayed in Table 1, and details about various migration methods are in the Seismic Migration section in the *Encyclopedia of*

Solid Earth Geophysics. The traces that only contain scattered arrivals are obtained by muting the direct arrivals; and the ensemble of these traces is symbolized by the vector $\mathbf{d}^{\text{scatt.}}$. Instead of computing the Green's functions in the integral equations by a finite-difference solution to the wave equation, various approximations such as ray-based Green's functions (Kirchhoff migration), one-way wave equation approximations (phase-shift type migration), and Gaussian Beam (beam-like migration) are used for migration

parameter (Xu et al. 1998), or subsurface offset coordinate (Rickett and Sava 2002; Sava and Biondi 2004; Robein 2010).

To understand why we seek a velocity model that flattens events in the image domain, consider the 2D migration image $m(x, z, s_0)$ in Fig. 3a obtained by migrating one shot gather (the source is at the surface with shot index s_0). If the migration velocity is correct, then all of the single-shot migration images should be similar in appearance. This means that all of the migrated reflection events should be flat in the common image gather (CIG) given by $m(x_{\text{CIG}}, z, s)$ for all values of s, z , and a fixed value of x_{CIG} (see Fig. 3b). Note that if the migration velocity is accurate, the reflector boundary denoted by the dotted horizontal line will be flat for a common image gather. If the migration velocity is too slow, then the imaged reflector boundary will curve upward as illustrated by the curved dashed line, and if too fast, the imaged reflector will curve downward.

With MVA, the goal is to find the velocity model so that, ideally, the predicted migration image $\mathbf{m}_{\text{mig.}}^{\text{pred.}} = \mathbf{L}^\dagger \mathbf{L} \mathbf{m}$ best fits the actual migration image $\mathbf{m}_{\text{mig.}} = \mathbf{L}^\dagger \mathbf{d}$. The associated misfit function can be constructed so that it is similar to that of Eq. 4, except that the norm of the *migration* residual

$$\varepsilon = \frac{1}{2} \left\| \mathbf{m}_{\text{mig.}}^{\text{pred.}} - \mathbf{m}_{\text{mig.}} \right\|_K^2 + \frac{\lambda^2}{2} \left\| \mathbf{C} \mathbf{m} \right\|_W^2 \quad (6)$$

is minimized rather than the *data* residual; in this case, $\mathbf{m}$ represents the velocity model. To find the velocity model, we can use the unregularized steepest descent equation:

$$\mathbf{m}^{(k+1)} = \mathbf{m}^{(k)} - \overbrace{\alpha \mathbf{L}^\dagger \mathbf{L} \delta \mathbf{m}_{\text{mig.}}^{(k)}}^{\text{migration-modeling of migration residual}}, \quad (7)$$

where $\delta \mathbf{m}_{\text{mig.}}^{(k)} = \mathbf{m}_{\text{mig.}}^{\text{pred.}} - \mathbf{m}_{\text{mig.}}$ is the migration residual at the k th iteration. The importance of this formula is that it shows

Seismic Imaging, Overview, Fig. 3 (a) Migration image $\mathbf{m}_{\text{mig.}}(x, z, s)$ cube in the model coordinates of x and z and the surface shot offset index s ; the common image gather $\mathbf{m}_{\text{mig.}}(x_{\text{CIG}}, z, s)$ is computed by migrating the shot gathers and displaying the migration image at the fixed value of

$x = x_{\text{CIG}}$ for all shot s and depth z values. (b) Common image gather $\mathbf{m}_{\text{mig.}}(x_{\text{CIG}}, z, s)$ for the common image point at x_{CIG} . The migration image should only be non-zero along the interface between the brick region and open region shown above

that the gradient term is computed by modeling the migration residual to get the *filtered* data residual $\mathbf{L}\delta\mathbf{m}_{\text{mig.}}^{(k)}$, and then the velocity model is updated by smearing this filtered (the filtered data residual is constructed by migrating and modeling the actual data residual; hence, it is a filtered version of the actual data residual) data residual into the model by the migration operation $\mathbf{L}^\dagger[\mathbf{L}\delta\mathbf{m}_{\text{mig.}}^{(k)}]$. These filtered residuals are smeared along wavepaths for each source-receiver pair of traces, and the migration and modeling operators are updated after each iteration. This leads to a moderate resolution of the velocity model because the filtered, not unfiltered, data are kinematically fitted. Moreover, MVA is largely a curve fitting exercise that is mostly insensitive to subtle amplitude variations in the migration traces; ignoring such information will blind MVA to subtle variations in the impedance distribution.

To reduce computational costs and increase robustness at the expense of reduced model resolution, MVA is sometimes implemented with the following steps:

1. Automatically pick the depth residual $\Delta z_i = z_i - z_i^{\text{ref.}}$ of a coherent CIG event in Fig. 3b at the i th shot position; here, z is the picked depth of the targeted reflection at the x_{CIG} offset in the i th migrated shot gather. The depth $z_i^{\text{ref.}}$ of the reference event for that reflector, is estimated from the near-offset trace in that CIG. A computer algorithm can window about the near-offset reflection of interest and use cross-correlation with neighboring traces in the CIG to estimate the depth lag $z_i - z_i^{\text{ref.}}$ associated with the strongest correlation energy.
2. The misfit function is then defined as

$$\varepsilon = 1/2 \sum_i (\Delta z_i)^2 + \text{model smoothness constraints}, \quad (8)$$

for each CIG and the summation is over the shot index in Fig. 3b. Sometimes the misfit function is the sum over all CIGs.

3. The velocity model is iteratively updated by a gradient optimization method until ε is minimized.

An example of the above procedure is shown in Fig. 4, where the left column of images depict the (a) migration image obtained with an inaccurate velocity model, (b) the CIG with curved events, and (c) the migration velocity model. After seven iterations of MVA, the right column of figures is obtained. Note the flat events in the CIG, and the final velocity model is almost the same as the actual velocity model.

The Fréchet derivative $\frac{\partial \varepsilon}{\partial c(\mathbf{x})}$ associated with the gradient of ε can be numerically computed by using a ray-tracing scheme (Stork 1992; Chauris et al. 1998) to determine the change in depth z_i of a migrated reflection point with respect to a change in the velocity parameter at $\mathbf{x}$. Sometimes, the depth residual Δz_i for the i th ray is converted into a time residual $\Delta \tau_i$, and, similar to traveltime tomography, this *converted* time residual is smeared along the reflection ray to iteratively update the velocity model. For arbitrary reflector geometries in a homogeneous media, an analytic conversion formula was derived

by Al-Yahya (1989), and a ray-tracing method was used by Stork (1992) and others (Robein 2010).

Similar to waveform inversion, MVA seeks to predict the wiggly migration traces seen in the migration image $\mathbf{L}^\dagger \mathbf{d}$ and, therefore, can easily get stuck in the many local minima of ε . To avoid this problem, Symes and Carazone (1991) proposed the smoother differential semblance misfit function (Chauris et al. 1998; Shen et al. 2003):

$$\varepsilon = 1/2 \left\| \sum_{x,y} \left[\gamma \sum_z \sum_h \partial m(x,y,z,h)_{\text{mig.}} / \partial h^2 \right] \right\|^2 + \text{constraints.} \quad (9)$$

that rewards flat events (i.e., accurate velocity models) in the CIG domain. Here, γ is a normalization term that depends on (x, y) . Empirical tests by Chauris et al. (1998) suggest that the semblance based ε is much smoother than that in Eq. 6 and is nearly devoid of local minima in misfit function. Some links between MVA and FWI are established in Symes (2008), and MVA compared to several tomography methods is presented

Seismic Imaging, Overview,

Fig. 4 (a) Migration image (Sun 2001) obtained by prestack migration using the smooth homogeneous velocity model in (c) that is far from the true model approximated in (f); (b) common image gather in the shot offset index, where the curved events indicate an incorrect velocity model; (c) incorrect migration velocity model used to compute (a); (d) migration image obtained after seven iterations of MVA; (e) CIG after seven iterations of MVA; and (f) velocity model inverted by seven iterations of MVA. This result closely resembles the true velocity model

by Le Bégat et al. (2004). The subsurface offset domain can be exploited for MVA (Sava and Biondi 2004) and extraction of scattering angle information (Rickett and Sava 2002), and an excellent summary of MVA research is given in Robein (2010).

In summary, the exploration community heavily favors MVA over many other velocity estimation methods because it is robust, efficient, and the picking of depth residuals is easily automated in the migration image domain. (Traveltimes picked from traces are notoriously difficult to automate because waveforms often interfere with one another. In comparison, migration untangles these events and focuses them to their origin along the reflectors so that automatic picking is easier in the CIG. Sometimes semblance methods are used to find the best fit hyperbolic or parabolic curve to the data [Robein 2010].) Its chief disadvantage is that an MVA image lacks the detailed resolution of waveform inversion, which suggests that MVA should be used to estimate the starting velocity models for waveform tomography.

Recent Advances in Seismic Imaging

In the last 15 years, several breakthroughs have enabled practical waveform inversion of seismic data. One of these advances is the relentless increase in computational capabilities of cluster computers and GPU-like processors, and two others are multiscale inversion and phase-encoded waveform inversion.

Multiscale Waveform Inversion

One of the main difficulties with waveform inversion is that the misfit function is plagued by many local minima. If the starting velocity model is moderately far from the actual model (an erroneous velocity might be one where the modeled events arrive by more than a period after the actual arrivals), then the iterative gradient solution gets stuck there and never reaches the global minimum or actual model.

The partial cure to this local-minima problem is a multiscale approach (Bunks et al. 1995), where the initial iterations estimate a coarse-grid velocity model from low-frequency data. For a reasonable starting model, this often prevents getting stuck in local minima because the predicted low-frequency arrivals are more likely to arrive within a period of the arrivals in the low-pass filtered data. After a number of iterations, the velocity model is refined to a finer scale (the grid interval is halved) and intermediate frequency data are iteratively inverted to update the velocity model. After suitable reduction of the data misfit, the model grid is refined again and higher-frequency data are inverted until a satisfactory model is reconstructed. One of the first relevant demonstrations of multiscale FWI applied to real data in a complex environment was performed by Ravaut et al. (2004). Other

results with both synthetic and field data (Sirgue and Pratt 2004; Sirgue et al. 2007; Plessix 2009; Vigh and Starr 2007, 2008; Sirgue et al. 2010) convincingly demonstrate the effectiveness of this approach. As mentioned earlier, improved model reconstructions can be achieved if more accurate starting models are employed, lower frequency data are recorded, and wider offset data are acquired. The new challenges are to employ modeling and inversion codes that robustly take into account the effects of viscoelasticity and anisotropy in the data.

Phase-Encoded Multisource Waveform Inversion

A major difficulty, until recently, is the enormous computational expense of waveform inversion. Each shot gather of residuals must be migrated at each iteration, which for 3D problems can be too demanding even for the most powerful computers. To relieve this problem, Krebs et al. (2009), Operto et al. (2009), and Dai and Schuster (2009) proposed summing phase-encoded shot gathers into supergathers and migrating the supergathers at each iteration; a supergather is modeled with just one finite-difference simulation, where the computational cost is the same as that for one shot gather. This is similar to the phase-encoding RTM of Romero et al. (2000), except iterations are used to reduce the crosstalk noise in supergather migration. The result can be an enormous cost savings compared to conventional waveform inversion or migration.

Figure 1h shows an example of phase-encoding shot gathers, where each trace in a shot gather has the same random time shift but different shots have different time shifts. In this case, 12 shot gathers were time-shifted and blended together into one supergather; there were 192 traces per shot gather. A total of 16 nonoverlapping supergathers were input into the iterative waveform inversion code, where each supergather migration costs the same as the migration of one shot gather because 12 shots were excited at nearly the same time. Hence, the Fig. 1h tomogram costs 1/12 that of the Fig. 1g tomogram. For 3D inversion, the computational cost savings can be more than two orders of magnitude compared to conventional waveform inversion.

For a 3D example, Fig. 5a shows results after waveform inversion of 3D synthetic data, where the model size is $800 \times 800 \times 186$ grid points and the spatial sampling interval is 20 m. There are 1089 sources evenly distributed along the surface with an interval of 500 m in the inline (X) and crossline (Y) directions. Multisource waveform inversion using the Krebs method (Krebs et al. 2009), static Quasi-Monte Carlo (QMC) phase encoding, and dynamic QMC phase encoding (Boonyasiriwat and Schuster 2010) are applied to this data set.

Figure 5b–d show that dynamic QMC phase encoding provides a higher-quality tomogram than the other methods, yet the computational cost is two orders of magnitude less

Seismic Imaging, Overview, Fig. 5 Depth slices at $z = 2.1$ km and cross-sections at $y = 8$ km of (a) true model, and inverted models using (b) the Krebs method (1089 CSGs/supergather), (c) static QMC method (99 CSGs/supergather), and (d) dynamic QMC method (99 CSGs/

supergather) after 40 iterations. A greater number of CSGs/supergather require a greater number of iterations to get the same accuracy in the final tomogram; the dynamic encoding strategy is more effective than the static strategy. (Figures courtesy of C. Boonyasiriwat)

than that of conventional waveform inversion. The Krebs strategy is the most efficient because 1089 shot gathers were blended into one supergather, compared to the QMC strategies that used 99 CSGs/supergather. Dynamic phase encoding changed the time shifts of each shot gather after each iteration, while the static strategy kept the phase encoding the same.

Current Status and Future of Seismic Imaging

Reverse time migration is becoming the preferred means for seismic imaging beneath complex regions such as salt bodies. Earthquake seismologists are now recognizing the benefits of migration imaging earthquake records for tectonic structures such as subduction zones (Bostock et al. 2001) or using wide-angle seismic experiments to image the crust (Brenders and Pratt 2007) and mantle (Montelli et al. 2006). Least squares migration and waveform inversion are now being considered as viable upgrades to standard migration because of the tremendous speed up from phase-encoded multisource methodology. There is still a debate about whether waveform inversion should be computed in the frequency (there are additional advantages by formulating the problem in the Laplace transform domain [Shin and Ha 2008]) or time domains (Vigh and Starr 2007; Warner 2008), but there is no debate that we eventually need to account for viscoelastic and anisotropic effects in the data.

3D waveform inversion of earthquake records for whole earth tomograms greater than 1 Hz is still too computationally demanding except at very low frequencies, and the same can be said for 3D exploration geophysics at frequencies above 50 Hz. Challenges still remain, especially in the critically important area of anisotropic RTM (Zhang and Zhang 2009; Fowler et al. 2010) and waveform inversion; estimation of accurate anisotropic migration velocity models is an ongoing line of research. Earthquake seismologists are now testing the possibility of using earthquake records for inverting basin structures and velocity models so as to improve their simulation-based predictions of earthquake hazard. Passive seismic recordings and the use of interferometry to extract surface wave records (Shapiro and Campillo 2004; Shapiro et al. 2005), followed by inversion for S-velocity tomograms are playing an increasingly important role in earthquake seismology.

Synonyms

Seismometry

Definition

Datalogger. Device for recording electrical signal from a seismometer, usually in digital form and with accurate time information.

Geophone. Another name for seismometer, used in geophysical exploration.

Seismometer. Device for providing a record of ground motion, usually by converting it into an electrical signal.

Strainmeter. Device for continuously measuring the deformation of the Earth, either as extension along a line, or volume change.

Introduction

Seismic instruments give a time record of ground motion caused by elastic waves. The first instruments were built at

the end of the nineteenth century; subsequent developments have evolved towards wider coverage of both the frequency and amplitude of the waves that could be recorded. Over most of the twentieth century much of this evolution, and of the diversity of instrument types, was related not to how ground motion was sensed but to how it was recorded; the last three decades have seen such rapid development in digital technology, especially in data storage, that recording techniques unique to seismology are no longer needed. Modern seismic systems all consist of a seismometer for converting some aspect of ground motion into an electrical signal, and a datalogger for recording this signal. In exploration geophysics, the name geophone is a common synonym for seismometer; now that data recording is clearly separated from sensing ground motion, the old term seismograph could probably be abandoned. Since dataloggers are not unique to seismology, this article discusses only the general requirements for them, focusing instead on the designs of seismic sensors, or seismometry. Three recent reviews cover seismometry in more detail: Wielandt (2002), Havskov and Alguacil (2004), and Bormann (2009).

Requirements for Instruments

The frequencies to be measured by seismometers range from 0.31 mHz (the slowest free oscillation) up to 1 kHz (in near-surface geophysics): roughly six orders of magnitude. Fig. 1 shows the amplitudes that can occur over most of this frequency range, from the background noise level at quiet sites (Berger et al. 2004) to the large signals that have been observed at moderate distances from very large earthquakes, to the even larger, and damaging, strong ground motions close to an earthquake. The large signals are infrequent, but also of considerable scientific importance – but so are very small signals, which can be seen only if the seismometer has lower noise than the ground does.

Since digital dataloggers can record over a much wider range of amplitudes and frequencies than the older analog recorders could, modern seismic systems can be characterized as broadband (covering a wide band of frequencies) and high dynamic range (a wide range of amplitudes). But the range from noise to the largest signal covers over 10 orders of magnitude, too much for any single instrument and datalogger. Since most seismometer designs require practical tradeoffs between low-frequency capability and other performance goals, seismometers are still classified by what frequencies and amplitudes they cover best. Systems for recording the largest signals without distortion are called *strong-motion* seismometers, and have usually been designed to meet the needs of earthquake engineers rather than seismologists, though digital technology is blurring this distinction.

Inertial Seismometers: Basic Principles

Almost all seismometers measure motion of the ground using the inertia of an internal mass, and so are called *inertial* sensors. This mass, of amount m , is subject to five forces: (1) constraints that restrict the mass motion to be in a particular direction (denoted by a unit vector $\mathbf{e}$) making the system one with a single degree of freedom; (2) the gravitational force vector, $\mathbf{g}m$, along that direction, namely, $\mathbf{e} \cdot \mathbf{g}m$; (3) an elastic restoring force (from a spring), $-k(x - x_0)$, where k is the spring constant and x the displacement (in the direction $\mathbf{e}$) away from an equilibrium position x_0 ; (4) a viscous damping force proportional to velocity $-d\dot{x}$; (5) additional forces F_b that may be applied by a feedback system (discussed below).

The displacement of the mass relative to an inertial frame is $x + \mathbf{e} \cdot \mathbf{u}$, where x is the motion of the mass relative to the Earth, which is what we can measure, and $\mathbf{u}$ is the (vector) motion of the Earth relative to the inertial frame, which is that of the Earth in the absence of seismic waves (we can neglect non-inertial effects from the Earth's rotation). Combining forces (2), (3), and (4), and applying the momentum equation, the acceleration of the mass is given by

$$m(\ddot{x} + \mathbf{e} \cdot \ddot{\mathbf{u}}) = \mathbf{e} \cdot \mathbf{g}m - k(x - x_0) - d\dot{x}$$

where we allow the possibility of variations in both $\mathbf{e}$ and $\mathbf{g}$. With no motion, we assume that the mass position is x_0 , so that $\mathbf{e}_0 \cdot \mathbf{g}_0 m = -kx_0$. Then the above equation becomes, for small variations in $\mathbf{e}$ and $\mathbf{g}$, and after some rearrangement of terms,

$$\frac{k}{m}x + \frac{d}{m}\dot{x} + \ddot{x} = -\mathbf{e}_0 \cdot \ddot{\mathbf{u}} - \mathbf{e}_0 \cdot (\mathbf{g} - \mathbf{g}_0) - (\mathbf{e} - \mathbf{e}_0) \cdot \mathbf{g}_0$$

more usually written as

$$\ddot{x} + 2\gamma\dot{x} + \omega_0^2 x = -\mathbf{e}_0 \cdot \ddot{\mathbf{u}} - \mathbf{e}_0 \cdot (\mathbf{g} - \mathbf{g}_0) - (\mathbf{e} - \mathbf{e}_0) \cdot \mathbf{g}_0 \quad (1)$$

where $\omega_0 = \sqrt{k/M}$ is the natural frequency of the seismometer ($T_0 = 2\pi/\omega_0$ is called the free period); $\gamma = d/2M$ is the damping constant. These names describe the behavior of the seismometer if the right-hand side of the equation is zero and $x = x_0$ at $t = 0$; the subsequent motion of the seismometer mass is then

$$x(t) = x_0 \cos\left(\frac{2\pi t}{T_0}\right) e^{-\gamma t},$$

which is a decaying sinusoid with period T ; the damping γ needs to be large enough to avoid ringing (a sign of resonance effects), and is usually set to about 0.8.

The right-hand side of Eq. 1 shows that an inertial sensor responds to three inputs:

1. The acceleration of the ground, $\ddot{\mathbf{u}}$; this is why inertial sensors are often called accelerometers.
2. Changes in the gravitational vector $\mathbf{g}$ along the direction of sensitivity; if this is the dominant signal, the sensor is usually referred to as a gravimeter (see *Gravimeters*).
3. Changes in the direction of sensitivity relative to the direction of gravity. If $\mathbf{e}_0$ and $\mathbf{g}_0$ are parallel (the mass moves vertically), then to first order $\mathbf{e} - \mathbf{e}_0$ is perpendicular to $\mathbf{g}_0$, and this contribution is zero. However, if $\mathbf{e}_0$ and $\mathbf{g}_0$ are perpendicular (the mass moves horizontally), then to first order $\mathbf{e} - \mathbf{e}_0$ is parallel to $\mathbf{g}_0$, and this contribution can be significant; if this is the dominant signal, the sensor would be referred to as a tiltmeter, since changes in $\mathbf{e}$ reflect tilting of the sensor (or the ground it is attached to).

Much confusion has been created by the use of these different terms for what is the same kind of sensor, when the difference actually refers to the type of signal being measured.

Ignoring the tilt and gravity terms, suppose that the ground displacement is purely sinusoidal, $u(t) = Ue^{i\omega t}$ (U being complex, and the real part being taken). Then the mass motion will be $Xe^{i\omega t}$, where

$$\frac{X}{U} = \frac{\omega^2}{\omega_0^2 - \gamma i\omega + \omega^2} \quad (2)$$

is the frequency response of the seismometer. For ground motion at frequencies much higher than the natural frequency ω_0 , $X \approx U$: the mass motion looks like ground displacement. For ground motion at much lower frequencies, $X \approx U\omega^2/\omega_0^2$: the mass motion looks like ground acceleration, scaled by the inverse of the natural frequency of the seismometer.

The minimum noise level of any inertial sensor is set by the thermal (Brownian) motion of the mass in equilibrium with its surroundings. This noise level can be expressed as an equivalent ground acceleration, with a flat power spectral density of $8\omega_0\lambda k_B\theta/m$, where k_B is Boltzmann's constant and θ is the temperature (Aki and Richards 2002). For a temperature of 310 K and $\gamma = 0.8$, this expression is $1.72 \times 10^{-19}/(mT_0) \text{ m}^4 \text{ s}^{-3}$, with m in kilograms and T_0 in seconds. The dotted lines in Fig. 1 show noise levels for two cases that cover the range of designs: $mT_0 = 10^{-4}$ (1 g mass and free period of 0.1 s), which cannot resolve ground noise at the longer periods, and $mT_0 = 3$ (300 g and 10 s), which shows that a moderately large mass and long period are necessary and sufficient for this thermal noise limit to fall below ground noise at all frequencies.

Seismic Instrumentation,

Fig. 1 Seismic and instrument noise levels. The solid and long dashed lines show the lowest levels of vertical and horizontal ground motion observed by the stations of the Global Seismographic Network. The dotted lines show the seismometer Brownian noise limit for two different values of the product of the sensor mass and free period. The dashed lines show the noise levels for a high-quality short-period system using a moving-coil transducer (Rodgers 1994), for a MEMS sensor used for measuring strong motion (Evans et al. 2005), for a sensitive broadband system (Ringler and Hutt 2009), and for GPS used at seismic frequencies

Mechanical Design

In an inertial sensor, the mass needs to be constrained to move in one direction only, with a restoring force that is both exactly linear in the mass displacement and of whatever amount needed for the sensor to have the desired free period. The free period enters into the design partly because of Eq. 2: the longer the period, the greater the displacement of the mass for a given acceleration at periods longer than the free period; that is to say, the higher the long-period sensitivity, and the lower the noise. Sensors designed to measure only high frequencies, such as the geophones used in geophysical exploration, can have a short free period, which means that the springs used can be relatively stiff (large k) and rugged. Seismometers for high frequencies use elastic elements both to constrain mass motion to a straight line and to provide a linear restoring force (Fig. 2a). The latest innovation for short-period instruments is the MEMS (Micro-Electronic Mechanical Systems) sensor, in which the mass-spring system is machined from monolithic silicon and packaged with integral electronics; these are mass-produced for non-seismological applications and so are relatively inexpensive. While not as

sensitive as traditional seismometers, they are already useful for measuring strong ground motions.

The high sensitivity needed for scientific purposes makes the mechanical design more challenging. If the mass moves vertically, it must be stably suspended against gravity while the restoring force is also kept low. In most long-period seismometers, the mass is constrained by hinges and stops to move along a small part of the circumference of a circle, which for most applications is an adequate approximation to a straight line (departures from this cause cross-coupling (Rodgers 1968; LaCoste 1967)). For sensing horizontal motion, the circle is slightly tilted from a horizontal plane, in which case the hinged mass is a horizontal pendulum (also called a garden-gate suspension, shown in Fig. 2b). The restoring force then comes from gravity and is easily adjusted by tilting the instrument.

Long-period sensors that measure in other directions use a spring arranged to give a weak, but still linear, restoring force. One common design is the LaCoste suspension (Fig. 2c), which uses a *zero-length spring*: a helical spring that exerts a force exactly proportional to its physical length. The

Seismic Instrumentation,

Fig. 2 Mechanical designs for seismometers, shown in cartoon form. (a) is a simple mass on a spring. (b) is the “garden-gate” design used for long-period horizontal instruments; note that the support post is not vertical. (c) shows the geometry of a LaCoste suspension; the restoring force of the spring must be equal to its physical length. (d) shows a vertical sensor that uses a leaf spring (elastica) to supply the restoring force. (e) and (f) show the design of a single sensor in a triaxial seismometer, and how three such sensors are arranged to record orthogonal motions

geometry of the spring and hinged mass is chosen to make the restoring force nearly independent of mass position, giving a very long period. An alternative method uses a single sheet of elastic material, bent to form a leaf spring (Fig. 2d), to create a long-period system with adequate linearity over the actual range of motion.

The traditional arrangement of seismometers is an orthogonal pair for horizontal motion, and a single sensor of vertical motion; if only one sensor is used, it is usually a vertical to give the best signal-to-noise ratio for P waves. Many systems now use a “triaxial” arrangement, with three identical systems measuring motion at an angle of 54.73° to the vertical, and at azimuths 120° apart; this also gives three orthogonal directions, namely those of the edges of a cube balanced on a corner (Fig. 2e, f).

Any seismometer requires careful design to ensure that the only vibration that takes place is the mass motion, or at least that other modes of vibration (called *parasitic resonances*) will not produce any signals if excited by ground motion. Long-period seismometers need special materials that do not creep much under load and whose dimensions and elastic constants are insensitive to temperature changes; even then, isolation and active environmental control may be needed to reduce the effects of changes in air temperature, air pressure (which causes varying buoyancy of the mass), and magnetic fields (which affect spring materials).

Electronic Design

Sensing the mass motion in a seismometer is now almost always done electronically, in one of two ways (Agnew 1986). In the first, electrodynamic method, permanent magnets and coils of wire are arranged so that the motion of the sensor produces an induced voltage $V = G\dot{x}$, where G is the generator constant; this voltage is then amplified and recorded. This method is simple and rugged, and provides damping if some of the induced current flows through a resistor. However, because the voltage produced depends on the velocity of the mass, and because the noise in the amplifiers rises with low frequency, electrodynamic sensing cannot resolve ground noise at periods longer than about 10 s.

The second method is active sensing of the mass motion. An oscillating voltage is input to a variable capacitor or inductor attached to the mass, which produces an output voltage with the same frequency and amplitude proportional to x ; this output voltage is then demodulated to produce $V = Sx$, where S is the sensitivity. Up to the point of demodulation, the signal is at a frequency (several kHz) at which electronics noise is relatively low, so such displacement sensors can be made sensitive enough to measure motions less than an atomic diameter.

This output voltage can be recorded directly, but more often is used in a feedback system: the integral of this voltage (over some frequency band) is used to apply an additional

force to the mass, usually with a coil and magnet, acting against the mass displacement. Because this force acts against the apparent force of ground acceleration, this is called a force-balance accelerometer. Feedback does not decrease noise, but does have three other merits. First, it can be used to vary the seismometer response much more than mechanical modifications can; for example, a mechanical system with a free period longer than 10 s is difficult to make, but this is easy to create electronically; and the response of the electronic system will be much more stable over time. Second, because the feedback force reduces the mass motion, the mechanical system needs to be linear over a smaller range. Finally, the calibration depends on the relation between voltage and feedback force, and this is very stable over time.

Calibration

Equation 2 is an example of the transfer function of a seismometer: the relation, as a function of frequency, between the ground motion and the output. In that example, the output was assumed to be mass motion x ; a more realistic example would include a displacement sensor that generates a voltage $V = Sx$ followed by a datalogger that digitizes the voltage and produces a number $N = AV$. The total transfer function of the system, from input Earth displacement to digital output, would then be

$$\frac{AS\omega^2}{\omega_0^2 - \gamma i\omega + \omega^2}. \quad (3)$$

Seismometer calibration consists of determining all the parameters in expressions like this one. Some components, such as the datalogger, are calibrated by putting a known signal in and recording the output. For the seismic sensor, this requires producing a known ground motion, which can be done with a shake table before the seismometer is installed. After installation, a seismometer calibration can be checked by putting a signal into the seismometer electronics that will apply force to the mass without otherwise disturbing the output.

Calibration information is usually provided in a form like Eq. 3: a leading constant, and the (complex) polynomials that give the response as a function of a frequency. Often the polynomials are specified by giving their roots in the complex plane, referred to as poles and zeros. The frequency response can usually be found quite accurately, though the absolute response to ground motion is usually difficult to estimate to better than 1%. Sometimes mundane aspects of the calibration, such as the actual direction of measurement, can be in error by significant amounts.

Installation

An ideal seismometer installation should maximize signals of interest whether distant earthquakes or the shaking of a building, while minimizing noise that might hide these signals.

Any actual installation will be a compromise between this ideal and such practical matters as access and cost. For earthquake signals, putting an instrument deeper below the Earth's surface will give better results, but if this requires a deep drill-hole, a shallower installation may be all that can be done. An extreme example of low-quality installations being accepted for reasons of cost is ocean-bottom seismometers, for which the standard installation is the seismometer sitting on the bottom, sometimes on very soft sediments, however it happens to land after being dropped off a ship.

On land, the shallowest installations are for temporary instruments used in geophysical exploration, with seismometers planted on the surface with an attached spike to hold them in place. More permanent installations range from instruments set on surface rock exposures or in shallow holes in soil, to purpose-built deep vaults, caves (if available), and drill-holes. Deeper installations reduce the noise from wind and the range of temperature variation, and even a meter of soil will attenuate daily fluctuations. It is advisable, though not always possible, for instruments to be installed away from noise sources such as roads, machinery, rivers, and trees; in an urban setting borehole installations at depths of a few hundred meters may be the only way to reduce the noise to reasonable levels.

Displacement Seismometry Using Satellites

Because the mass motion is proportional to acceleration for motions with periods longer than the seismometer free period, data from inertial seismometers has to be integrated twice to find long-period displacements. This integration can introduce significant error, especially if the response is slightly nonlinear or the sensor tilts.

Direct sensing of displacement can now be done using repeated distance measurements between a ground sensor and Earth satellites, since the satellites define an inertial reference frame unaffected by ground motion. Distances between satellites of the Global Positioning System (GPS) and a receiver on the ground can be measured to within less than a millimeter precision, even over short times and in the presence of large accelerations; the actual ground displacement can be found after some processing (Bilich et al. 2008). The accuracy of GPS distance measurements is lower than their precision because of propagation effects, including interference from signals reflected from nearby objects (known as multipath), but it has proved possible to determine horizontal ground displacements to within a few millimeters over time spans up to several minutes and at rates up to 10 Hz. This sensitivity is too low to measure most earthquake signals, but can provide high-quality displacement data for ground motions near large earthquakes; a combination of inertial and GPS sensors is the optimal way to measure strong motion.

Deformation Seismometers

A final class of seismometers measures, not the displacement at a point, but quantities related to the displacement gradient. For a vector displacement $\mathbf{u}$, the gradient $\nabla\mathbf{u}$ is a tensor, which can be decomposed into two parts: a symmetric part, the strain tensor, which describes local deformation; and an antisymmetric part, which is equivalent to a vector that describes local rotation, tilting about horizontal axes and rotating about the vertical axis.

Two types of instruments, both known as strainmeters, can measure components of the strain tensor (Agnew 1986). Extensometers measure relative displacement along a line between two end points; this displacement divided by the baseline (the distance between the points) gives the extensional or compressional strain. Extensometers with baselines as short as a few centimeters are installed in boreholes, and ones with baselines up to tens of meters in tunnels. In both of these, the measurement is made relative to a solid length standard. Much longer instruments use optical methods to measure strain over hundreds of meters. The other class of strainmeter is the volumetric type, in which the change in a volume of fluid is found by sensing the displacement of fluid in and out of a container cemented in a borehole: such an instrument measures the volume strain, or dilatation.

Measuring the rotation vector requires either a stable direction of reference or some way of measuring rotation directly with respect to inertial space. Until recently, no technology existed that could do this with the low noise levels required. A few instruments measure rates of rotation around a vertical axis using Sagnac interferometers, also called laser gyroscopes (Schreiber et al. 2009). These sense the difference in frequency between two light beams propagating in opposite directions around a closed loop.

Seismic Data Recording

Three specialized requirements for seismological dataloggers are: (1) a high dynamic range, to capture all the signals possible; (2) large amounts of storage, since it may be necessary to record for a long time to capture unpredictable events; and (3) accurate absolute timing, to relate seismic-wave travel times to a common system. In all three areas, the progress of electronics has meant rapidly improving performance at ever-lower cost.

Many seismic dataloggers use specialized systems to provide 24 bits of range (about 5×10^7); this is accomplished by oversampling followed by digital filtering. The amount of storage depends on the sample rate; except in limited situations, a rate of about 200 Hz will capture all seismic data without aliasing. A day of 3-component data with this resolution and sample rate comes to just over 50 Mb, an amount that in the last two decades has gone from requiring specialized and

bulky storage to something easily dealt with. Cross-correlation methods can find time delays to a precision of 0.1 of the sample interval, and so the time of each sample point should be known well: for 200 Hz sampling, this requirement would be 500 μ s. This too is a level of accuracy that until recently was not easily attained. It can be reached without much difficulty if radio signals from the GPS satellites are available, though providing it over long times in the absence of such a signal still requires expensive equipment. Lower levels of accuracy can be obtained from other radio signals, and, over intervals of a few days, from inexpensive crystal oscillators.

Often, a single system records data telemetered from multiple sensors, forming an array (if the region covered spans only a few wavelengths of the waves being recorded) or network (if larger). The most precise timing then requires corrections for the transmission time of the data (latency) unless a separate datalogger is used for each sensor.

Summary

With over a century of development, inertial seismic sensors are a mature technology, usually capable of recording ground motion much better than it can be modeled. While no single sensor can cover the full range of amplitudes and periods of seismic waves, only a few instruments are needed to provide a faithful record of ground motion. Since other developments in electronics have largely routinized digital recording of seismic data, most users treat seismometers as a “black box” system that can be acquired and used with little specific expertise: a usually justifiable assumption, though as always it is important to know enough to recognize poor performance when it does occur.

Definition

Seismic microzonation	The mapping of an area on the basis of various factors that can affect the intensity of ground shaking, such as seismic hazard, geological conditions, and topographical features, so as to account for the effects of local conditions on earthquake-induced damage.
-----------------------	---

Introduction

Local site conditions affect the intensity of ground shaking, and as a consequence, the extent of earthquake-induced damage. The amplitude, frequency content, and duration of strong ground motion are significantly influenced by local site conditions. A well-known example is the 1985 Mexico City earthquake. Although the fault rupture of the earthquake was about 350 km away from Mexico City, the city sustained

catastrophic damage due to the strong amplification of the ground motion by soft soil deposits (Seed et al. 1988). The 1989 Loma Prieta earthquake caused extensive damage in the San Francisco Bay Area. The San Francisco Bay mud significantly influenced the amplitude, frequency content, and duration of ground shaking and resulted in the collapse of the northern portion of the I-880 Cypress Viaduct (Earthquake Engineering Research Institute 1990; Kramer 1996). Seismic microzonation provides the basis for site-specific risk analysis, which can assist in the mitigation of earthquake-induced damage.

Methodology

Seismic microzonation typically involves the mapping of predominant periods, soil amplification factors, topographical conditions, liquefaction susceptibility, etc. To draft microzonation maps for a particular region, various data such as existing geological maps, borehole survey data, seismic observation data, and microtremor observation data are collected. Since seismic microzonation entails spatial classification of soil conditions in a small area (e.g., a city), geological data are required for not just a single location but for many locations. In this regard, geological classification maps are most often used as one of the data sources. However, to classify the target area in a more quantitative manner, actual soil profiles obtained from borehole survey data or seismic observation data are better sources. Unfortunately, in most cases, the borehole survey data and/or seismic observation data available for a small area are insufficient. Thus, microtremor observation data have emerged as a popular source for dense spatial information on site amplification characteristics. Three examples of seismic microzonation are described hereafter.

Example 1: Seismic Microzonation Based on Geomorphological Classification Maps

Several seismic microzonation studies in Japan have employed geomorphological and geological data from the Digital National Land Information (DNLI), which is a geospatial information system (GIS) database that covers the whole of Japan with a 1×1 km mesh, to estimate site amplification characteristics (Matsuoka and Midorikawa 1995; Fukuwa et al. 1998; Yamazaki et al. 2000).

Wakamatsu et al. (2004) drafted the Japan Engineering Geomorphologic Classification Map (JEGM) on the basis of the analysis of local geomorphological features at scales of 1:50,000, and all the attributes were digitized and stored in a GIS database. Wakamatsu and Matsuoka (2013) extended the JEGM to 250×250 m grid cells that were categorized into 24 classes on the basis of geomorphological characteristics.

The shear-wave velocity averaged over the upper 30 m (V_s^{30}) is often used as a simplified index of site conditions

(Building Seismic Safety Council 2003). Region-wide site condition maps for California were constructed on the basis of V_s^{30} and the classification of geological units (Wills et al. 2000). The Next Generation of Ground-Motion Attenuation Models (NGA) project was launched in an attempt to collect all publicly available site condition information at strong motion stations. V_s^{30} is used in the absence of site condition information (Chiou et al. 2008). Matsuoka et al. (2006) constructed a nationwide V_s^{30} distribution map using the nationwide shear-wave velocity datasets for Japan, which were obtained from 1000 K-NET and 500 KiK-net seismic stations and the JEGM.

The National Research Institute for Earth Science and Disaster Resilience (NIED), Japan, has developed an open web system that interactively provides seismic hazard maps for Japan; this system is called the Japan Seismic Hazard Information Station (J-SHIS) (Fujiwara et al. 2006). J-SHIS uses the JEGM and V_s^{30} distribution map to draw probabilistic seismic hazard maps for the whole of Japan made by the Headquarters of Earthquake Research Promotion, Japan (Fig. 1).

Example 2: Seismic Microzonation Based on Dense Borehole Data and GIS

Since 2001, the Tokyo Gas Co., Ltd. has been operating the *Super-Dense Real-time Monitoring of Earthquakes* (SUPREME) system, having about 4000 seismometers (SI-sensors), in order to control natural gas supply soon after the occurrence of earthquakes (Shimizu et al. 2006).

This system employs a GIS to interpolate the monitored spectral intensity (SI) values by using subsoil data from 60,000 boreholes. The digitized borehole data specify the location, depths of soil layers, classification of subsurface soil, standard penetration test (SPT) blow counts, surface elevation, and elevation of the ground water table. Thus, microzonation of the area on the basis of individual borehole data is possible. Shear-wave velocities are estimated from an empirical relationship by using the SPT-N values; then, the average shear-wave velocities in the top 20 m of soil at a borehole site are used to estimate the amplification factors of the SI values (Fig. 2).

The accuracy of seismic microzonation can be confirmed after several years of operating a dense seismic network by evaluating the seismic records obtained for moderate to small earthquake events occurring in that period. The SUPREME system was activated during the 2011 Great East Japan Earthquake, and Tokyo Gas confirmed its effectiveness in emergency response after an earthquake (Inomata and Norito 2012).

Example 3: Seismic Microzonation Based on Microtremor Measurements

Microtremor measurements have emerged as a popular tool for determining the dynamic properties of soil layers and,

Seismic Microzonation,**Fig. 1** V_s^{30} distribution map for the whole of Japan**Seismic Microzonation,****Fig. 2** Site amplification map of Tokyo and surrounding areas, developed using dense borehole data

hence, are being widely employed for seismic microzonation. In this method, ambient vibrations (of the order of microns) on the earth's surface are measured. The main sources of these vibrations are traffic and industrial and human activities (Kanai 1983; Lermo and Chavez-Garcia 1994). Microtremor measurements can be used to determine the predominant period of vibrations at a site. Nakamura (1989) proposed the horizontal-to-vertical (H/V) spectral ratio method, in which the predominant periods of ground vibrations are determined from the ratio of horizontal and vertical Fourier spectra of the microtremors recorded at a site. Konno and Ohmachi (1998) drafted a map of fundamental periods and amplification

factors for the 23 wards of Tokyo on the basis of microtremor measurements carried out at 546 stations.

Tuladhar et al. (2004) drew a seismic microzonation map for the greater Bangkok area, Thailand, on the basis of microtremor observations carried out at 150 sites. The predominant periods of these sites were obtained by using the H/V method. The estimated predominant periods were validated by comparing them with the transfer functions obtained from one-dimensional wave-propagation analysis conducted at eight sites. According to the variation in the predominant period of the ground, the greater Bangkok area was classified into four zones as follows: Zone I (period less than 0.4 s), Zone II

Seismic Microzonation, Fig. 3 Microzonation of greater Bangkok area on the basis of variation in predominant period

(0.4–0.6 s), Zone III (0.6–0.8 s), and Zone IV (longer than 0.8 s). Figure 3 illustrates the microzonation of the greater Bangkok area on the basis of variation in the predominant period. Based on microtremor array measurement, Jirasakjamroonsri et al. (2019) also evaluated site response characteristics of soft soil deposits in the Bangkok Metropolitan region using the horizontal-to-vertical (H/V) spectral ratio method and the spatial autocorrelation (SPAC) method. Spatial variations of the predominant period and shear-wave velocity profile are presented in a seismic microzonation map.

Summary

The objectives and methodologies to perform seismic microzonation are described and some examples are presented. The three major methods introduced to achieve seismic microzonation are the uses of geomorphological classification maps, dense borehole datasets, and microtremor measurements. The results of seismic microzonation are compiled for a GIS to draft microzonation maps, and they can be used to predict ground motions during disastrous earthquakes and thus can assist in the mitigation of earthquake-induced damage.

OSI	On-site inspection
TTBT	Threshold Test Ban Treaty
UNE	Underground Nuclear Explosion

Definition

We take this title to mean the methods of acquiring records of ground motion (seismograms) and of analyzing them for purposes of detecting and identifying those seismic signals that originate from a nuclear explosion and the work of characterizing that explosion.

Introduction

The original development of nuclear weapons, and their first use in 1945, was followed by several decades of further weapon development in which more than two thousand nuclear test explosions were conducted. About 500 of these were carried out in the atmosphere, mostly in the 1950s and 1960s. They generated radioactive fallout that was detected worldwide with some regional concentrations and aroused widespread public opposition to nuclear testing. A few nuclear tests were carried out underwater and in space. Most nuclear test explosions, about 1500, were conducted underground in ways that greatly reduced fallout – the first of them in 1957, in Nevada, USA – generating signals that have been intensively studied by seismologists. Hundreds of these individual nuclear tests consisted of multiple nuclear devices, exploded almost simultaneously.

A ban on nuclear testing in the atmosphere, underwater, or in space was negotiated and went into effect in 1963 between the USA, the USSR, and the UK. Known as the Limited Test Ban Treaty (LTBT), it has since been ratified or acceded to by more than a hundred countries. Though France and China did not sign, and China carried on with nuclear testing in the atmosphere up to 1980, eventually both these countries came to abide by its terms.

The concept of a Comprehensive Test Ban Treaty (CTBT) emerged in the 1950s, intended as a restraint upon nuclear weapon development. It was debated in many forums for more than 40 years and finalized in terms of specific treaty text in September 1996. But this treaty is not in effect (as of 2019), due to continuing debate in specific countries that have not ratified this treaty and whose ratification is needed as a condition for the CTBT to enter into force. They include the Democratic People's Republic of Korea (DPRK), India, and Pakistan (not signed or ratified) and China, Israel, and the USA (signed but not ratified). Those countries that have signed the treaty are effectively adhering to a moratorium on

nuclear testing. They include the five countries recognized as nuclear weapon states by the Non-Proliferation Treaty which went into effect in 1970. Listing them in the order in which they acquired nuclear weapons capability, these are the USA, the USSR (whose CTBT obligations have been assumed by Russia), the UK, France, and China. The two countries that by far have conducted the most nuclear test explosions – the USA with 51% of the world total and the USSR/Russia with 35% – ended nuclear testing in the early 1990s (see Yang et al. 2003, for lists of nuclear explosions conducted in the twentieth century). India and Pakistan carried out nuclear explosive tests in May 1998. To date (November 2019), only the DPRK has conducted such tests in the present century – six of them, in October 2006, May 2009, February 2013, January and September 2016, and September 2017.

Seismic monitoring of nuclear explosions has been an important activity ever since the first nuclear test in July 1945 in New Mexico. Such monitoring is driven by two different objectives that have engaged a range of different institutions and organizations. The first objective, which dominated for the early decades of nuclear testing up to the early 1990s when nuclear explosions were being conducted on average about once a week, was to acquire basic information about military weapons being tested, especially if (from the point of view of the monitoring organization) the tests were being carried out by a potential adversary. Relevant questions were: What countries had nuclear weapon programs, developed to the level of carrying out nuclear explosive tests? And how big were these explosions? The second objective has been in the context of a major initiative in nuclear arms control, namely, to achieve confidence in the capability to monitor compliance with a CTBT, recognizing that many countries – considering whether or not to support such a treaty and to be bound by its terms – would need to have confidence in the monitoring system to some adequate degree. Given that monitoring cannot be done all the way down to zero yield, evaluation of progress toward this second objective entails questions such as: Down to what small size can nuclear explosions be detected, located, identified, and attributed with high confidence? And what are the specific capabilities of different types of monitoring program, applied to different parts of the world, to catch evidence of a nuclear test, should one occur?

Seismology is the most effective technology for monitoring nuclear tests carried out underground, which is the one environment that was not covered by the LTBT and which is also the hardest environment to monitor. The importance of achieving the two objectives stated above has shaped modern seismology itself, in that much of the funding that has led to the facilities and bodies of knowledge now used widely in seismological research, including studies of seismic hazard, was stimulated by government programs intended to improve capabilities for seismic monitoring of nuclear

explosions. These facilities and methods include high-quality ► **“Seismic Instrumentation”**, global networks that monitor for earthquakes as well as explosions, quantitative methods of characterizing seismic sources (various magnitude scales, the moment tensor), theoretical understanding of seismic wave propagation in Earth models of increasing and more realistic complexity, our knowledge of the Earth’s internal structure, and methods of seismic signal detection and interpretation.

The technical capability to monitor explosions, or a perceived lack of such capability, has played a role in the development of policy options on weapons testing and/or arms control and the content of international treaties. A key technical question arising in debates has been down to what value of yield can monitoring be accomplished – and with what level of confidence? Some seismologists claim now that there is no fundamental technical problem with monitoring explosions down to 1 kt, even if determined efforts at evasion must be considered. But there have been assertions that it is possible to muffle and thus hide (or confuse the procedures for identifying) the seismic signal even from a substantial underground explosion at the level of 10 kt or more. These latter assertions do not appear plausible after review of the technical difficulties (NAS 2012); but, as assertions, one finds that they continue to survive.

Seismic monitoring for underground nuclear explosions must be done with recognition of the great variety and number of earthquakes, chemical explosions, and other nonnuclear phenomena that generate seismic signals every day. Efforts to sort out and identify signals from underground nuclear explosions in the midst of signals from these other phenomena have made great progress since they commenced in the 1950s, and improvements in monitoring capability will surely continue to be made.

Sections below describe basic properties of earthquake and explosion signals and different steps in seismic monitoring for nuclear explosions. A review is given of methods used for decades in the era when thousands of kilometers separated nuclear weapon testing activity and monitoring stations (“teleaseismic monitoring”), when nuclear weapon testing was commonplace and there was little incentive to hide testing activity. Descriptions are then given of modern methods (“regional monitoring”) that monitor for very small explosions and the possibility of tests conducted in ways intended to evade discovery. Examples are given of special events that were important in developing effective and in some cases new discriminants; and finally a brief summary is given of monitoring capabilities, as of 2019, emphasizing the utility of data and data products from the International Monitoring System and its associated International Data Centre that are operated today by the Preparatory Commission of the CTBT Organization, headquartered in Vienna, Austria (www.ctbto.org).

Basic Properties of Earthquake and Explosion Signals

Seismic monitoring for underground nuclear explosions has to face the reality of hundreds of earthquakes, chemical explosions, and other nonnuclear phenomena, generating seismic signals daily that will be recorded at multiple stations by any effective monitoring network. But after decades of effort, an extensive infrastructure of national and international agencies now sorts out and identifies the signals from earthquakes, chemical explosions, and the occasional underground nuclear explosion. Modern methods of nuclear explosion monitoring are vastly more capable than they were when this work began in the late 1950s. The improvements have mostly been steady as data quality and quantity from monitoring networks increased but with occasional jumps in capability as new types of analysis have been developed, validated, and eventually applied by different agencies.

Seismic signals are traditionally grouped into teleseismic waves and regional waves, depending on the distance at which they are observed. Teleseismic waves propagate either as ► **“Body Waves”** through the Earth’s deep interior, emerging with periods typically in the range 0.2–10 s at distances greater than about 1500 km, or as ► **“Surface Waves”**, analogous to the ripples on the surface of a pond, with periods of about 15–100 s.

Teleseismic waves were the basis of most US monitoring of foreign nuclear tests prior to 1987. Teleseismic body waves are further subdivided into *P*-waves and *S*-waves. (*P*-waves, which are the fastest-traveling seismic waves and are therefore the first to arrive, are excited efficiently by explosions. Earthquakes tend to excite *S*-waves and surface waves more efficiently.)

For small (subkiloton) explosions, teleseismic signals can be too weak for detection at distant stations, and monitoring then requires regional signals. Regional seismic waves are of several types, including *P*-waves and *S*-waves, all propagating only at shallow depths (less than 100 km below the Earth’s surface) with periods as short as 0.05 s (frequencies as high as 20 Hz, i.e., cycles per second). Regional waves reach distances up to 1500 km and sometimes beyond, depending on source size and whether the propagation path is an attenuating one or not. They are regional also in the sense that they have speeds and attenuation properties that vary according to details of local structures in the Earth’s crust and uppermost mantle – so they can vary from place to place within continents and oceans.

Figure 1 shows a regional seismogram of a Soviet underground nuclear explosion in Kazakhstan recorded in July 1989 at a distance of slightly less than 1,000 km by a high-quality seismographic station in northwestern China. The original recording is shown in red. Different signals derived from it are shown in blue, each of them filtered to pass information in a particular band of frequencies.

Seismologists characterize the size of seismic signals by means of logarithmic magnitude scales (see *Earthquake, Magnitude*), with each scale based on a different type of seismic wave. A magnitude scale using teleseismic surface waves was first described in the 1930s based on the logarithm (to the base 10) of amplitude of maximum ground displacement due to surface waves with periods about 20 s. It is known as the M_s scale. Another widely used magnitude scale is that based on the amplitude of teleseismic *P*-waves. Known as m_b , it entails measurement of ground motion at about 1 s period. As part of the assignment of M_s and m_b values, for a particular seismic event as recorded at a particular station, a standard correction is applied to account for the distance between the source and the receiver at which the data was obtained. Magnitudes range from about –3 for the smallest observable microearthquakes up to above 9 for the largest earthquake. A 1 kt underground explosion has an m_b roughly about 4, and each year there are about 7500 shallow earthquakes worldwide with $m_b > 4$ (Ringdal 1985). Although use of seismic moment has superseded use of m_b and M_s in much of modern seismology, and magnitude is only an empirical estimator of seismic event size, magnitude scales are still often used in discussion of seismic monitoring because this is a practical way to relate that discussion directly to properties of signal strength. For example, monitoring capability is often characterized in terms of contour maps or shaded maps indicating the magnitude levels down to which detection or identification is deemed possible with given resources, such as signals from a particular network. We conclude this article with such a map (see Fig. 8). Explosion energy is measured in kilotons. A kiloton is formally defined as a trillion calories and is roughly the energy released by exploding a thousand tons of TNT.

The Different Steps in Explosion Monitoring

Nuclear explosion monitoring entails a series of steps, beginning with *detection* of signals (did a particular station detect anything?) and *association* (can we gather all the different signals, recorded by different stations, that originate from the same “event”?). The next steps involve making a *location* estimate and an *identification* (did it have the characteristics of an earthquake, a mining blast, a nuclear weapon test?). Then follow the steps of *yield estimation* (how big was it?) and *attribution* (if it was a nuclear test, what country carried it out?). Once the CTBT is formally in effect, the possibility arises of conducting an on-site inspection (OSI) on the territory of a CTBT signatory state, at and near the location where objective evidence indicates that a nuclear test has occurred. Extensive rules govern procedures for making an OSI request, for its consideration and possible approval by a 51-member Executive Council of the CTBO, for its conduct if approved

Seismic Monitoring of Nuclear Explosions, Fig. 1 The vertical-component seismogram recorded at station WMQ in northwestern China, for an underground nuclear explosion on July 8, 1989, in Kazakhstan at a distance of almost 1,000 km, is shown in red (top). Filtered versions of the original trace in different frequency bands are shown in blue. Time in seconds at bottom is with respect to the time the explosion occurred. Different types of seismic wave propagate at different frequencies, and hence their ground motions show up in different bands. *P*-waves, in this case the regional wave called *Pn* which travels in the uppermost mantle, arrive about 120 s after the explosion at this distance,

involving short-period (high-frequency) motions. Long-period surface waves can be seen in the top two blue traces. Some surface waves arrive up to 600 s after the explosion at this distance and thus travel as much as five times slower than *P*-waves. *S*-waves (weak in this example) are shear waves, traveling slower than *P* waves. A high-frequency wave marked as *Lg*, which is often the largest wave at regional distances from an earthquake but is only weakly excited by explosions, is dominated by shearing motions and is largely trapped in the Earth's crust. The amplitude of ground motion in the longest period band is less than 2% of the amplitude in the short period band from 1 to 5 Hz

(at least 30 votes in favor are required), and for consequential actions if an OSI supports the accusation of a treaty violation. OSIs can involve seismic monitoring for explosion-induced aftershocks, which (from experience in the USA and the former Soviet Union) are known to occur after some underground nuclear test explosions.

Detection

Concerning detection, nuclear explosion monitoring is often done with arrays of sensors, deployed as a group spread out over an area roughly 10 km across, that facilitate methods to enhance signal-to-noise ratios. This is done typically by stacking signals from independent sensors, often with appropriate delays to increase signal strength and reduce noise. Array data can also give estimates of the direction from which signals are arriving.

In making assessments of detection capability, one of the key concepts widely used in seismology is the *magnitude threshold*, above which 90% of the seismic events can be detected at more than three stations (the least number of stations for making routine estimates of the location of the event). Transferring from magnitude to yield, one infers the capability for detecting nuclear tests above a certain size (NAS 2002; NAS 2012).

Association

Association is the effort to identify those sets of detected signals, from different stations, which all originate from the same seismic event. It is one of the hardest steps in practice, particularly when multiple seismic sources around the world are active at roughly the same time (within minutes), resulting in signals from different events that are interlaced in the

waveforms recorded by each station. In such cases, array data can be helpful in resolving which signals correspond to which event.

Location

To obtain a location estimate, typically the arrival times of various seismic waves are measured from the recorded waveforms such as shown in Fig. 1. They are used to find four parameters: the latitude, longitude, depth, and origin time. In this work, it is necessary to know the travel time from any hypothesized source location to any particular seismographic station for any type of seismic wave that the station might observe. In practice, locating seismic events accurately on a global basis (say, to within 10 km of their true location) using networks with stations several hundred km apart requires extensive efforts in station calibration. Thus, it is important to include path-specific travel time corrections to standard travel time models to account for lateral variations of Earth structure (Murphy et al. 2005; Myers et al. 2010). Many authors have shown that greatly improved precision of location estimates can be achieved for a given region if seismic events are located relative to each other and in large numbers – preferably thousands of them or more, all at the same time – rather than one at a time (Waldhauser and Schaff 2008; Schaff et al. 2018b).

Methods of Identification

Identification of the nature of a seismic source on the basis of its seismic signals – that is, making a determination from seismograms as to whether it could be a nuclear explosion, or a natural earthquake, or a mine blast, or something more exotic such as a bolide impacting our planet and exploding in the atmosphere – is a large subject in view of the many possibilities. See, for example, Richards (1988), OTA (1988), Dahlman et al. (2009), and Bowers and Selby (2009). Seismic events generate many different types of seismic wave, in various different frequency bands as shown in Fig. 1, and different types of seismic source generate a different mix of seismic waves. We can make an analogy here with sound waves and the capability of the human ear and brain to analyze them. A deep bass voice, a gunshot, a whistle, and rolling thunder constitute a set of sound sources that are easily distinguished from each other on the basis of their different frequencies, their emergent or impulsive nature, and their duration. It is the mix of information in both the time domain and the frequency domain that is effective.

Seismic methods for discriminating between earthquakes and explosions are based on interpretation of the event location (including its depth); on the relative excitation of a variety of body waves and surface waves; and on features of the frequency spectrum for signals associated with each of these two different types of source. Within these three broad categories, many different methods have been tried, with various degrees of success. As the capabilities of each method

are probed, the question of interest is often: “Down to what size of seismic event does this method of discrimination work?” In some cases discrimination is unambiguous even at very small event size. (For example, however small an event, it may be presumed to be an earthquake if it is located at a depth greater than 15 km below the Earth’s surface. And, even a small event will attract attention, if it occurs in an area that is geologically stable and that for decades has had no seismic activity.)

The most useful methods for discrimination can be listed as follows:

- Interpretation of the location. Is the event in a seismic or an aseismic area? Below the floor of an ocean? At depth below a continent? There is an important role here for common sense: seismic events in Canada attract less attention from western monitoring agencies than such events in the DPRK (though a seismic event in the Canadian Shield would still attract attention and intensive study).
- Relative amplitude of body waves and surface waves. This can be studied by plotting the event of interest on an M_s : m_b diagram, as shown in Fig. 2. The surface-wave amplitude is read typically on the vertical component from signals with period about 20 s and the body-wave amplitude at about 1 s period. (Though effective for large enough events, an explosion with m_b much below 4.5 may not have large enough surface-wave signals at teleseismic distances to apply this method dependably.)
- Use of the observed “first motion” of the ground. Does the initial P -wave motion of the ground indicate compressions radiated to all directions from the source, leading to upward motions, as would be the case for a simple explosion? Or, are dilatations recorded at some azimuths, leading to downward motions – as would sometimes be expected from earthquakes but not from explosions?

The methods described so far in this section have concerned the use of teleseismic signals, which can be used to monitor effectively for high magnitudes and on down to somewhere in the magnitude range from 4.0 to 4.5. Since the late 1980s/early 1990s, there has been growing recognition of the merits of regional waves, to enable monitoring down to far lower magnitudes, often well below magnitude 3. The method is based upon the general observation that explosion signals, when compared to earthquakes, have much stronger P -waves at high frequency, whereas signals from earthquakes have stronger S -waves (and surface waves).

This modern method is being studied with frequencies in the range 0.5–20 Hz. and sometimes even higher. An example is shown in Fig. 3 comparing regional seismic signals of a very small earthquake and a small explosion. The method has been demonstrated by seismologists in China, even down to around m_b 2 (Pan et al. 2007).

Seismic Monitoring of Nuclear Explosions, Fig. 2 An M_s : m_b diagram from Bowers and Walter (2002). It can be seen here that for seismic events of the same M_s value, earthquakes have a significantly smaller m_b value than do the explosions. The offset is about 0.8 m_b units, at $M_s = 5$. Because magnitudes are based on logarithmic scales, and $10^{0.8} \sim 6$, it follows that at frequencies near those at which body wave magnitude is measured (about 1 Hz), the P -waves from an underground nuclear explosion are typically about 6 times larger than such waves from an earthquake having the same strength of surface waves. Also, indicated by the red star are the body-wave and surface-wave magnitudes of an interesting but fortunately rare event, a large mine collapse with P -wave magnitude greater than 5. This event, which plots with the explosion population, is discussed further below – see Fig. 6

As an important example of this development, Fig. 4 shows the results of an analysis of the P -wave and S -wave spectra, pertinent to identifying the very small underground nuclear explosion conducted by the DPRK on October 9, 2006, and a larger test nearly 3 years later on May 25, 2009. The smaller explosion took place at 0135 hours (GMT), and by 0706 hours the US Geological Survey (USGS) had issued a report based on seismic signals from 20 stations around the world including sites in China, the Republic of Korea (ROK), Russia, Japan, Kazakhstan, Kyrgyzstan, Alaska, and Nevada. Its magnitude, about 4, indicated a subkiloton yield (see Koper et al. 2008, who discuss the uncertainty of estimating yield in view of the variability of seismic signal excitation for shots of different depth). From teleseismic signals, the explosive nature of such a small seismic event can be difficult to recognize (they could be signals from an earthquake). Fortunately, discrimination for events such as this is very clear providing high-quality regional data is available.

In this analysis, the original seismograms from station MDJ, located in China, are filtered to pass narrow frequency bands as illustrated in blue in Fig. 1 but this time with bands centered on each of the frequencies from 1, 3, 5, 7, 9, 11, 13, to 15 Hz as indicated for the horizontal axis in Fig. 4. Here the amplitudes of the Pg and Lg waves are measured in each narrow band. The amplitude ratio is formed (the “spectral ratio”), and the quantitative comparison can begin. Figure 4 shows how this ratio varies with frequency for the set of eight earthquakes and for the set of four small chemical explosions. The ratio differs for these two populations as frequency rises, and the separation between them is very clear at the high frequencies (from 9 to 15 Hz in this case). The spectral ratios

Seismic Monitoring of Nuclear Explosions, Fig. 3 Typical vertical-component records from an earthquake and an explosion. Traces plotted are unfiltered (top); low-frequency band-pass filtered (middle); and high-frequency band-pass filtered (bottom). (From Kim et al. 1993)

Seismic Monitoring of Nuclear Explosions, Fig. 4 Spectral ratios are shown, for nuclear explosions carried out by the DPRK in 2006 and 2009, as measured from waveforms recorded at station MDJ in China (distance, about 370 km). They are compared with these ratios for a small group of earthquakes and another group of chemical explosions, all in the vicinity of the DPRK's nuclear test site (about 370 km to the south of MDJ). Colored bars represent $\pm$ one standard deviation in the ratios for chemical explosions (yellow) and small earthquakes (magenta). The spectral ratios for these two events in the DPRK are both explosion-like

of the signals recorded for the nuclear events of 2006 and 2009 are like those of the known chemical explosions.

This successful seismic discriminant based upon regional waves is important in enabling capability to be extended down to lower magnitudes than can be monitored teleseismically. In practice, there is often very little difference between the magnitude thresholds for detection (at enough stations to enable a useful location estimate) and identification, since so many regions of the Earth are now monitored to low magnitude for earthquakes as part of investigations into seismic hazard. It may take only one regional seismogram to enable discrimination to be carried out with high confidence (provided the recording is of adequate quality and is for a station that has an archive of signals from previous known earthquakes and explosions).

Along with the use of regional seismic waves and their spectral ratios at 5 Hz and higher, another successful method for distinguishing between earthquakes and explosions is the use of observed seismic waveforms to make estimates of the set of forces that appear to be acting at the seismic source. The set of forces here is quantified by what seismologists call the *moment tensor*. As shown by Ford et al. (2009) from study of numerous earthquakes and underground explosions, seismic events separate into specific populations as determined by the way their moment tensors behave – whether they are more

representative of the all-around (isotropic) features of an explosion, or of the type of shearing motions more typical of an earthquake.

In general for underground tests, seismic data alone cannot distinguish between nuclear explosions and chemical explosions in which all the material making up the explosive was fired within less than about a tenth of a second. But chemical explosions, if large, are very rarely fired in this way. In the case of the DPRK tests of 2006 and 2009, both of which were announced as nuclear, objective evidence for the nuclear nature of the 2006 explosion came from several different detections of radionuclides that are diagnostic of a nuclear explosion. Although such radionuclides were not detected from the 2009 explosion, it was so large as to be implausible as a chemical explosion, since it would have to have consisted of literally thousands of tons of explosive material.

We return later in this article to a discussion of additional nuclear tests in the DPRK up to 2017, some of which generated small earthquakes (explosion-induced aftershocks).

Yield Estimation

Yield estimation was of particular importance in the years following 1974 when a bilateral treaty between the USA and the USSR was negotiated, intended to go into effect in 1976. This was the Threshold Test Ban Treaty (TTBT), limiting the size of underground nuclear explosions conducted by these two countries to a yield of not more than 150 kt. The TTBT proved contentious, with each side sending the other several inquiries asserting that the agreed-upon limits had possibly been exceeded (Timerbaev 2007). But this treaty, and a related treaty placing yield limitations on so-called Peaceful Nuclear Explosions, finally entered into force in 1990.

Both treaties have become less important since the CTBT was finalized and a nuclear testing moratorium by the signatory countries began in 1996. Yield estimation is however still important as an exercise in the interpretation of signals from the few underground explosions since that date, specifically those of India and Pakistan in 1998 and of the DPRK in the present century.

For several tens of underground nuclear explosions, most of them at the Nevada Test Site in the USA or at Kazakhstan's Semipalatinsk Test Site when it was part of the Soviet Union, the yield has subsequently been announced by agencies involved in the conduct of the test. It has therefore been possible to calibrate observed seismic magnitudes for these tests against the announced yields, and an example is given in Fig. 5 using m_b values and yields reported for Nevada explosions in tuff and rhyolite.

The line $m_b = 4.05 + 0.75 \log(\text{yield})$ fits the data well (yield in kilotons). Such a calibration curve can be applied to obtain a seismic yield estimate for Nevada explosions with unannounced yield. But it requires correction, prior to its use in obtaining a seismic yield estimate for an explosion at a

different site. This must be done, to allow for physical and geological differences between the sites. For example, in different rock types, there can be different efficiencies in the coupling of nuclear yield into seismic energy and differences in the propagation efficiencies as seismic waves travel out from the source of interest, as compared to seismic signals from a Nevada explosion. In this connection, it is of interest to note the m_b value and yield for the US nuclear explosion LONGSHOT (conducted in 1965 in the volcanic breccias of an Aleutian island). The m_b value is 5.9, corresponding to a yield of about 300 kt. if the Nevada curve of Fig. 5 is applied directly. But the announced yield for LONGSHOT is 80 kt. One way to obtain a calibration curve for the Aleutians is therefore to add a correction of about 0.4 m_b units to the Nevada values of m_b at a given yield, before the curve of Fig. 5 is used to supply a seismic yield estimate in this new location. This m_b correction, for a site differing from that where a calibration curve is directly available, is called the *test site bias*. If the bias correction is not applied, then a Nevada magnitude–yield curve can give too high a seismic yield estimate for a non-Nevada explosion.

Note that the Nevada Test Site is in a region of active tectonics, with significant episodes of volcanism in the last few million years, resulting in high temperatures within the upper mantle and thus anomalous attenuation of seismic waves propagating through the hot and partially molten upper layers of the Earth, 100 or 200 km in thickness beneath the Nevada Test Site. Such propagation through an attenuating medium is presumed to be a contributing cause of bias.

The existence of m_b bias has long been known in seismology in connection with what is called “station bias.” By this

term is meant the systematic difference between mean m_b values (obtained for a particular seismic event by averaging reported m_b from seismometers all over the globe) and m_b reported by just one station. For example, the station BMO in Oregon (another region of active tectonism) has reported m_b values that for a given earthquake are typically about 0.3 units below the global average; and station KJN in Finland (in a stable shield region) reports values about 0.15 m_b units higher than the average. Their station bias values are thus -0.3 and $+0.15$, respectively. Station bias values commonly range over ± 0.3 m_b units, so it may be expected that source region bias (which is what must be applied when a standard m_b –yield curve is used for different source regions) can also range over about 0.6 m_b units.

The nuclear weapon test site of the USSR that conducted the most underground nuclear explosions was near the city of Semipalatinsk, in northeastern Kazakhstan. Several multi-megaton underground explosions were conducted on Russia’s Novaya Zemlya island test site, far to the north of continental Eurasia (see Khalturin et al. 2005). But these were all prior to the intended date of entry-into-force of the TTBT (March 1976). After that date, the magnitude of the largest underground tests at Semipalatinsk rose higher and higher over several years, with some magnitudes exceeding 6.1. Such magnitudes, according to the Nevada Test Site formula discussed above, $m_b = 4.05 + 0.75 \log(\text{yield})$, implied yields greater than 500 kt, far in excess of the TTBT limit (150 kt). Intensive discussion in political and technical areas ensued, with stronger and stronger evidence accumulating to indicate a substantial test site bias between the Nevada and Semipalatinsk test sites. For example, it was of great interest that teleseismic signals from the largest underground explosions from these two tests, if recorded at the same station in a shield region, looked significantly different. The teleseismic P -wave from a large underground explosion at the site in Kazakhstan would routinely have frequency content at the 5 Hz level and sometimes higher (Der et al. 1985). The signal from Nevada would not contain such high frequencies. It was as if the signal from Nevada had passed through some type of filter, which of course would reduce its amplitude. Correcting for that effect would mean that the appropriate relation between magnitude and yield for an underground nuclear explosion at Semipalatinsk had the form

$m_b = 4.05 + \text{bias} + 0.75 \log(\text{Yield})$, and Ringdal et al. (1992) and Murphy (1996) among many others concluded that the appropriate formula relating teleseismic P -wave magnitude and yield at Semipalatinsk should be this equation with a bias of 0.4. Support for their conclusion came from many arguments (see Richards 1988, for a review). But in the political realm, the most persuasive was the very practical one associated with a Joint Verification Experiment of September 14, 1988, in which a team from the USA at the Semipalatinsk Test Site was allowed to make close-in measurements (within

Seismic Monitoring of Nuclear Explosions, Fig. 5 Seismic magnitude m_b vs announced yield, for 17 Nevada Test Site nuclear explosions in tuff and rhyolite. The straight line here, which fits the data quite well, can be used to make a yield estimate of other events at this test site, in similar rock, if the seismic magnitude is known. (Data from Nuttli 1986)

a few tens of meters) of a large Soviet underground nuclear explosion, in particular of the speed and extent of the shock wave it sent out into rock near the source at that test site. From such shock wave measurements, a reliable non-seismic method provided an accurate yield estimate (it was in the range 100–150 kt). Stations around the world provided measurements teleseismically, giving a seismic magnitude around 6.1 – comparable with the largest magnitudes of Semipalatinsk explosions since 1976, indicating that they too had been conducted in a way that respected the 150 kt limit of the TTBT. A reciprocal Joint Verification Experiment had been conducted at the Nevada Test Site, on August 17, 1988, with a Russian team making its own close-in measurements of the shock wave from a large US underground nuclear test intended to be in the range 100–150 kt. Apparently, the yield of this explosion somewhat exceeded 150 kt. Timerbaev (2007) and news reports give it as 180 kt.

Special Events

The work of monitoring – for both earthquakes and explosions – is done in practice by hundreds of professionals who process the vast majority of seismic events routinely and who also look out for the occasional events that, in the context of monitoring for the possibility of underground nuclear explosions, exhibit interesting characteristics and which may then become the subject of special study.

These special events have stimulated the development of effective new discrimination techniques and a better appreciation of overall monitoring capability. Examples include a mine collapse in 1989 in Germany and two such collapses in 1995, in the Urals (Russia) and in Wyoming (USA); a small earthquake of magnitude 3.5 and its smaller aftershock in 1997 beneath the Kara Sea near Russia's former nuclear test site on Novaya Zemlya; the series of underground nuclear test explosions carried out by India and Pakistan in 1998; underwater explosions in 2000 associated with the loss of a Russian submarine in the Barents Sea; and a number of small seismic events near the DPRK's nuclear test site in addition to the six announced nuclear test explosions at that location from 2006 to 2017.

The mining collapses were seismically detected all over the world. For example, teleseismic *P*-waves from the Wyoming event of 1995 were detected in South and North America, Europe, and Asia. Mining collapses such as these have caused concern because their mix of surface waves and body waves as recorded teleseismically can appear explosion-like using the classical M_s : m_b discriminant, as shown in Fig. 2 (see above). But a careful analysis of regional and teleseismic waves from these events has showed that although the surface waves were quite weak, and in this respect seemed explosion-like, they had the wrong sign. Therefore the motion at the

source was implosive (the ground had moved inward toward the source and thus downward), rather than explosive. Indeed, mining collapses are an implosion phenomenon, and it was important to learn that their implosive nature could be reliably determined from seismic recordings. Teleseismic waveforms from the Wyoming mine collapse are shown in Fig. 6. This is an example of the use of what seismologists call the “first motion” of the *P*-wave, which is clearly downward in these data.

The Kara Sea earthquake was too small to apply the M_s : m_b discriminant (the surface waves were too small to measure reliably). This event showed the importance of accurate locations and of using spectral ratios of regionally recorded *P*- and *S*-waves to discriminate small events (Richards and Kim 1997).

As we have discussed earlier, the DPRK nuclear test of 2006 was of interest as an example of a nuclear explosion that was promptly detected globally, though its yield has been estimated as less than 1 kt. This event required regional seismic data in order to determine that indeed an explosion had been carried out and that the signals were not from an

Seismic Monitoring of Nuclear Explosions, Fig. 6 The *P*-wave signals of the Wyoming mine collapse are shown at six teleseismic stations, processed to bring out the fact that the first motion of the ground at these stations is downward, indicative of an implosion rather than explosion (for which the first motion would be upward). (From Bowers and Walter 2002)

earthquake (Kim and Richards 2007). Subsequently, xenon radionuclides were detected that decisively identified this explosion as nuclear.

The DPRK at this time of writing (November 2019) has conducted six nuclear explosive tests, the first (October 9, 2006) with m_b about 4 and the last (September 3, 2017) with m_b greater than 6. The magnitude of the largest test has been assigned values lying mostly in the range from 6 to 6.3, reflecting the fact that the number of seismographic instruments providing data today is roughly a hundred times the number available in the 1980s and 1990s when magnitude–yield relations were being worked out, and the effects of station bias (for many new stations) are not yet quantified. Of interest as a demonstration of capability to monitor for even small seismic events is that the huge 2017 explosion (with yield around 200 kt) was followed by tens of seismic events that were detected and intensely analyzed by groups in neighboring countries – including China and the Republic of Korea (ROK) – as well as in distant countries and by the Vienna-based IDC using IMS data. These events have been identified as small earthquakes, down to magnitude of about 2.2, apparently induced by the very large explosion of 2017 (e.g., Kim et al. 2018; Schaff et al. 2018a). As shown in Fig. 7, thirteen of these small earthquakes occurred from Sept 2017 to April

2018 close to a northeast–southwest line about 700 m long, lying about 8 km to the north of the main mountain – Mount Mantap – in which most of the DPRK’s test explosions took place. Low-magnitude seismic activity has continued in the region, with events in January and June of 2019. The earthquakes have relative locations determined via analysis of whole waveforms recorded regionally in China and ROK (Schaff et al. 2018b). Their overall location to the north of the test site is determined from work of Tian et al. (2018), who had access to data from numerous seismic stations in China.

The overall point here is that the small 2006 nuclear explosion in the DPRK was promptly well-characterized; and in later years it has become possible to detect, locate, and identify seismic events in the region that are a hundred times smaller.

Evasion

Several methods have been proposed, by which underground explosions might be concealed. One method is simply to make them small enough; but then there would be relatively little to learn, from the point of view of a weapon designer. The more important methods are those which combine as many features as possible, designed to reduce seismic signal-to-noise ratios at all relevant monitoring stations. Proposed methods include emplacement of the nuclear device in material such as dry alluvium, to reduce the coupling of explosion energy into seismic signal (but that method is likely to result in leakage of detectable radioactivity); waiting until a sufficiently large natural earthquake occurs fairly near a test site (which presents the formidable challenge of identifying the event within a few minutes of its occurrence as large enough and then within a couple of minutes executing the weapon test so that its seismic signals would hopefully be swamped by the large and prolonged signals from the earthquake); and setting off a sequence of several explosions that are designed to simulate a natural earthquake signal.

Careful study of each of these methods indicates that they are relatively ineffective in comparison with the methods known as cavity decoupling and mine masking, which we next discuss and which are widely regarded as setting the practical levels down to which seismic monitoring of nuclear explosions is possible.

When an underground explosive device is tightly packed into its hole (“tamped” or “fully coupled”) and is detonated at sufficient depth to contain all radioactive products, a shock wave travels some distance from the shot point out into the surrounding rock at speeds that exceed the normal P -wave speed. This nonlinear phenomenon reduces at sufficient distance from the shot point, and thereafter the wave propagation can be regarded as elastic. The so-called elastic radius for a tamped explosion, i.e., the radius beyond which wave

Seismic Monitoring of Nuclear Explosions, Fig. 7 A map showing locations for the summit of Mount Mantap (black triangle); the first of the DPRK’s UNEs (small star), to the east and south of this summit; five subsequent UNEs conducted within the mountain (larger stars) including the large test explosion of September 3, 2017; and a series of small aftershocks aligned over several hundred meters, about 8 km to the north of Mount Mantap (red circles). (Adapted from Kim et al. 2018)

propagation is linear, is roughly 100 m times the cube root of the yield (in kilotons).

If the explosion is set off inside a large underground cavity instead of being tamped, then the shock wave set up in the rock can be weakened or even eliminated, in which case only elastic waves are radiated. The explosion is said to be fully decoupled if only elastic waves result, and theoretical work begun in 1958 has addressed the question of how much weaker the seismic signal might be made. Theoretical work has indicated that signals could thereby be reduced by factors in the range 50–100, compared to a tamped explosion. The cavity radius itself is the “elastic radius” for a fully decoupled shot. For salt, the cavity radius required for full decoupling has been estimated as about 25 m times the cube root of the yield (in kilotons). For hard rock the cavity size for full decoupling is comparable; for weak salt it is somewhat greater. See Sykes (1996) for further discussion and Denny and Goodman (1990) for estimates of the decoupling factor derived from the practical experience in 1966 of carrying out a small nuclear explosion (about 0.38 kt) in the cavity produced by a tamped shot of 5.3 kt conducted 2 years earlier in a Mississippi salt dome. They conclude that the amplitude reduction is about 70, at low frequencies, for salt. At frequencies that have conventionally been used for seismic monitoring, the seismic signal strength is proportional (very roughly) to the volume within the elastic radius. This volume is substantially reduced by fully decoupling, which is the reason why cavity decoupling has been proposed as offering the technical possibility of a clandestine program of nuclear testing. However, the signal strength is not nearly so strongly reduced, by decoupling, at frequencies above that associated with resonances of the internal surface at the elastic radius. In practice, the frequency above which decoupling is likely to be substantially less effective is around 10–20 Hz, divided by the cube root of the yield (in kt). The overall effect on the seismic signals from a fully decoupled shot of yield Y , given the results of Denny and Goodman, is to make these signals look like those from a tamped shot of yield $Y/70$.

A thorough discussion of decoupling as an evasion scenario would have to include several non-seismological considerations. These are reviewed in NAS (2012) and include the military significance of being able to carry out nuclear tests up to various different yield levels (e.g., 0.1, 1, or 10 kt.) and the political consequences if an attempted clandestine test program was uncovered. Technical considerations include methods of (clandestine) cavity construction and the capabilities of non-seismological surveillance techniques. Preventing the leakage of radioactivity from an underground cavity would be a challenge, given that much of the energy of a decoupled explosion goes into pumping up the pressure in the cavity. While some assert that clandestine use of cavity decoupling would be so difficult to execute that it belongs to the realm of fantasy, others have been persuaded that the risk

might indeed be manageable and that estimates of concealable yields, under this evasion scenario, must be made. The NAS (2002) report describes ten “layers of difficulty” with successfully hiding an underground nuclear explosion via cavity decoupling, concluding that even a nation committing significant resources to this work could not have confidence in being able to get away with tests above 1 or 2 kt.

The evasion scenario known as mine masking hypothesizes the execution of an underground nuclear weapon test explosion in a mining region, concurrently with a large mine blast. Such blasts in a big commercial operation consist of hundreds of separate charges, fired in sequence to break and/or move as much rock as possible, in a procedure known as ripple firing (Khalturin et al. 1998). Regardless of the logistical difficulties of such a scenario, estimates of the possibilities of concealment via this approach can come from taking examples of signals from large mine blasts, and signals from small underground nuclear explosions, and then adding them together before subjecting them to the methods used to discriminate between various types of seismic events. What is typically found is that the maximum size of the identifiable waves (e.g., the P -waves) from the mine blast is about that expected from individual sub-blasts (commonly called “delays”), and these amplitudes are spread out over a longer time in seismograms.

A study of mine masking possibilities by Smith (1993) used several different examples of mine blast seismograms together with single-fired explosion records and found a number of features that could be used to identify a simultaneous shot within a ripple-fired blast. He concluded that to conceal a single-fired deep detonation (depth is required for containment of radionuclides), the single explosive shot should not exceed 10% of the total explosive.

The conclusion here is that mine blasts are not effective for concealing large releases of energy at the level associated with kiloton-scale nuclear weapons tests, unless the nuclear explosion was subject to efforts at decoupling. Again non-seismic considerations arise, including an assessment of the plausibility of carrying out a complicated decoupled nuclear explosion at the same time and location as a large mine blast that would itself attract some level of monitoring attention – particularly if the seismic signals seemed unusual in comparison with those from prior blasting in the region.

Event Detection Capability of the International Monitoring System

In 1976, a group of international scientists was established at the Conference on Disarmament in Geneva, for the study of monitoring technologies and data analysis methods in the context of supporting a future test ban treaty. This group of scientific experts (GSE) played an essential role in laying

the scientific groundwork for the final stage of CTBT negotiations conducted from 1994 to 1996. Prior to the final stage, GSE organized a series of technical tests which contributed significantly to the development of the international system being built today to support treaty verification.

The text of the CTBT includes a description of networks to monitor treaty compliance using hydroacoustic, infrasound, and radionuclide technologies as well as seismological methods. The CTBT Organization (CTBTO) operates an International Monitoring System, as well as an International Data Centre to analyze signals sent via satellite to headquarters in Vienna. Extensive descriptive material on these networks is available online (see <http://www.ctbto.org>).

To implement the CTBT seismic monitoring system, a sequential four-step process is needed to build each station

(CTBTO PrepComm 2009): (1) site survey; (2) installation; (3) certification; and (4) operation. It must be demonstrated for IMS stations that data received at the International Data Centre (IDC) are *authentic*. This is achieved through a special digital “signature” embedded in the data flow from each station. The IMS station must be certified to ensure that all of its equipment, infrastructure, and settings meet the technical specifications set by the CTBTO and to ensure also that all data are transmitted to the IDC through the Global Communication Infrastructure (GCI) in a timely manner.

Here, we note that the primary seismographic network is to consist of 50 stations, many of them arrays; and that location estimates are based upon detection of signal at three stations or more. An auxiliary network of 120 continuously operating stations is to provide seismic waveform

Seismic Monitoring of Nuclear Explosions, Fig. 8 A map illustrating detection capability of the IMS primary seismographic network. This network is intended to have 50 stations, but it is incomplete as of 2019. Here, is shown the capability of the network, based on practical experience with 43 stations. The capability is represented by the magnitude of the smallest seismic event that would be detected with a 90% probability

by three stations or more. The method used to develop such maps is described by Kværna and Ringdal (2013). A complete IMS network (50 stations) may be expected to lower the illustrated magnitude threshold by about 0.1 magnitude units, in some regions. (Figure, courtesy of T. Kværna.)

data, again via satellite, in order to help characterize the events detected by the primary network. Although these two networks are not completely built (as of August 2019, 44 primary and 108 auxiliary stations have been certified), enough stations operate to provide good indications of what the detection capability will be when all stations are installed and providing data. Their performance today, although the networks are incomplete, is considerably better than what was envisaged for the IMS and IDC during the CTBT negotiations of the 1990s.

Figure 8 shows a map of the detection capability of the primary seismic network of the IMS, based on practical experience with 43 operating stations. This network is planned eventually to have 50 stations. Capability is expressed in terms of magnitude thresholds, above which 90% of the seismic events are expected to be detected at enough stations to provide a location estimate. The work of identifying events is left to member states. We note that event identification is not just a technical matter since it is a political act for one country to make an allegation that another country has committed a treaty violation. The evidence in support of such an allegation can come from the IMS and IDC, as well as from the National Technical Means of member states, and/or from a subset of the thousands of seismographic stations operated around the world for purposes not directly related to monitoring for nuclear explosions.

Summary

We have described the basic steps in monitoring for nuclear explosions and have emphasized the seismic monitoring system specified by the Comprehensive Nuclear-Test-Ban Treaty of 1996.

When the treaty was being negotiated, the goal for the International Monitoring System was that it be capable of detecting and identifying treaty violations – nuclear explosive tests – at the 1 kt level and higher, if they are not evasively tested. Recognizing that a 1 kt underground nuclear explosion has a magnitude in the range about 4–4.5, if it is conducted in the way that almost all the more than 1500 prior underground nuclear explosions were carried out (i.e., well-tamped and not with intent to reduce the signals picked up by monitoring networks), the evidence from Fig. 8 is that this design capability has been significantly exceeded. For almost all of the northern hemisphere, including Eurasia and North America, capability is good down to about magnitude 3.3. This corresponds to a yield of less than 100 t (0.1 kt) for a well-tamped explosion in hard rock. Only time will tell whether this capability, combined with other monitoring assets, is deemed adequate to support entry into force of the CTBT.

Seismic Noise

Dhananjay Kumar^{1,2} and Imtiaz Ahmed²

¹Chevron, Houston, TX, USA

²BP, Houston, TX, USA

Definition

Seismic noise	Noise is the undesirable part of seismic data that is not signal, and signal is what fits our conceptual model.
Multiple	A seismic event that experiences more than one reflection in the subsurface.
SNR	Signal-to-noise ratio – is a measure of strength of signal compared to noise, and it is a measure of seismic data quality.
Active seismic	Seismic data recordings of artificial manmade sources such as dynamite and vibroseis in land surveys and air gun in marine surveys. Example: exploration and engineering seismology.
Passive seismic	Seismic data recordings of natural sources such as earthquake, solar waves, and ocean waves. Example: earthquake seismology.

Introduction

Seismic noise comprises all of the unwanted recorded energy that contaminates seismic data. A part of the seismic energy is considered noise if it does not fit the conceptual model of seismic signal. Seismic noise can be random or coherent. The identification of seismic noise depends on the type of data analysis and the type of data available – a part of data treated as noise in one application can be signal in another application. For example, the S-wave energy is generally considered noise in a P-wave processing project; vice versa, the P-wave energy is considered noise in an S-wave processing project.

Historically, only the traveltime information of the seismic data was used to study the subsurface. For example, the knowledge about the earth's deep interior was primarily derived from seismic traveltime information recorded during deep earthquakes. Also, only the traveltime information was used to derive the structural image of subsurface for exploration projects. As seismic technology has advanced and the appetite for understanding complicated geological features has increased, there has been a push toward technologies using the complete waveforms (amplitude and traveltime) in seismic analysis. Full waveform inversion technology (Tarantola 1986) is one such example that uses the complete waveform to estimate properties of the subsurface from the

seismic data. The success of such technologies is understandably very dependent on clean, noise-free seismic data.

It is essential that seismic data are carefully processed to derive high quality seismic images (see Yilmaz 2001 for seismic data processing). One of the major challenges in seismic data processing is to separate noise from signal or to attenuate noise. In practice, noise cannot be completely attenuated and occasionally it is not even desired to attenuate noise but to use it as signal. The objective of the noise attenuation or noise separation process in seismic data processing is to enhance signal-to-noise ratio (SNR). There have been significant progress in data processing to improve SNR; advances have been made in random noise attenuation (Yilmaz 2001) and coherent noise attenuation (see Weglein and Dragoset 2005 for multiple attenuation methods).

Recently, there have been various efforts to use seismic noise as signal, for example: (1) using multiple reflected energy (multiples) in seismic migration and inversion to image subsurface; and, (2) using very low and very high frequency passive seismic signal for reservoir monitoring. In the following sections, we write brief descriptions about the types of seismic noise, the noise attenuation techniques, and how seismic noise can be useful.

Types of Seismic Noise

There are two types of seismic noise: random noise and coherent noise. In a multichannel seismic dataset, random noise does not correlate either with the neighboring channels (i.e., no spatial correlation) or along the same channel (i.e., no temporal correlation). Coherent noise, however, is part of the data that correlates spatially and/or temporally. Random noise is easier to attenuate during seismic data processing. Coherent noise is difficult to attenuate in processing; therefore, residual coherent noise can interfere with real signal and be misinterpreted as signal. The possible sources of these seismic noises can be placed under four categories: (1) ambient sources, (2) wave propagation related noise, (3) data acquisition related noise, and (4) data processing artifacts. The severity and types of noise can differ between marine and land acquisition environment.

Ambient noise is the noise from unwanted sources like wind, swell, power line, activities on nearby road, surface facility, marine activities like ships and marine animals, and other cultural noise. Ambient noise can be present in various forms on seismic data, such as linear features, localized very high amplitude response, and mono-frequency events. Ambient noise can be random noise and coherent noise.

Wave propagation related noise includes the surface waves, multiples, and geologic noise. Seismic response for an active source survey include primary reflection event (e.g.,

incident P-wave reflected back as P-wave), refraction, ground roll, mode converted event (e.g., incident P-wave reflected as S-wave), and several events reflected multiple times in the subsurface (multiples). In reflection seismology, we are interested in P-wave (and/or S-wave) primary reflections. All the other coherent energies recorded are considered noise. Multiples are considered the major source of coherent noise in the seismic experiment and are really difficult to attenuate. Wave propagation related noise also includes seismic response from unwanted geology (complicated stratigraphy, shallow gas, and faults) not considered in seismic analysis; they are known as geologic noise.

Data acquisition related noise is due to poor source and receiver coupling to the earth, source and recording instruments-generated noise, and acquisition footprint related to the acquisition design. Noise from poor coupling and noise related to instruments can be easily identified and attenuated. Acquisition footprint related to the acquisition design, observed as linear trend in seismic amplitude map view, is common in seismic data and can be suppressed in processing.

Seismic data processing is another source of noise in processed seismic data. There are various factors affecting seismic reflection amplitude that do not contain subsurface information (Sheriff 1975), but it is impossible to correct for all the factors affecting amplitudes. Many approximations and assumptions are made in seismic data processing depending on computer resources availability, project timeline, understanding of the physics of wave propagation, and the type of seismic data available. Some of these factors may alter the data and may introduce noise in the recorded data. Some examples are: (1) noise introduced in seismic data due to poor multiple attenuation and poor normal move-out (NMO) correction (Fig. 1); (2) noisy subsurface image due to imperfect velocity model used and/or approximate physics used for migration; (3) noise introduced due to inaccurate amplitude calibration of the raw amplitudes from the processed seismic data with synthetic seismic amplitude for quantitative AVO/AVA (amplitude variation with offset/angle) analysis; (4) artifacts introduced from the process of frequency enhancement to broaden frequency bandwidth for better depth resolution; and (5) artifacts introduced from the process of interpolation and regularization to compensate for the irregular acquisition geometry.

Enhancing Signal Over Noise

There is always some noise present in the seismic data. Figure 2 schematically shows amplitude spectra of various seismic signals and noise, and noise is present in the whole signal bandwidth. Thus, the objective is to enhance SNR by noise attenuation or separation so that data can be effectively

Seismic Noise, Fig. 1 Example of seismic noise. Shown in this figure is normal move-out (NMO) corrected synthetic seismic angle gather for AVA analysis with angle (in degrees) as x-axis and two-way traveltimes (in seconds) as y-axis for: noise-free case (a), with noise (b), and the noise present in data (c). The response in the third panel (c) is the difference between response in the first panel (a) and the second panel (b). On the top of angle gather is the root mean square (RMS) amplitude

value as a function of angle; the RMS value is computed in entire time gate shown here. In (c), the dipping coherent noises are multiples and the strong amplitudes at far angles are residual data after NMO. Thus, part of the data became residual data (un-flattened data after NMO in (b) is noise in AVA analysis) due to imperfect seismic velocity and/or seismic modeling method used in NMO (see red lines marked at 3,100 ms across three gathers for residual data)

Seismic Noise, Fig. 2 Schematic amplitude spectrum: for conventional broadband seismic data (active seismic for exploration range 10–60 Hz, and passive seismic for earthquake range from 10–100 Hz), low frequency passive seismic data (typically less than 10 Hz), high frequency passive seismic (microseismic) data (typically 30–300 Hz), and noise. Because noise is present at all frequencies, there is a need to do noise attenuation so that we get signal-to-noise ratio greater than 1. Spectrum is plotted for near zero frequency to Nyquist frequency. Nyquist frequency is the highest frequency without aliasing; beyond this frequency signal cannot be reliably estimated. Note that passive low and high frequency data can be treated as noise in broadband seismic data

used for analysis. An important step in noise attenuation/separation is to identify signal from noise. White (1984) discusses spectral methods for signal and noise estimation on seismic reflection data. Kanasevich (1990) and Chap. 6 of Yilmaz (2001) have good discussion on noise and multiple attenuation methods with data examples. Noise level in data compared to signal can be estimated as the ratio of autocorrelation of data to a cross correlation of data. This is because autocorrelation of data represents both signal and noise but cross correlation of data with a representative signal trace (can be local partial stack of data) represents signal in data. Signal and noise separation process can be broadly divided into two methods: prediction based methods and separation based methods. By performing seismic simulation over a known (conceptual) model and comparing synthetics to the field seismic data, signal and noise can be identified on data, and therefore noise can be attenuated. Also, signal and noise representation differs in different data domains. Therefore, a suitable data domain can be identified for the optimum separation of the two. Figure 3 schematically shows various seismic events for a three-layer model in native acquisition (X-T) domain and transformed domains: (1) X-T domain (represents spatial-time domain), (2) F-K domain (represents frequency – wave number domain), and (3) τ -p domain

Seismic Noise, Fig. 3 Seismic responses in various data domains for a three-layer model. The time domain earth model is shown in left (a) with seismic velocity for three layers as V1, V2, and V3. The second from left is the seismic response for a three-layer model in X-T domain (b), where D represents direct arrival, L represents linear noise, such as ground rolls, R1 and R2 are primary reflection events from 1st and 2nd layer interfaces, and H1 and H2 are refraction events. The third from left shows the

seismic response in F-K domain (c), where noise (D, L events) is on the upper right corner with apparent velocity less than the reference apparent velocity (V) and signal (R1, R2, H1, H2 events) are on the lower left corner corresponding to lower wave numbers. The right most plot (d) shows the seismic response in the τ -p domain, where the linear event in X-T domain plots on a point in the τ -p domain (Diebold and Stoffa 1981)

(representing zerooffset traveltime – ray parameter domain). The key to successful noise attenuation is large separation between signal and noise in a specific data domain. Different types of noise may require different domains for better separation between signal and noise. For example, a linear event on a shot gather (X-T domain) maps to a radial line in the F-K domain and it maps onto a point in the τ -p domain, and thus can be rejected by F-K filtering and τ -p filtering, respectively. Caution should be observed while performing the forward and inverse transforms, as some implementations may not be completely reversible and may also introduce artifacts.

Random noise is not correlated and can be attenuated easily during data processing. One of the most robust methods to attenuate random noise on multichannel data by a factor of square root of N is by stacking (compositing) data from N channels. If prestack data is needed, however, F-X deconvolution (predictive deconvolution) is effective in random noise attenuation, where F-X corresponds to frequency – space domain. Deconvolution operation (Yilmaz 2001) is designed in space domain to predict coherent signals, and then coherent signals can be subtracted from the seismic record.

Coherent noise is relatively more difficult to attenuate. An appropriate data domain (Fig. 3) can be selected to distinguish signal from noise using the noise characteristics, like velocity and frequency. Radon filtering in τ -p domain and wavelet transform filtering in F-K domain is very effective method for coherent noise attenuation. In many field data cases, signal

and noise are not well separated in any data domain and therefore it is very difficult to attenuate the noise. Recently a version of F-K filtering called Curvelet transform filtering has shown better results for both random and coherent noise attenuation (Neelamani et al. 2008). Multiples are example of coherent noise present in the data. There has been extensive research in the field of multiples suppression. The surface related multiple elimination (SRME) has been heavily relied upon to suppress multiples (Berkhout and Verschuur 1997). This technique is based on the stationary phase theory of the seismic signal and the multiples are predicted by convolving traces with one another and then stacking these convolved traces.

Another way to have better SNR in seismic data is via improved seismic acquisition techniques. There have been various developments in seismic acquisition on land and in marine environment. For example, over/under marine seismic acquisition promises better SNR in both low and high frequency range (Moldoveanu et al. 2007). In over/under towed-streamer acquisition pairs of streamer are deployed at two different depths in the same vertical plane. Other advances in seismic acquisition promise cleaner and better seismic images, for example, Multicomponent Ocean Bottom recording, Wide Azimuth recording, and Simultaneous Sources recording. The multiples suppression is strongly dependent on the acquisition effort. For example, the suppression of multiples in the case of Wide Azimuth acquisition is the result of a natural weighting of the traces going into the stack

because of the areal nature of the acquisition (VerWest and Lin 2007).

Some noise will always remain in the seismic data even after careful seismic processing. Also, there are some noises that are still not understandable and difficult to attenuate. Therefore, it is important to incorporate noise in the seismic data analysis – for example, in seismic inversion the data should not be over fitted as it might be fitting the noise.

Use of Noise as Signal

There have been significant efforts recently to use all of the recorded energy in the seismic data. Traditionally, only the primary reflection wavefield is used in reflection seismic imaging, while the multiple/ghost is discarded. However, the ghost/multiples can be used as signal, for example, as an input to mirror migration (Verm 1987) to produce superior shallow images for the sparse receiver ocean bottom data where illumination holes deteriorate the primary images (Clarke et al. 2006; Dash et al. 2009). Note that multiples are also generated from the same source as primary, they travel longer paths and contain more information than primary, and therefore in some circumstances multiples can be more useful than primaries. Full waveform inversion is another technique that uses both the primary and the multiples to invert for the subsurface parameters more effectively.

Multiples have also been used to interpolate for missing near offsets in seismic recording using the technique of interferometry (Schuster 2009). Seismic interferometry can also be used to extract primary signal from background noise and multiples by simply cross-correlating recorded data at two different stations (Sabra et al. 2005; Curtis et al. 2006; Draganov et al. 2007).

Some new seismic acquisition methods have been useful in using conventional multiples to improve SNR and/or extract primary. For example, over/under towed-streamer acquisition technology uses multiples to improve seismic data quality (Moldoveanu et al. 2007), and there is a possibility to estimate primaries from surface multiples from data recorded with simultaneous sources also called blended data (van Groenestijn and Verschuur 2010). In the simultaneous source acquisition (Berkhout 2008; Hampson et al. 2008) multiple sources are fired in a short time interval to speed up the acquisition.

Converted S-wave data, regarded as noise in reflected P-wave data imaging, has been quite successful in imaging gas reservoirs and areas where we have shallow gas anomalies (Tatham and McCormack 1991). The property that S-wave does not get as attenuated as P-wave when the wavefield travels through these porous medium helps

create better images through pure S-wave or converted S-wave imaging.

Low frequency earth's ambient passive response caused by natural phenomenon (such as wind, ocean waves, and human-made noise) and high frequency passive seismic response due to small earthquakes (microseisms) caused by induced fractures in a petroleum reservoirs are considered noise in a broadband active seismic data, but they can be effectively used to study subsurface. Low frequency earth's ambient noise can be used to extract signal (Draganov et al. 2007), and the low frequency passive seismic anomaly can be correlated with the presence of hydrocarbon (Saenger et al. 2009); however the research is still in its early stages. High frequency passive seismic data (also called microseismic data) are effectively used in hydraulic fracture monitoring (Warpinski 2009) by locating microseisms induced by hydrocarbon production related activities.

Summary

Seismic noise is an integral part of the seismic record and is defined as all unwanted seismic energy on data. It can be divided into two categories: random and coherent noises. Random noise is not correlated among traces and is easier to attenuate compared to coherent noise that is spatially and/or temporally correlated. Multiples and geologic noise that are coherent noise are more difficult to attenuate and often interfere with seismic signal and makes seismic analysis challenging. Strategies for seismic noise attenuation are needed to preserve the seismic signal of interest and to improve signal-to-noise ratio (SNR). The success in noise attenuation lies in identification and then separation or prediction of signal and noise. Transformation of data to different data domains (X-T, F-K, τ -p, curvelet, wavelet domains) have helped in better separating noise from signal. Wave-equation extrapolations, inverse scattering methods, surface related multiple elimination, deconvolution, etc., model the noise and/or data in the process of noise attenuation. Advances in seismic data acquisition and processing have been made to improve SNR. Recently various efforts have been made to use noise as signal and are an active topic of research. This includes using multiples as well as primaries in seismic migration and inversion, and using low and high frequency passive seismic data in imaging subsurface.

Seismic Phase Nomenclature: The IASPEI Standard

Johannes Schweitzer ¹, Dmitry A. Storchak ² and Peter Borman (Deceased)

¹NORSAR, Kjeller, Norway

²International Seismological Centre (ISC), Thatcham, UK

Definition

Different types of seismic waves can travel through the Earth. Their propagation depends on the wave type and the seismic velocities in the Earth. Due to the internal structure of the Earth (propagation velocities), the different wave types may be split at internal discontinuities (reflection, refraction, and conversion of waves) and will be recorded at seismic stations separated in time. The onsets of the different, separated waves are called seismic phases. Depending on their type and path through the Earth, seismic phases are labeled with different names, which are standardized for use by the seismological community.

Introduction

The working group (hereinafter WG) on the standard seismic phase names was set up by the IASPEI Commission on Seismological Observation and Interpretation (CoSOI) in 2001. The WG was chaired by D. A. Storchak and included R. D. Adams, P. Bormann, E. R. Engdahl, J. Havskov, B. L. N. Kennett, and J. Schweitzer. The WG put together a modified standard nomenclature of seismic phases that was meant to be concise, consistent, and self-explanatory on the basis of agreed rules. The list was not meant to satisfy specific requirements of seismologists to name various phases used in a particular type of research. Instead, it was hoped that the new list would ensure an expanded standardized data reporting and exchange by data analysts and other users. After numerous consultations with the seismological community, the standard seismic phase list was finalized and adopted by the CoSOI/IASPEI at its meeting in Sapporo on July 04, 2003.

The original list of standard seismic phase names was first published as part of the *New Manual of Seismological Observatory Practice* (Storchak et al. 2002), and then the version formally approved by the IASPEI was published in the *Seismological Research Letters* (Storchak et al. 2003). Various updates (e.g., in the revised second edition of the *New Manual of Seismological Observatory Practice* (Bormann et al. 2013)) to the list were required due to progress in observational

seismology and relevant changes in other observational standards. This entry accommodates the advances made in the nomenclature since its last publication.

The new nomenclature partially modified and complemented an earlier one published in the 1979 edition of the (Willmore 1979). It is more in tune with modern Earth and travel-time models. As opposed to former practice, the WG tried to make sure that the phase name generally reflects the type of wave and the path it has traveled. Accordingly, symbols for characterizing onset quality, polarity, etc. are no longer part of the phase name. The WG was also aware that seismic phases exist that are common in some regions but are only rarely or not found in other regions, such as Pb (P*), PnPn, PbPb, etc. The names and definitions of acoustic and hydroacoustic phases are likely to be reviewed and revised based on new analysis practices being established in the data centers.

The extended list of phase names as presented below reflects significantly increased detection capabilities of modern seismic sensors and sensor arrays, even of rather weak phases, which were rarely observed on the classical analog records. It also accounts for improved possibilities of proper phase identification by means of digital multichannel data processing such as frequency-wavenumber (f-k) analysis and polarization filtering, by modeling the observations with synthetic seismograms or by showing on the records the theoretically predicted onset times of phases. Finally, the IASPEI Seismic Format (ISF) (<http://www.isc.ac.uk/standards/isf/download/isf.pdf>) is much more flexible than the older formats previously used by the ISC, the NEIC, and other data centers. It also allows reporting, computer parsing, and archiving of phases with long or previously uncommon names. ISF also accepts complementary parameters such as onset quality, measured backazimuth and slowness, amplitudes and periods of other phases in addition to P and surface waves, for components other than vertical ones, and for instruments with nonstandard response characteristics.

This increased flexibility of the parameter-reporting format requires improved standardization, which limits the uncontrolled growth of incompatible and ambiguous parameter data. Therefore, the WG agreed on certain rules. They are outlined below prior to the listing of the standardized phase names. To facilitate the understanding of the phase names, ray diagrams are presented below. They have been calculated for local seismic sources on the basis of an average one-dimensional two-layer crustal model and for regional and teleseismic sources using the global 1D Earth model *ak135* (Kennett et al. 1995).

Before assigning abbreviated shortcut seismic phase names, one should agree first on the language to be used and its rules. As in any other language, we need a suitable alphabet (here plain Latin letters); numbers (here Arabic

numbers and $\pm$ signs); an orthography, which regulates, for example, the use of capital and lowercase letters; and a syntax, which describes the rules of correct order and mutual relationship of the language elements. One should be aware, however, that like any historically developed language, the seismological nomenclature will inevitably develop exceptions to the rules and depend on the context in which it is used. Although not fully documented below, some exceptions will be mentioned. Note that our efforts are mainly aimed at standardized names to be used in international data exchange so as to build up unique, unambiguous global databases for research. Many of the exceptions to the rules are related to specialized, mostly local research applications. The identification of related seismic phases often requires specialized procedures of data acquisition and processing that are not part of seismological routine data analysis. Also, many of these exceptional phases are rarely or never used in seismic event location, magnitude determination, source mechanism calculations, etc., which are the main tasks of international data centers. We focus, therefore, on phases that are particularly important for seismological data centers as well as for the refinement of regional and global Earth models on the basis of widely exchanged and accumulated parameter readings. In addition, we added references to the first definition of some wave types and phase names.

Standard Letters, Signs, and Syntax Used for Describing Seismic Phases

Capital Letters

Individual capital letters that stand for primary types of seismic body waves include:

P	Longitudinal wave that has traveled through the Earth's crust and mantle, from <i>undae primae</i> (Latin) = first waves (Von Dem Borne 1904)
K	Longitudinal wave that has traveled through the Earth's outer core, K, from Kern (German) = core (Sohon 1932; Bastings 1934)
I	Longitudinal wave that has traveled through the Earth's inner core (Jeffreys and Bullen 1940)
S	Transverse wave that has traveled through the Earth's crust and mantle, from <i>undae secundae</i> (Latin) = second waves (Von Dem Borne 1904)
T	Wave that has partly traveled as sound wave in the sea, from <i>undae tertiae</i> (Latin) = third waves (Linehan 1940)
J	Transverse wave that has traveled through the Earth's inner core (Bullen 1946)

Exceptions

- A capital letter *N* used in the nomenclature does not stand for a phase name but rather for the number of legs traveled

(or $N-1$ reflections made) before reaching the station. N should usually follow the phase symbol to which it applies. For examples see syntax below.

- The lowercase letters p and s may stand, in the case of seismic events below the Earth's surface, for the relatively short *upgoing leg* of P or S waves, which continue, after reflection and possible conversion at the free surface, as downgoing P or S wave. Thus seismic depth phases (e.g., pP , sP , sS , pPP , sPP , $pPKP$, etc.) are uniquely defined. The identification and reporting of such phases are of utmost importance for source depth determination (Schrade 1931; Stechschulte 1932; Gutenberg et al. 1933; Macelwane et al. 1933).
- Many researchers working on detailed investigations of crustal and upper mantle discontinuities denote both the up- and downgoing short legs of converted or multiple-reflected P and S phases as lowercase letters p and s , respectively.

Individual or double capital letters that stand for surface waves include:

L	(Relatively) long-period surface wave, unspecified, from <i>undae longae</i> (Latin) = long waves (Von Dem Borne 1904)
R	Rayleigh waves (short- to very long-period waves in crust and upper mantle) (Angenheister 1921)
Q	Love waves, from <i>Querwellen</i> (German) = transverse waves (Angenheister 1921)
G	(Very long-period) global (mantle) Love waves, firstly observed and reported by Gutenberg and Richter (1934); in honor of Gutenberg, Byerly proposed the usage of G for these waves (Richter 1958)
LR	Long-period Rayleigh waves, usually relating to the Airy phase maximum in the surface wave train
LQ	Long-period love waves
PL	Fundamental leaking mode following P onsets, firstly observed and reported by Somville (1930, 1931)

Lowercase Letters and Signs

Single lowercase letters generally specify the part of Earth's crust or upper mantle in which a phase has its turning point or at which discontinuity it has been reflected and/or eventually converted:

g	Following the phase name characterizes waves "bottoming" (i.e., having their turning point in the case of P or S body waves) or just travel (surface waves) within the upper ("granitic") Earth's crust (e.g., Pg , Sg , Rg), (Jeffreys 1926)
b	Following the phase name characterizes body waves bottoming in the lower ("basaltic") Earth's crust (Jeffreys 1926) (e.g., Pb , Sb ; alternative names for these phases are P^* , S^* (Conrad 1925)); also used for phases radiated directly to the Earth's surface from events in the lower crust
n	Following the phase name characterizes a P or S wave that is bottoming in the Earth's uppermost mantle or traveling as head wave below the Mohorovičić discontinuity (e.g., Pn , Sn),

(continued)

	introduced after Andrija Mohorovičić discovered the Earth's crust and separated the crustal travel-time curve from the normal ($=n$) mantle phase (Mohorovičić 1910); also used for phases radiated directly to the Earth's surface from events in the uppermost mantle
m	(Upward) reflections from the outer side of the Mohorovičić (Moho) discontinuity (e.g., PmP , SmS)
c	Reflections from the outer side of the core-mantle boundary (CMB), usage proposed by James B. Macelwane (see Gutenberg 1925)
i	Reflections from the outer side of the inner core boundary (ICB)
z	Reflections from a discontinuity (other than free surface, CMB or ICB) at depth z (measured in km). Upward reflections from the outer side of the discontinuity may additionally be complemented by a $+$ sign (e.g., $P410+P$; this, however, is not compulsory), while downward reflections from the inner side of the discontinuity must be complemented by a $-$ sign (e.g., $P660-P$)

An exception from these rules is the use of lowercase p or s to indicate arrivals of longitudinal or transverse waves that were first radiated to go up toward the free surface to be reflected/converted back into the Earth as normal P or S waves (see near-source surface reflections and conversions section of the phase list below).

Naming phases radiated directly to the Earth's surface in the near-source region from events in the lower crust (Conrad discontinuity) as Pb and from below the Moho as Pn is a pragmatic decision, which helps analysts and source-location programs to separate different branches of the travel-time curves.

Double lowercase letters following a capital letter phase name indicate the travel-time branch to which this phase belongs. Due to the geometry and velocity structure of the Earth, the same type of seismic wave may develop a triplication of its travel-time curve with different, in some cases, well-separated, branches. Thus, it is customary to differentiate between different branches of core phases and their multiple reflections at the free surface or the CMB. Examples are $PKPab$, $PKPbc$, $PKPdf$, $SKSac$, $SKKSac$, etc. The separation of the different PKP branches with letters ab , bc , and df was introduced by Jeffreys and Bullen (1940).

Three lowercase letters may follow a capital letter phase name to specify its character, e.g., as a forerunner (pre) to the main phase, caused by scattering (e.g., $PKPpre$) or as a diffracted wave extending the travel-time branch of the main phase into the outer core shadow (e.g., $Pdif$ in the outer core shadow for P).

Syntax of Generating Complex Phase Names

Due to refraction, reflection, and conversion in the Earth, most phases have a complex path history before they reach the station. Accordingly, most phases cannot be described by a single capital letter code in a self-explanatory way. By

combining the capital and lowercase letters as mentioned above, one can describe the character of even rather complex refracted, reflected, or converted phases. The order of symbols (syntax) regulates the sequence of phase legs due to refraction, reflection, and conversion events in time (from left to right) and in space.

Examples for Creating Complex Standard Phase Names

Traditional examples of complex phase names are as follows.

Refracted and Converted Refracted Wave

- PKP is a pure refracted longitudinal wave. It has traveled the first part of its path as P through the crust and mantle, the second through the outer core, and the third again as P through the mantle and crust. An alternative name for PKP is P' (Angenheister 1921), which should be read as “P prime.”
- PKIKP (alternative to PKPdf) is also a pure refracted longitudinal wave. It has traveled the first part of its path as P through the crust and mantle, the second through the outer core, the third through the inner core, and the fourth and fifth parts back again through the outer core and mantle/crust.
- SKS is a converted refracted wave. It has traveled as a shear wave through the crust and mantle, being converted into a longitudinal P wave when refracted into the outer core and converted back again into an S wave when entering the mantle.
- SKP or PKS are converted refracted waves with only one conversion from S to P when entering the core or from P to S when leaving the core, respectively.

Pure Reflected Waves

- In the case of (downward only) reflections at the free surface or from the inner side of the CMB, the phase symbol is just repeated, e.g., PP, SS (Geiger 1909), PPP, SSS, KK, KKK, etc.
- In the case of (upward) reflections from the outer side of the Moho, the CMB, or the ICB, this is indicated by inserting symbols m, c, or i, respectively, between the phase symbols, e.g., PmP, PcP, ScS, and PKiKP.
- Reflections from any other discontinuity in the mantle or crust at depth z may be from the inner side (–; i.e., downward back into the mantle) or from the outer side (+; i.e., back toward the surface). To differentiate between these two possibilities, the sign has to follow z (or the

respective number in km), for example, P410+P or P660–P.

- To abbreviate names of multi-leg phases due to repeated reflections, one can also write Phasename N. This type of abbreviation is customary in the case of multiple phases with long phase names such as PmP2 for PmPPmP (free-surface reflection of PmP), SKS2 for SKSSKS (the alternative name for $S'2$, the free-surface reflection of SKS), PKP3 for PKPPKPPKP (double free-surface reflection of PKP; alternative name to $P'3$), or P4KP for PKKKKP (triple reflection of P at the inner side of the CMB).

Two additional notes are to be made. First, PKP2 = PKPPKP are now alternative names for $P'2$ or $P'P'$, respectively. This should not be mistaken for the old usage of PKP2 for PKPab. Secondly, in the case of multiple reflections from the inner side of the CMB, the WG followed the established tradition of placing the number N not after but in front of the related phase symbol K.

Reflected Waves with Conversion at the Reflection Point

In the case that a phase changes its character from P to S, or vice versa, one writes:

- PS (first leg P, second leg S) or SP (first leg P, second leg S) in the case of reflection/conversion from the free surface downward into the mantle (Geiger and Gutenberg 1912a, b).
- PmS or SmP, respectively, for reflection/conversion from the outer side of the Moho.
- PcS or ScP for reflection/conversion from the outer side of the CMB.
- Pz+S or Sz–P for reflection/conversion from the outer (+) side or inner (–) side, respectively, of a discontinuity at depth z . Note that the – is compulsory, the + is not.
- pS or sP reflection/conversion at the free surface for body waves with a direct upgoing first leg.

In this context, it is worth mentioning that mode conversion is impossible for reflections from the inner side of the CMB back into the outer core because the liquid outer core does not allow the propagation of S waves.

The WG determined the new IASPEI standard phase names along these lines and rules. Where these deviate from other traditionally used names, the latter are given as well. Either the traditional names are still acceptable alternatives (alt) or they are old names (old), which should no longer be used.

Ray-Path Diagrams for Some of the IASPEI Standard Phases

We show ray paths through the Earth for many of the mentioned phases. The three diagrams for crustal phases are sketches illustrating the principal ray paths in a two-layer crust (Fig. 1). The rays in all other figures (Figs. 2, 3, 4, 5, and 6) were calculated by using the ray picture part of the WKB3 code (Chapman 1978; Dey-Sarkar and Chapman 1978); as velocity model, we chose the standard Earth model *ak135* (Kennett et al. 1995). For some types of P and S phases, the ray paths through the Earth are very similar

because the velocity ratio V_P/V_S does not change enough to give very different ray pictures. In these cases, we calculated only the ray paths for the P-type ray (i.e., P, Pdif, pP, PP, P660P, P660–P, PcP, PcP2, and PcP4) and assumed that the corresponding ray paths of the respective S-type phases were very similar. To show the different ray paths for phases with similar phase names, we show on many figures rays leaving the source once to the left and once to the right in different colors. The three most important discontinuities inside the Earth are indicated as black circles (i.e., the border between the upper and lower mantle, the CMB, and the ICB).

Seismic Phase Nomenclature: The IASPEI Standard,

Fig. 1 Seismic “crustal phases” observed in the case of a two-layer crust in local and regional distance ranges ($0^\circ < D < \text{approximately } 20^\circ$) from the seismic source in the (a) upper crust, (b) lower crust, and (c) uppermost mantle

Seismic Phase Nomenclature: The IASPEI Standard, Fig. 2 Mantle phases observed at teleseismic distance ranges ($D > \text{approximately } 20^\circ$)

Seismic Phase Nomenclature: The IASPEI Standard, Fig. 3 Mantle phases reflected from the Earth's core

IASPEI Standard Seismic Phase List

Crustal Phases

Pg	At short distances, either an upgoing P wave from a source in the upper crust or a P wave bottoming in the upper crust; also, at larger distances, arrivals caused by multiple P-wave reverberations inside the whole crust with a group velocity around 5.8 km/s
Pb	(alt:P*) Either an upgoing P wave from a source in the lower crust or a P wave bottoming in the lower crust
Pn	Any P wave bottoming in the uppermost mantle or an upgoing P wave from a source in the uppermost mantle
PnPn	Pn free-surface reflection

(continued)

PgPg	Pg free-surface reflection
PmP	P reflection from the outer side of the Moho
PmPN	PmP multiple free-surface reflection; <i>N</i> is a positive integer. For example, PmP2 is PmPPmP
PmS	P to S reflection/conversion from the outer side of the Moho
Sg	At short distances, either an upgoing S wave from a source in the upper crust or an S wave bottoming in the upper crust; also, at larger distances, arrivals caused by superposition of multiple S-wave reverberations and SV to P and/or P to SV conversions inside the whole crust
Sb	(alt:S*) Either an upgoing S wave from a source in the lower crust or an S wave bottoming in the lower crust
Sn	Any S wave bottoming in the uppermost mantle or an upgoing S wave from a source in the uppermost mantle
SnSn	Sn free-surface reflection

(continued)

SgSg	Sg free-surface reflection
SmS	S reflection from the outer side of the Moho
SmSN	SmS multiple free-surface reflection; N is a positive integer. For example, SmS2 is SmSSmS
SmP	S to P reflection/conversion from the outer side of the Moho
Lg	A wave group observed at larger regional distances and caused by superposition of multiple S-wave reverberations and SV to P and/or P to SV conversions inside the whole crust. The maximum energy travels with a group velocity of approximately 3.5 km/s
Rg	Short-period crustal Rayleigh wave

Mantle Phases

P	A longitudinal wave, bottoming below the uppermost mantle; also an upgoing longitudinal wave from a source below the uppermost mantle
PP	Free-surface reflection of a P wave leaving a source downward
PS	P, leaving a source downward, reflected as an S at the free surface. At shorter distances, the first leg is represented by a crustal P wave
PPP	Analogous to PP
PPS	PP which is converted to S at the second reflection point on the free surface; travel time matches that of PSP
PSS	PS reflected at the free surface
PcP	P reflection from the core-mantle boundary (CMB)
PcS	P converted to S when reflected from the CMB
PcPN	PcP reflected from the free surface $N - 1$ times; N is a positive integer. For example, PcP2 is PcPPcP
Pz+P	(alt:PzP) P reflection from the outer side of a discontinuity at depth z ; z may be a positive numerical value in km. For example, P660+P is a P reflection from the top of the 660 km discontinuity
Pz-P	P reflection from the inner side of a discontinuity at depth z . For example, P660-P is a P reflection from below the 660 km discontinuity, which means it is precursory to PP
Pz+S	(alt:PzS) P converted to S when reflected from the outer side of discontinuity at depth z
Pz-S	P converted to S when reflected from the inner side of a discontinuity at depth z
PScS	P (leaving a source downward) to ScS reflection at the free surface
Pdif	(old:Pdiff) P diffracted along the CMB in the mantle
S	Shear wave, bottoming below the uppermost mantle; also an upgoing shear wave from a source below the uppermost mantle
SS	Free-surface reflection of an S wave leaving a source downward
SP	S, leaving a source downward, reflected as P at the free surface. At shorter distances, the second leg is represented by a crustal P wave
SSS	Analogous to SS
SSP	SS converted to P when reflected from the free surface; travel time matches that of SPS
SPP	SP reflected at the free surface
ScS	S reflection from the CMB

(continued)

ScP	S converted to P when reflected from the CMB
ScSN	ScS multiple free-surface reflection; N is a positive integer. For example, ScS2 is ScSScS
Sz+S	(alt:SzS) S reflection from the outer side of a discontinuity at depth z ; z may be a positive numerical value in km. For example, S660+S is an S reflection from the top of the 660 km discontinuity
Sz-S	S reflection from the inner side of discontinuity at depth z . For example, S660-S is an S reflection from below the 660 km discontinuity, which means it is precursory to SS
Sz+P	(alt:SzP) S converted to P when reflected from the outer side of a discontinuity at depth z
Sz-P	S converted to P when reflected from the inner side of a discontinuity at depth z
ScSP	ScS to P reflection at the free surface
Sdif	(old:Sdiff) S diffracted along the CMB in the mantle

Core Phases

PKP	(alt:P') unspecified P wave bottoming in the core
PKPab	(old:PKP2) P wave bottoming in the upper outer core; ab indicates the retrograde branch of the PKP caustic
PKPbc	(old:PKP1) P wave bottoming in the lower outer core; bc indicates the prograde branch of the PKP caustic
PKPdf	(alt:PKIKP) P wave bottoming in the inner core
PKPpre	(old:PKhKP) a precursor to PKPdf due to scattering near or at the CMB
PKPdf	P wave diffracted at the inner core boundary (ICB) in the outer core
PKS	Unspecified P wave bottoming in the core and converting to S at the CMB
PKSab	PKS bottoming in the upper outer core
PKSbc	PKS bottoming in the lower outer core
PKSdf	PKS bottoming in the inner core
P'P'	(alt:PKPPKP) Free-surface reflection of PKP
P'N	(alt:PKPN) PKP reflected at the free surface $N - 1$ times; N is a positive integer. For example, P'3 is P'P'P'
P'z-P'	PKP reflected from the inner side of a discontinuity at depth z outside the core, which means it is precursory to P'P'; z may be a positive numerical value in km
P'S'	(alt:PKPSKS) PKP converted to SKS when reflected from the free surface; other examples are P'PKS and P'SKP
PS'	(alt:PSKS) P (leaving a source downward) to SKS reflection at the free surface
PKKP	Unspecified P wave reflected once from the inner side of the CMB
PKKPab	PKKP bottoming in the upper outer core
PKKPbc	PKKP bottoming in the lower outer core
PKKPdf	PKKP bottoming in the inner core
PNKP	P wave reflected $N - 1$ times from the inner side of the CMB; N is a positive integer
PKKPpre	A precursor to PKKPdf due to scattering near the CMB
PKiKP	P wave reflected from the inner core boundary (ICB)
PKMIKP	P wave reflected $N - 1$ times from the inner side of the ICB
PKJKP	P wave traversing the outer core as P and the inner core as S

(continued)

PKKS	P wave reflected once from the inner side of the CMB and converted to S at the CMB
PKKSab	PKKS bottoming in the upper outer core
PKKSbc	PKKS bottoming in the lower outer core
PKKSdf	PKKS bottoming in the inner core
PcPP'	(alt:PcPPKP) PcP to PKP reflection at the free surface; other examples are PcPS', PcSP, PcSS', PcPSKP, and PcSSKP
SKS	(alt:S') unspecified S wave traversing the core as P
SKSac	SKS bottoming in the outer core
SKSdf	(alt:SKIKS) SKS bottoming in the inner core
SPdifKS	(alt:SKPdifS) SKS wave with a segment of mantle-side Pdif at the source and/or the receiver side of the ray path
SKP	Unspecified S wave traversing the core and then the mantle as P
SKPab	SKP bottoming in the upper outer core
SKPbc	SKP bottoming in the lower outer core
SKPdf	SKP bottoming in the inner core
S'S'	(alt:SKSSKS) Free-surface reflection of SKS
S'N	SKS reflected at the free surface $N - 1$ times; N is a positive integer
S'z-S'	SKS reflected from the inner side of discontinuity at depth z outside the core, which means it is precursory to S'S'; z may be a positive numerical value in km
S'P'	(alt:SKSPKP) SKS converted to PKP when reflected from the free surface; other examples are S'SKP and S'PKS
S'P	(alt:SKSP) SKS to P reflection at the free surface
SKKS	Unspecified S wave, traversing the core as P with one reflection from the inner side of the CMB
SKKSac	SKKS bottoming in the outer core
SKKSdf	SKKS bottoming in the inner core
SNKS	S wave reflected $N - 1$ times from the inner side of the CMB; N is a positive integer
SKiKS	S wave traversing the outer core as P and reflected from the ICB
SKJKS	S wave traversing the outer core as P and the inner core as S
SKKP	S wave traversing the core as P with one reflection from the inner side of the CMB and then continuing as P in the mantle
SKKPab	SKKP bottoming in the upper outer core
SKKPbc	SKKP bottoming in the lower outer core
SKKPdf	SKKP bottoming in the inner core
ScSS'	(alt:ScSSKS) ScS to SKS reflection at the free surface; other examples are ScPS', ScSP', ScPP', ScSSKP, and ScPSKP

Near-Source Surface Reflections and Conversions (Depth Phases)

pPy	All P-type onsets (Py) as defined above, which resulted from the reflection of an upgoing P wave at the free surface or an ocean bottom. WARNING: The character "y" is only a wild
-----	--

(continued)

	card for any seismic phase, which could be generated at the free surface. Examples are pP, pPKP, pPP, pPcP, etc.
sPy	All Py resulting from the reflection of an upgoing S wave at the free surface or an ocean bottom, for example, sP, sPKP, sPP, sPcP, etc.
pSy	All S-type onsets (Sy) as defined above, which resulted from the reflection of an upgoing P wave at the free surface or an ocean bottom, for example, pS, pSKS, pSS, pScP, etc.
sSy	All Sy resulting from the reflection of an upgoing S wave at the free surface or an ocean bottom, for example, sSn, sSS, sScS, sSdif, etc.
pwPy	All Py resulting from the reflection of an upgoing P wave at the ocean's free surface
pmPy	All Py resulting from the reflection of an upgoing P wave from the inner side of the Moho

Surface Waves

L	Unspecified long-period surface wave
LQ	Love wave
LR	Rayleigh wave
G	Mantle wave of Love type
GN	Mantle wave of Love type; N is an integer and indicates wave packets traveling along the minor arcs (odd numbers) or major arc (even numbers) of the great circle
R	Mantle wave of Rayleigh type
RN	Mantle wave of Rayleigh type; N is an integer and indicates wave packets traveling along the minor arcs (odd numbers) or major arc (even numbers) of the great circle
PL	Fundamental leaking mode following P onsets generated by coupling of P energy into the waveguide formed by the crust and upper mantle
SPL	S wave coupling into the PL waveguide; other examples are SSPL and SSSPL

Acoustic Phases

H	A hydroacoustic wave from a source in the water, which couples in the ground
HPg	H phase converted to Pg at the receiver side
HSg	H phase converted to Sg at the receiver side
HRg	H phase converted to Rg at the receiver side
I	An atmospheric sound arrival, which couples in the ground
IPg	I phase converted to Pg at the receiver side
ISg	I phase converted to Sg at the receiver side
IRg	I phase converted to Rg at the receiver side
T	A tertiary wave. This is an acoustic wave from a source in the solid Earth, usually trapped in a low velocity oceanic water layer called the SOFAR channel (SOund Fixing And Ranging)
TPg	T phase converted to Pg at the receiver side
TSg	T phase converted to Sg at the receiver side
TRg	T phase converted to Rg at the receiver side

Seismic Phase Nomenclature: The IASPEI Standard, Fig. 4 Seismic rays of direct core phases

Amplitude Measurements

The following set of amplitude measurement names refers to the IASPEI Magnitude Standard of 2013 (see http://www.iaspei.org/commissions/commission-on-seismological-observation-and-interpretation/Summary_WG_recommendations_20130327.pdf), compliance to which is indicated by the presence of leading letter I. The absence of leading letter I indicates that a measurement is nonstandard. Letter A indicates a measurement in nm made on a displacement seismogram, whereas letter V indicates a measurement in nm/s made on a velocity seismogram. All amplitude measurements for standard magnitudes, with the exception for M_L , are made on vertical-component seismic records.

IAML	Displacement amplitude measured according to the IASPEI standard for local magnitude M_L
IAMs_20	Displacement amplitude measured according to the IASPEI standard for surface-wave magnitude $M_S(20)$
IVMs_BB	Velocity amplitude measured according to the IASPEI standard for broadband surface-wave magnitude $M_S(BB)$
IAmb	Displacement amplitude measured according to the IASPEI standard for short-period teleseismic body-wave magnitude m_b
IVmB_BB	Velocity amplitude measured according to the IASPEI standard for broadband teleseismic body-wave magnitude $m_B(BB)$
AX_IN	Displacement amplitude of phase of type X (e.g., PP, S, etc.), measured on an instrument of type IN (e.g., SP, short-period; LP, long-period; BB, broadband)
VX_IN	Velocity amplitude of phase of type X and instrument of type IN (as above)

(continued)

A	Unspecified displacement amplitude measurement
V	Unspecified velocity amplitude measurement
AML	Displacement amplitude measurement for nonstandard local magnitude
AMs	Displacement amplitude measurement for nonstandard surface-wave magnitude
Amb	Displacement amplitude measurement for nonstandard short-period body-wave magnitude
AmB	Displacement amplitude measurement for nonstandard medium to long-period body-wave magnitude
END	Time of visible end of record for duration magnitude

Unidentified Arrivals

x	(old:i, e, NULL) unidentified arrival
rx	(old:i, e, NULL) unidentified regional arrival
tx	(old:i, e, NULL) unidentified teleseismic arrival
Px	(old:i, e, NULL, (P), P?) unidentified arrival of P-type
Sx	(old:i, e, NULL, (S), S?) unidentified arrival of S-type

Summary

Since the early days of instrumental seismology, seismograms showed distinguished onsets of different seismic phases with different characteristics. Seismologists developed an own nomenclature for these phases, which is basic for any seismogram interpretation. This entry includes the historical development and currently established definitions of the seismic phase nomenclature as recommended by IASPEI.

Seismic Properties of Rocks

Nikolas I. Christensen

Department of Earth and Ocean Sciences,

University of British Columbia, Vancouver, BC, Canada

Synonyms

Rock P and S velocities

Definition

- | | |
|------------------------------|--|
| Compressional (P) waves | Seismic waves in which the rock particles vibrate parallel to the direction of wave propagation. |
| Shear (S) waves | Seismic waves in which the rock particles vibrate perpendicular to the direction of wave propagation. |
| Poisson's ratio (σ) | The ratio of the lateral unit strain to the longitudinal unit strain in a body that has been stressed longitudinally within its elastic limit ($2\sigma = (R^2 - 2)/(R^2 - 1)$ where $R = V_p/V_s$). |
| Transversely isotropic | Anisotropic solids with a single symmetry axis. Rock symmetry axes are usually normal to foliation, cleavage, or layering. |

Introduction

Although many disciplines have contributed significantly to our knowledge of the Earth's interior, none has a resolution comparable to seismology. For nearly seven decades, seismic studies have provided geophysicists with worldwide information on crustal and upper mantle compressional (P) and shear (S) wave velocities. Significant data have recently become available on velocity gradients, velocity reversals, compressional and shear wave velocity ratios, and anisotropy in the form of azimuthal variations of compressional wave velocities, as well as shear wave splitting. Reflections within the crust and mantle originate from contrasts of acoustic impedances, defined as products of velocity and density. The interpretation of this seismic data requires detailed knowledge of rock velocities provided by laboratory techniques to a precision at least comparable with that of seismic measurements. In particular, to infer composition of the Earth's upper 30–50 km, the “crust,” requires studies of the elasticity of rocks at conditions approaching those that exist at these depths. Of fundamental importance is the presence of mean compressive stress and temperature increasing with depth and on the average reaching about 1 GPa and 500 °C at the base of the crust. Because of this, the most relevant velocity measurements for identifying probable rock types within the crust have been measurements at elevated pressures and temperatures. These measurements often allow the seismologist to infer mineralogy, porosity, the nature of fluids occupying pore spaces, temperature at depth, and present or paleolithospheric stress based on mineral and crack orientations.

Francis Birch (Fig. 1) was the pioneer in the study of rock velocities. In addition to his laboratory work on physical properties of rocks and minerals at high pressures and temperatures, he was well-known for his studies of heat flow and theoretical work on the composition of the Earth's interior. Two of his benchmark papers on compressional wave velocities in rocks (Birch 1960, 1961) set the stage for modern experimental studies of rock elasticity and have been frequently cited during the past five decades. These papers for the first time provided information on compressional wave velocities for many common rock types, as well as major findings on their anisotropies and relations to density. It is interesting to note that these measurements were carried out to pressures of 1 GPa, a pressure at which even today only a limited number of laboratories generate for modern rock seismic velocity measurements.

Measurement Techniques

Rock velocities are usually measured in the laboratory using the pulse transmission technique. The transit time of either a

Seismic Properties of Rocks, Fig. 1 Francis Birch (1903–1992), a pioneer in rock physics research

compressional or shear wave is measured along the axis of a cylindrical rock specimen of known length. The cores are usually taken from rock samples using a 2.54 cm inner diameter diamond coring bit. The cores are trimmed and ground flat and parallel on a diamond grinding disk. The volume of each core is obtained from the length and diameter. The cores are weighed, and densities are calculated from their masses and dimensions. The cores are then fitted with a copper jacket to prevent penetration of high-pressure oil into the rock samples. For measurements at high temperatures, where gas is the pressure medium, the samples are usually encased in stainless steel. Transducers are placed on the ends of the rock core (Fig. 2). Compressional and shear waves are often generated by means of lead zirconate titanate (PZT) and AC cut quartz transducers with resonant frequencies of 1 MHz. The sending transducer converts the input, an electrical pulse of 50–500 V and 0.1–10 μ s width, to a mechanical signal, which is transmitted through the rock. The receiving transducer changes the wave to an electrical pulse, which is amplified and displayed on an oscilloscope screen (Fig. 3). Once the system is calibrated for time delays, the travel time through the specimen is determined directly by a computer or with the use of a mercury delay line. The major advantage of the delay line is that it increases the precision, especially for signals with slow rise times, because the gradual onset of the first arrival from the sample is approximated by the delay line. The velocity is the ratio of the length of the specimen to the travel time of the compressional or shear wave. The total error limits for V_p and V_s are estimated to be less than 1%.

Interfacing the pressure system with a computer for data acquisition and storage permits automatic calculations of velocities as successive readings are taken. Using a least-squares routine, the computer fits a curve to the data points and calculates velocities for selected pressures. A velocity versus pressure curve is plotted along with recorded data points. Sample length, density, measured pressure velocity pairs, traces of the waveforms at selected pressures, the curve fit equations, and calculated pressure velocity pairs are recorded and stored digitally.

Hydrostatic pressure generating systems capable of producing true hydrostatic pressures as high as 3 GPa, equivalent to a depth of approximately 100 km, have been used for rock velocity measurements. Low-viscosity synthetic petroleum and argon for high-temperature measurements are frequently used as pressure media. An alternate technique for obtaining velocities under quasi-hydrostatic conditions has used a

triaxial press with cubic samples. Transducers are placed on the six pistons, and corrections are made for travel times through the pistons. Rock velocities obtained using this technique have provided valuable information on the effect of temperature on velocity but have been limited to pressures of 0.6 GPa.

The behavior of a rock's velocity as a function of pressure is primarily dependent upon mineralogy and porosity. Many igneous and metamorphic rocks have porosities of the order of a few tenths of 1%, which are present as thin openings between grain boundaries. As pressure is applied to the rock, the cracks close and velocities increase. Once the cracks close, any increase in velocity with increasing pressure is related to the intrinsic effects of pressure on the mineral velocities. This is illustrated in Fig. 4 for a garnet granulite. Velocities first increase rapidly over the first 100 MPa as cracks close and then increase slowly as pressure is increased. Also the velocity determined at a given pressure depends upon whether the pressure is approached from lower or higher pressure (Fig. 4). This hysteresis is usually quite small if sufficient time is taken for measurements between pressure increments.

A considerable number of investigations have also focused on the influence of temperature on rock velocities. These studies have used either resonance techniques or more frequently the pulse transmission method. Early studies demonstrated that the application of temperature to rock at atmospheric pressure results in the creation of cracks that often permanently damage the rock and dramatically lower velocities. Thus reliable measurements of the temperature derivatives of velocities are obtained only at confining pressures high enough to prevent crack formation. At elevated confining pressures, $\delta V_p / \delta T$ for common rocks often ranges from -0.3×10^{-3} to -0.6×10^{-3} km/s/°C, and $\delta V_s / \delta T$ varies between -0.2×10^{-3} and -0.4×10^{-3} km/s/°C.

At high temperatures, usually between 650 °C and 1200 °C, rocks undergo partial melting. Several factors influence partial melting, including rock composition, pressure, and the involvement of aqueous and carbonic fluids. For rocks in which velocities are not modified by temperature-induced phase changes, it has been observed

Seismic Properties of Rocks, Fig. 2 Transducer and rock core assembly for velocity measurements at elevated pressures

Seismic Properties of Rocks, Fig. 3 Electronics for velocity measurements using a mercury delay line

Seismic Properties of Rocks, Fig. 4 Compressional wave velocity measurements as a function of confining pressure for a mafic granulite

that as temperature increases, velocities decrease linearly below partial melting temperatures and then drop significantly at the onset of partial melting.

Rock Velocities

Seismic velocities have been measured for practically all igneous and metamorphic rock types believed to be important constituents of the lithosphere. Because rock classification schemes allow for considerable variations in mineralogy for a given rock type, many rocks have wide ranges in elastic properties. However, some lithologies, such as the monomineralic rocks hornblende and dunite with little or no alteration, have fairly well-defined velocities. For detailed summaries of rock seismic properties, the reader is referred to the compilations of Birch (1960), Christensen (1982, 1996), Gerbade (1982), Ji et al. (2002), Rudnick and Fountain (1995), and Mavko et al. (1998).

Table 1 contains average velocities, in the order of increasing compressional wave velocity, for several common igneous and metamorphic rocks. Volcanic rocks usually have lower velocities than their plutonic equivalents. This is due to the presence of glass, abundant alteration products, and vesicles in volcanic rocks, all of which have lower velocities. In general, for a given composition, velocity increases with increasing metamorphic grade. For example, mica- and quartz-bearing schists have higher velocities than slates and phyllites. Low-grade metamorphosed basalts have lower velocities than higher-grade amphibolite and mafic granulite. Eclogites have the highest velocity of mafic rocks. Note that shear velocities are relatively high in quartzites and low in serpentinites.

Early attempts to infer crustal composition by comparing laboratory- and field-derived velocities relied primarily on compressional wave velocities. However correlations

Seismic Properties of Rocks, Table 1 Average compressional (V_p) and shear (V_s) wave velocities, velocity ratios (V_p/V_s), and Poisson's ratios (σ) at 1 GPa for common rock types (Christensen 1996)

Rock	V_p (km/s)	V_s (km/s)	V_p/V_s	σ
Serpentinite	5.607	2.606	2.152	0.36
Andesite	5.940	3.177	1.870	0.30
Quartzite	6.091	4.054	1.502	0.10
Basalt	6.118	3.291	1.859	0.30

Pyroxenite	7.935	4.519	1.756	0.26
Eclogite	8.198	4.594	1.785	0.27
Dunite	8.399	4.783	1.756	0.26

between compressional wave velocity and composition are limited due to the similar velocities of many common crustal rock types. Because of this nonuniqueness of compressional wave velocity laboratory and field data comparisons, many recent studies have focused on investigations of crustal composition using both compressional and shear wave velocities. In these studies the ratio V_p/V_s or Poisson's ratio (σ) calculated from V_p/V_s have resolved some of the ambiguities.

The values of V_p/V_s and σ , assuming isotropic elasticity, are given in Table 1 for several common igneous and metamorphic rocks at 1 GPa. This high pressure eliminates cracks so the values only reflect mineralogy. The relatively low σ for quartzites (0.10) agrees well with isotropic aggregate calculations based on the elastic constants of single crystal alpha quartz. Anorthosites, on the other hand, have relatively high Poisson's ratios (<0.31). As expected, values for the granites and granitic gneisses, consisting primarily of quartz and feldspar, fall in between those of quartzites and anorthosites and are relatively low. Thus, crustal regions, where field measured values of $\sigma \leq 0.25$ are observed, are likely quartz-rich. Serpentinities containing lizardite, the variety of serpentine stable at crustal PT conditions, have extremely high values of Poisson's ratio (0.36), whereas unaltered dunites and peridotites have Poisson's ratios in the range of 0.25–0.26. Partially serpentinized dunites and peridotites have Poisson's ratios that fall between these limiting values. Laboratory measurements have established

a well-defined relationship between Poisson's ratio, percent serpentinization, and density. Changes in Poisson's ratio with progressive metamorphism of mafic igneous and pelitic rocks are considerably more complicated than the above examples (Christensen 1996).

Velocity Anisotropy

Most crustal and upper mantle rocks show some degree of velocity anisotropy, which can originate from several processes. Laminar flow within magma and lava will orient elongate crystals such as feldspars along flow directions. Tabular sediments may settle preferentially, and anisotropy may be enhanced by sediment compaction. Plastic flow and recrystallization during metamorphism often produce strong mineral orientations parallel to foliation and banding. In shallow crustal rocks, oriented cracks producing anisotropy often originate from differential principle stresses. Anisotropy observed in laboratory measurements at pressures above approximately 100 MPa, where cracks are closed, often originates from preferred orientations of highly anisotropic minerals such as micas, amphiboles, pyroxenes, and olivine.

In general, for a given propagation direction in an anisotropic rock, there are three waves, one compressional, and two shear. Their vibration directions form an orthogonal set, which usually are not parallel or perpendicular to their propagation direction. Compressional and shear wave velocities vary with propagation direction, and two shear waves travel in a given direction through the rock with different velocities. This latter property of anisotropic rocks, termed shear wave splitting, was first recognized in laboratory studies and has been observed by field studies in several crustal and upper mantle regions.

Anisotropy is usually studied in the laboratory by taking cores from a rock in different directions. Following the early investigations of Birch (1960, 1961), it is common practice to take three mutually perpendicular cores for velocity measurements. If the rock has a planar structure, such as a foliation, cleavage, or bedding, two cores are oriented with their axes within the planar structure. One of these cores is oriented parallel to a lineation, if present. In general, three velocities are measured per core: the compressional wave velocity, the velocity of the shear wave vibrating parallel to the layering, and the velocity of the shear wave vibrating in a plane perpendicular to layering. For cores taken perpendicular to layering, shear wave velocities are measured with vibration directions parallel to the axes of the cores taken in the layering.

It has been demonstrated that the above procedure provides information on maximum compressional wave anisotropy and maximum shear wave splitting. In general, the highest compressional wave velocities propagate in the

plane of the foliation and parallel to lineations. Maximum shear wave splitting is observed for propagation within the planar structures. At near-normal incidence, there is often minimal shear wave splitting.

Velocity measurements using multiple cores have provided detailed information on anisotropic velocities for non-axial propagation (e.g., Johnston and Christensen 1995; Christensen and Okaya 2007). The number of measurements necessary to completely describe wave propagation depends on the symmetry of the rock fabric. In the most general anisotropic elastic solid, 21 independent constants are required to describe the equations of motion. Examples of materials with this type of behavior are minerals possessing triclinic symmetry such as kyanite and some feldspars. For many rocks, the existence of symmetry elements in the elastic properties leads to the vanishing of some elastic constants along with simple algebraic relations between others (e.g., Auld 1990). Some crustal and upper mantle metamorphic rocks behave as elastic solids with orthorhombic symmetry, which require nine independent constants to describe the elastic tensors. Shales and many low- to medium-grade metamorphic rocks often have well-developed bedding or foliation and behave as transversely isotropic elastic solids (hexagonal symmetry with the symmetry axis normal to bedding or foliation). Transversely isotropic solids have five independent elastic constants, which can be calculated from five independent velocity measurements (two compressional wave velocities, one quasi-compressional wave velocity, and two shear wave velocities) and density. In an isotropic solid, only two independent constants are required for a complete description of elastic behavior, and wave velocities are independent of propagation direction.

To describe three-dimensional wave propagation in anisotropic rocks, phase velocity surfaces can be calculated using the Kelvin-Christoffel equations (e.g., Auld 1990), and elastic constants can be determined from velocity and density measurements. For transversely isotropic rocks, these surfaces describe variations in velocity as a function of angle to the bedding or foliation (Fig. 5). Three velocity surfaces are calculated, one for the quasi-compressional wave, one for the shear wave vibrating parallel to the planar structure, and one for the quasi-shear wave vibrating in a plane perpendicular to the foliation or bedding. For propagation parallel and perpendicular to the foliation, all wave modes are pure. The velocities shown in Fig. 5 were calculated from velocity measurements at 600 MPa for a transversely isotropic quartz-mica schist from South Island, New Zealand. They show several important features about elastic wave propagation in this rock, which are typical of many foliated rocks. First, compressional wave velocities do not increase significantly until propagation directions greater than about 45° from foliation normal are reached. At larger angles, compressional wave velocity increases rapidly and reaches a maximum for

Seismic Properties of Rocks, Fig. 5 Compressional wave anisotropy (*upper curve*) and shear wave splitting (*lower curves*) for a transversely isotropic quartz-mica schist

propagation parallel to the foliation. Shear wave singularities (directions in which two shear waves have equal velocities) occur for propagation parallel to and at approximately 50° to the symmetry axis. Shear wave splitting occurs for all other propagation directions and reaches to maximum of 90° from the normal to the foliation.

Summary

Beginning with the compressional wave velocity measurements of Birch (1960, 1961), much has been learned about elastic wave propagation in rocks. Compressional wave velocities are now available for most common rock types at pressures existing in the continental crust and uppermost mantle. Additional important contributions include laboratory measurements of shear wave velocities, velocity ratios, and the influence of temperature on velocities. Estimates of crustal composition from compressional wave velocities are nonunique, but this ambiguity is often reduced by complimentary shear wave velocity (and Poisson's ratio) observations. Recent field studies have found that seismic anisotropy is an important crustal feature. Thus systematic laboratory studies of compressional wave anisotropy and shear wave splitting will be critical in understanding crustal composition and deformation, just as they have been in investigations of the upper mantle.

Seismic Quiescence and Activation

Gennady Sobolev

Institute of Physics of the Earth, Russian Academy of Sciences, Moscow, Russia

Definition

Seismic quiescence: Relative decrease in number of earthquakes or energy in any area of a seismic active region within a certain time interval in comparison with long-term observations in the same region.

Seismic activation: Relative increase in number of earthquakes or energy in any area of a seismic active region within a certain time interval in comparison with long-term observations in the same region.

Introduction

Both seismic quiescence and seismic activation before large earthquakes have been repeatedly described in the scientific literature. Earthquakes causing destruction of buildings, loss of life and economic damage are usually considered as large ones. Comparative size of different earthquakes is measured by their magnitude M (see ► “[Earthquake, Magnitude](#)”). The most destructive earthquakes fall in the range of magnitudes 7–9; and seismic energy released from an earthquake’s source (see ► “[Earthquakes, Energy](#)”) lies in the range of 10^{22} – 10^{25} ergs and the intensity of seismic shaking at the Earth surface (see ► “[Earthquakes, Intensity](#)”) exceeds the 7 level of the 12-degree-scale.

Just the first condition of detection of quiescence or activation follows from the stated above: a necessity of long-term history of seismic observations. However, for the purpose of rigorously proven detection of such occurrences one should be sure that any seismic event, magnitude of which exceeded some minimum threshold, was not missed within the observation period. Just in the second half of the twentieth century development of seismic networks of observation equipped with calibrated seismographs lead to creation of instrumental catalogues of earthquakes what enabled to judge objectively about appearance of seismic quiescence and activation.

The first sufficiently founded reports of appearance of seismic quiescence before large earthquakes were published at the beginning of the 1960s in Japanese and were practically unknown outside Japan. Then, in 1969 K. Mogi, on the basis of a visual analysis of seismicity maps, formulated a hypothesis that a seismic quiescence may be a precursor of a large earthquake (Mogi 1979). At the end of the 1980s M. Wyss and R. Habermann studied instrumental seismic catalogues of a number of regions of the Earth and determined basic rules of a formal detection of a seismic quiescence (Wyss and Habermann 1988). In brief, they may be summarized as follows: (1) evaluation of homogeneity of a seismic catalogue for the analyzed time interval, including magnitude calculations, taking into consideration changes in methods of determination of coordinates and depth of seismic events; (2) determination of a minimum magnitude of earthquakes being recorded without any omissions; (3) removal of groups and aftershocks in order to analyze so-called background seismicity; (4) quantitative evaluation of size and significance of an anomaly whereas significance shall be considered a statistically proven difference of an anomaly from random variations of the background seismicity; (5) quantitative determination of beginning of an anomaly; and (6) evaluation of sizes of an anomalous region. M. Wyss and R. Habermann determined that numerous events of seismic quiescence described in the literature are explained by changes of a minimum representative magnitude which were not taken into account owing to expansion of a seismic network or

development of information processing technique. However, there remain dozens of published events of seismic quiescence which may not be explained by any omissions of technical nature (artifacts).

Description of certain events of seismic quiescence exceeds the limits of this entry. We will mention only as an example two widely discussed events. M. Ohtake et al. studied the seismicity along the Pacific Ocean coast of Mexico and found that after the middle of 1973 the seismicity rate in the region of 16.5°N and 96.5°W with the linear dimensions of about 100–200 km declined sharply what was interpreted as a seismic quiescence (Ohtake et al. 1977). On November 29, 1978, after 5.5 years, the Oaxaca earthquake occurred with $M = 7.6$ in this region. C. Kisslinger found a seismic quiescence before an Andreanof Islands earthquake of May 7, 1986, with $M = 8$ (Kisslinger 1988). Our task does not include any evaluation of authenticity and significance of these and other events, especially because it is not correctly to do it without the authors’ participation. We will note only that about 100 authors of scientific works published their investigations of seismic quiescence in regions with different geological and tectonic structure. It may be assumed that such phenomenon exists objectively in the nature and sometimes arises before a large earthquake. Since a seismic process to a great extent is self-similar in a wide range of magnitudes, a seismic quiescence most likely arises before a relative weak earthquake as well.

Main Phases of Seismic Quiescence and Activation

On the basis of thousands of observations of seismicity in various regions of the world there exists a generally accepted opinion among the seismologists that the large earthquake arises after a long-term (dozens of years) increase in seismicity in a relative region connected with a gradual growth of tectonic stresses. The latter, in their turn, arise at the joints of the earth’s crustal plates moving with a different rate. Let us name this period of increase in seismicity as a *phase of long-term seismic activation* (phase I at the Fig. 1). Spatial dimensions of a region of long-term activation before the large earthquake ($M = 7$ –8) may exceed 1,000 km.

On the background of such process, in some area of the region of long-term activation a mean seismicity rate decreases what, as a rule, results in decrease in rate of release of the seismic energy. A researcher has a task to detect such decrease in the seismic activation and to prove its significance at a quantitative level, that is, to detect the seismic quiescence. All the suggested methods are based somehow or other on an analysis of statistics of earthquakes which at the today’s level of development of seismological networks of observations includes events contained in catalogues, the magnitude of which is from three to four units less in comparison with the magnitude of the large earthquake. This statistics includes at

Seismic Quiescence and Activation, Fig. 1 Main phases of seismic quiescence and activation

best the first thousands of events within a period of some years what makes the task of quiescence detection difficult and not always solvable. Below we will describe in brief two methods which were analyzed to reveal a seismic quiescence before several earthquakes both *a retrospective one* (after the large earthquake) and *a prospective one* (before the large earthquake).

In the Z-value method there is calculated the standard deviate, Z, to estimate the significance of the rate change,

$$Z = (m_1 - m_2) / (S_1/n_1 + S_2/n_2)^{1/2},$$

where m is the mean rate, S the variance, and n is the number of events in the first and second period to be compared (Wyss and Habermann 1988).

For the purpose of significance evaluation there is applied the normal distribution law, but when having a rather large statistics of earthquakes the method gives plausible evaluations by other distribution law as well. The more the Z value is the more the difference between a rate of a seismic flow in the area of a supposed seismic quiescence and in comparison with a long-term rate. The calculations are carried out by the enumeration of nodes of the geographical grid and a changing number of earthquakes located near each node. It results the averaged Z values are presented in the form of maps in the researched seismic active region. The area of a seismic quiescence is determined according to high values of Z isolines, above the given rate of statistic significance. The experience showed that the more reliable results appeared in the task if there were removed swarms and aftershocks of previous earthquakes from the catalog.

The RTL-method uses three functions to measure the state of seismicity at a given location as a function of time (Sobolev 2001).

$$R(x, y, z, t) = \left[\sum \exp(-r_i/r_0) \right] - R_{ltr}$$

$$T(x, y, z, t) = \left[\sum \exp(-(t - t_i)/t_0) \right] - T_{ltr}$$

$$L(x, y, z, t) = \left[\sum (l_i/r_i)^p \right] - L_{ltr}$$

In these formulas, x, y, z, and t are the coordinates, the depth, and the analysis time, respectively. r_i is the epicentral distance from the location selected for analyses, t_i is the occurrence time of the past seismic events, and l_i is the length of rupture estimated by empirical relation with the magnitude. The R_{ltr} , T_{ltr} , L_{ltr} are the long-term averages of these functions. r_0 is a coefficient that characterizes the diminishing influence of more distant seismic events; t_0 is the coefficient characterizing the rate at which the preceding seismic events are “forgotten” as the time of analysis moves on; and p is the coefficient that characterizes the contribution of size of each preceding event. R, T, and L are dimensionless functions. They are normalized by their standard deviations. The product of the above three functions is calculated as the RTL-parameter, which describes the deviation from the background level of seismicity and is in units of the standard deviation, $\sigma_R \sigma_T \sigma_L$. The RTL decrease in relation to the background level means a seismic quiescence, and a structure of isolines of such parameter on the map indicates to the size of a quiescence area. In the RTL method the outgoing catalogue is cleaned of the aftershocks but the swarms are not removed.

An improvement of the method was proposed by Huang and Ding, which leads to a map of the quality of parameters. They select an area into the r_0 – t_0 space where at least 70% of the correlation coefficients over pairs exceeds a specified

threshold for r_0 and t_0 . Based on this map, they propose a method to find the optimal values of r_0 and t_0 (Huang and Ding 2012). Nagao et al. suggested a modified RTL algorithm, called the RTM algorithm, where magnitude parameter M_i was used instead of length of rupture L_i (Nagao et al. 2011).

Both methods (Z-value and RTL) require that the duration of period, which is included in calculations of the rate of background seismicity, must be by an order more than the supposed duration of the seismic quiescence. The experience of application of the described and other methods of revealing of the seismic quiescence in different tectonic conditions has shown (Sobolev 2011) that the duration of a quiescence period before the large earthquakes amounts to several years, that is, by an order less than the phase of the long-term activation (Fig. 1).

The area of significant values of the quiescence has linear dimensions about 300 km. In the most published works the seismic quiescence was determined by the application of only one method. The first exception, apparently, was a work by M. Wyss et al., in which a situation before the large earthquakes on the Sakhalin Island was analyzed by using of one and the same regional seismic catalogue but by the application of both methods mentioned above: Z-value and RTL (Wyss et al. 2004). The duration of quiescence anomalies before the Neftegorsk earthquake on May 27, 1995, $M = 7.1$, amounted according to results of both methods to 2.7 years. The size of a quiescence region was determined according to Z-value in the form of a rectangle with dimensions of 200×600 km, and according to the RTL data – in the form of a circle with the radius up to 400 km. The epicenter of the earthquake lied at the periphery of anomalies in both determinations. Before the Ulegorsk earthquake on August 4, 2000, $M = 6.8$, the duration of quiescence was according to Z-value 2.5 years and according to the RTL 3.0 years. The dimensions of the anomalous regions were determined in the form of a circle with the radius up to 165 and 200 km, respectively. The epicenter of the earthquake was also at the lateral part of quiescence area. The examination conducted with random catalogues has showed that the probability that the anomaly occurred by chance before the Neftegorsk earthquake did not exceed 1% and before the Ulegorsk earthquake 2% according to the results of both methods.

In spite of available facts of the seismic quiescence before some large earthquakes, the practical application of such anomaly for the forecast of earthquakes remains undecided. Authors of publications on the subject of seismic quiescence do not cite any data on a number of false alarms when no large earthquake occurred in the region of quiescence. According to our evaluations, the number of false alarms exceeds by several times the number of forecasts proven to be correct (even by a retrospective analysis). There is no statistic evaluation of a real *prospective* forecast with the use of such anomaly

indeed. Let us illustrate the above stated by a Fig. 2 where the areas of seismic quiescence in the region of the Kuriles arch are showed which were detected before the Simushir earthquake on November 15, 2006, $M = 8.2$. In this case the RTL method was applied, but it is not a matter of principal. The dark spots mean the areas of seismic quiescence. The main one of them with linear dimensions of about 200 km is located in the territory with coordinates of $46^\circ\text{--}48^\circ\text{N}$ – $151^\circ\text{--}154^\circ\text{E}$; the epicenter of the main shock is located at its periphery, and the strongest aftershock, $M = 8.1$, outside the anomaly. Another several anomalies of a lower size are showed in the figure: the territory with coordinates of 45°N – 147°E ; of 43.5°N – 145°E ; and of 50°N – 158°E . Any large earthquakes in these regions did not occur up to now.

It follows from the experience of investigations of the seismic quiescence that a large earthquake seldom occurs during the most significant rate of quiescence. It arises more often after the rate of seismic activity has increased again and even exceeded that which has been observed before the beginning of the quiescence. Let us name the time interval from minimal values of activity at the stage of quiescence to the moment of the large earthquake as a phase of foreshock activation (phase III on Fig. 1). Its duration has a wide range: from several days to the dozens of months. The area of the foreshock activation in general coincides with the area of aftershocks (see ► [“Earthquake, Aftershocks”](#)) and its size is estimated in hundreds of kilometers. These properties of the phase of foreshock activation bring to the understanding of the term “foreshock” in the broad sense. At the final step of development of such phase there may occur seismic events, the location of which coincide practically with the source of the following large earthquake. They are called traditionally foreshocks and should be understanding as foreshocks in the narrow sense (see ► [“Earthquake, Foreshocks”](#)). Usually they arise several hours before a large earthquake, reflecting apparently the nucleation of a rupture. This phenomenon is of great interest for a short-term forecast, but the practical application thereof has some difficulties because no reliable criteria are found till today in order to differentiate foreshocks from usual earthquakes. In exceptional events when a number of events occurring during several hours and at one and the same place amounts to dozens, they may be interpreted presumably as foreshocks of a future large earthquake and serve as a ground for a short-term forecast. The striking example is a prediction of the Highcheng earthquake, February 4, 1975, $M = 7.3$. The foreshocks determined after the large earthquake (retrospectively) are described in a great number of publications and the description thereof is beyond the scope of this entry.

Returning to the phase of foreshock activation (Fig. 1) we cite the example of its detection before the Simushir earthquake mentioned above as of November 15, 2006, $M = 8.2$. The RTL method developed for detection of a seismic

Seismic Quiescence and Activation, Fig. 2 Areas of seismic quiescence before the Simushir earthquake

quiescence allows also to identify the foreshock activation as a period of increase in the seismic activity after the quiescence. The situation showed in Fig. 3 is a continuation in time of that which appeared in this area of the Kurile Island arch during the seismic quiescence (Fig. 2). The development of the stage of seismic quiescence from the level of a long-term background to the lowest values of the seismic activity lasted in this event 1.5 years and the period of recovery of the stage of activity to the level of a long-term background (foreshock activation) lasted 1.5 years as well. The linear dimensions of foreshock activation amounted to about 100 km (Fig. 3). It was located in the area of aftershocks between the main shock with the $M = 8.2$ and the strongest aftershock, $M = 8.1$. Also, like at a seismic quiescence, within the region as showed on the map (Fig. 3) during the development of the main anomaly, there was selected a number of anomalies with a lower intensity: on the territory of coordinates 44°N – 149°E ; 45°N – 150.5°E ; 48.5°N – 154.5°E . In these places no large seismic events occurred up to now. Thus, the foreshock activation, like the seismic quiescence, is not of high reliability in the prognostic aspect because there exist anomalies qualified as false.

A detailed analysis of the redetermined earthquake catalog between 1996 and 2007, using a gridding technique (ZMAP), showed a pair of seismic quiescence and activation anomalies that start around the middle of 2005, and last about 30 months (Katsumata and Sakai 2013). The pair of quiescence and activation anomalies are located very close to each other. Nanjo et al. reported precursory seismic patterns prior to the 2016 Kumamoto earthquakes, as measured by four different methods: the b -value, the RTM-algorithm, the Z -value, and analysis of seismicity density in space and time. The 2016 Kumamoto earthquakes, including a magnitude $M7.3$ mainshock that struck on April 16, 2016, were preceded by periods of pronounced quiescence anomalies which lasted from 1.5 to >3 years (Nanjo et al. 2016).

Physical Mechanisms Leading to Seismic Quiescence and Activation

Let us consider possible physical mechanisms which bring to occurrences of the seismic quiescence and of the foreshock activation. There is no unified explanation at present and it is

Seismic Quiescence and Activation, Fig. 3 Areas of foreshock activation before the Simushir earthquake

expedient to discuss various hypotheses. We would like to note at first that except for the three phases discussed above and the occurrence of foreshocks in the narrow sense, there may appear sometimes also other anomalies. C. Scholz selected additional phases: doughnut pattern was observed in the period of development of the seismic quiescence around its external limits, and seismic silence was noticed just prior to the main event (Scholz 1990).

Let us consider in a more detailed manner hypotheses of nature of the stages of a seismic quiescence and of a foreshock activation. Ma et al. investigated the seismic patterns before nine large earthquakes in China (Ma et al. 1989). The authors did not select specially occurrences of a seismic quiescence or activation. They did describe mainly a migration of sources of seismic events for several years before large events in the regions adjacent to their epicenters with the dimensions of about first 100 km. Actual data cited by them are of interest as applied to a problem of physical nature of occurrences discussed in this entry. There was considered a migration of sources mainly with the magnitudes 3–6, while the large earthquakes had the magnitudes of above 8. The regions round the epicenters of large events were separated in three

parts: a hypocenter area A, which included a hypocenter of a large event; area of aftershocks B and external area C.

The following main characteristics of migration were selected. During 3–10 years till the moment of the large earthquake there was varied two phases in time. In the first one the events occurred mainly in the area C, while the areas A and B were characterized as relatively quiet. During the second phase which finished in the large earthquake the activity was detected in the areas A and B, while the seismic activity in the area C was reduced. As the second phase developed, the activity in the areas A and B continued to last up to several months or days in relation to the moments of the large earthquake; at the end of such series the activity either accumulated inside the hypocentral area A or continued to last in the area B, while the area A was calm. We should note that the authors did not cite any quantitative evaluations of the seismicity rate, thus conclusions may be made based in a qualitative manner only. Summarizing, there may be made a conclusion that the process of development of a large earthquake may occur according to various scripts, though in described events it related to continental events only.

The seismic quiescence may be a consequence of increase in the strength of rocks within the seismically active area. In the dilatancy-diffusion model the increase in the strength is explained by laboratory experiments, being a consequence of appearance of open microcracks and a relative drying of the rocks. However, it is not explained how such process can develop in the heterogeneous lithosphere in the spatial regions with the linear dimension of above 100 km.

The quiescence occurs also when the tectonic stress decreases. This can be a consequence of development of an unstable deformation in the source of a future large earthquake what constitutes one of the corner stones of the model of avalanche-like fracturing (Sobolev 2019). Expenditure of the accumulated potential energy brings to a decrease in stress both in the source and in the surrounding space. This explanation leads to expect an increase in seismic activity in the hypocentral area of a future large earthquake and a simultaneous occurrence of a seismic quiescence in the external area. This cannot always be observed. But the situation that the activation in the source occurs at the level of seismic events with small magnitudes, which are not registered by the available seismological network, cannot be excluded.

Decrease in the tectonic stress in some area of lithosphere can be a consequence of the motion of neighboring blocks with a different rate. If one of the blocks stops because of an strong asperity at its tectonic boundaries with any neighboring blocks, then the stress will be accumulated at points of a asperity, while in the middle of the stopped block it will relax gradually. The activation will start at boundaries of the stopped block and then it will migrate to central parts when the asperity is destroyed.

As a modification of such assumption is the situation when the stress increases and brings to the seismicity in the stronger blocks, and the block between them is relatively discharged. The quiescence occurring in the discharged block in such situation causes an effect of “false forerunners” as no large earthquake follows after them.

Kanamori suggested an explanation of different phases of seismicity based on a model of existence of a strong inclusion at a fault being heterogeneous in its strength (Kanamori 1981). When the stress increases gradually, the less strong inclusions disintegrate sequentially what brings to an accelerated growth of the stress at points being not disintegrated. There is observed a background seismicity at the low stress. As the stress increases, there occurs the doughnut pattern – a mass destruction of rocks around the strong inclusion. The latter has a seismic quiescence. When the stress approaches to a critical level, there occurs a destruction of subunits of the strong inclusion which characterizes the phase of foreshock activation. In this hypothesis, the facts of existence of the seismic quiescence at distances which significantly exceed the rupture sizes when a large earthquake occurs are not explained.

The reason of seismic quiescence can be a change of orientation of the tensor of the current stress due to development of a creep at the fault where a future earthquake will occur. The existing fractures, which get into new conditions, require the time for unstable development (kinetics of destruction). It is not proven that this, undoubtedly, existing phenomenon can cause a quiescence at distances which significantly exceed the length of a rupture of a future earthquake.

Another reason can be a transformation of the medium surrounding the source to the quasi-plastic state, for example, when the temperature or the hydrostatic compression increases. Then the process of fracturing will occur at a lower scale level which is beyond the registration of earthquakes by the seismic network. There remains a question what are the physical reasons of increase of the temperature or the compression in the lithosphere or the earth's crust within a relatively short time period (years).

It is necessary to mention another effect which influences on the fracturing in the geological medium. Laboratory and field observations prove that an increase or a decrease in the degree of water saturation of rocks results in a significant acceleration or retardation of occurrence of the seismic events (see ► [“Geomagnetically Induced Currents”](#)). Further, if the rate of the seismic activity increases due to that, then it results in a relative increase in the number of events with the relatively small magnitudes and in a decrease in the number of big events. The seismic quiescence may occur: (a) if a degree of water saturation decreases; (b) if under the influence of the increased water saturation the seismicity transforms to the level of small events being not registered by the seismic network. The activation is a direct consequence of the increased water saturation and may appear also in the form of swarms.

It follows from the most available experimental facts that the foreshock activation develops in the epicentral region. Its size is less than the area of seismic quiescence, and the centers of anomalous areas of these two phenomena do not coincide as a rule. There is a ground to suppose that the physics of foreshock activation is connected with the development of unstable deformation which is localized under the laws of mechanics in the zone of mainly two-dimensional extension. The complexity of fault systems, which display a fractal geometry, causes a successive occurrence of several zones of unstable deformation.

At the final period of foreshock activation there often occur clusters of seismic events, that is, groups of events, the distances between the hypocenters of which and the times between the successive events are less than mean values of the background seismicity. The occurrence of clusters at the phase of foreshock activation can be explained by two reasons. First, they occur by chance because of the increase in rate of formation of events in the narrow zone of unstable

deformation. Second, when the spatial density of accumulated active faults exceeds the critical level, there arise stress interactions among neighboring faults with the formation of the faults of a larger length. In the latter case such effect must appear with the increase of middle magnitudes of seismic events, that is, with the decrease of the *b*-value.

Braun and Peyrard investigated the origin of seismic quiescence with a generalized version of the Burridge–Knopoff model for earthquakes and found that it can be generated by a multi-peaked probability distribution of the thresholds at which contacts break. Such a distribution is not assumed a priori but naturally results from the aging of the contacts. It was shown that the model can exhibit quiescence as well as enhanced foreshock activity, depending on the value of some Parameters (Braun and Peyrard 2018).

Kawamura et al. applied two different approaches: the pattern informatics (PI) method and the ZMAP method, which is a gridding technique based on the standard deviate (*Z*-value) test and found that the epicenter of the 2013 ML6.2 Nantou earthquake was surrounded by three main seismic quiescence regions prior to its occurrence. The assumption that this is due to precursory slip (stress drop) on fault plane or its deeper extent of the ML6.2 Nantou earthquake was supported by previous researches based on seismicity data, geodetic data, and numerical simulations using rate- and state-dependent friction laws (Kawamura et al. 2014).

Yi-Ying Wen et al. investigated seismicity rate changes associated with the 2010 ML 6.4 Jiashan earthquake applying the RTL and pattern informatics algorithms (Wen et al. 2016). Both temporal and spatial results exhibited signatures of abnormal seismicity change related to the seismic activation and quiescence prior to main shock. Seismicity changes coincided with Coulomb stress change during the same period.

The 2004 Sumatra (Mw 9.1) earthquake was preceded by a seismic quiescence that began 13 years before the mainshock (Katsumata 2015). A detailed analysis of the earthquake catalog using a gridding technique (ZMAP) shows the quiescent area is located between 3° and 6° N, which covers the southeastern part of the focal area, including the rupture initiation point of the 2004 Sumatra earthquake. The observed spatial pattern of quiescence can be explained by stress perturbation due to a long-term slow slip located on the deeper edge of the mainshock fault.

Summary

It follows from the mentioned hypotheses that there exist various physical mechanisms of occurrence both of the seismic quiescence and of the foreshock activation. For the purpose of more fundamental understanding of such phenomena, the additional laboratory and field works are required. In our

opinion, special attention should be paid to the following directions:

To investigate on the same catalogues of earthquakes both the quiescence and the activation in a complex, paying attention to their distribution in space, time and to magnitudes
To compare, where possible, the seismic patterns with the field of deformations being estimated based on the data of satellite geodesy

To compare, where possible, the seismic patterns with the data of deep geoelectrical and hydrogeological investigations with the purpose of better understanding of the role of water

Definition

Seismic ray theory High-frequency asymptotic method of study of seismic wavefields in complex inhomogeneous isotropic or anisotropic media with curved structural interfaces.

Introduction

The ray theory belongs to the methods most frequently used in seismology and seismic exploration for forward and inverse modelling of high-frequency seismic body waves. In smoothly varying media with smooth interfaces, it can provide useful approximate solutions of the elastodynamic equation of satisfactory accuracy. Starting from an intuitive description of the propagation of seismic waves along special trajectories – rays, it has developed into a highly sophisticated method, described briefly in this review paper.

The ray method has its advantages and limitations. The basic advantages are its applicability to complex, isotropic or anisotropic, laterally varying layered media and its numerical efficiency in such computations. It provides a physical insight into the wave propagation process by separating the wavefield into individual elementary waves and by allowing their

identification. In addition, it makes possible to track the paths (rays) in the medium along which energy of individual waves propagates, an aspect very important in tomography. The ray method also represents an important basis for other related, more sophisticated methods, such as the paraxial ray method, the Gaussian beam summation method, the Maslov method, the asymptotic diffraction theory, various combinations of the ray method with perturbation theory, etc. The ray method also has some limitations. It is approximate and applicable only to smooth media with smooth interfaces, in which the characteristic dimensions of inhomogeneities are considerably larger than the prevailing wavelength of the considered waves. The ray method can yield distorted results and may even fail in some special regions called *singular regions*.

The seismic ray method owes a lot to optics and radio-physics. Although the techniques used in different branches of physics are very similar, there are some substantial differences. The ray method in seismology is usually applied to more complicated structures than in optics or radiophysics. There are also different numbers and types of waves considered in different branches of physics.

The first seismological applications of ray concepts date back to the end of the nineteenth century. Then, only *kinematics*, specifically travel times, were used. Probably the first attempts to use also *dynamics* (amplitudes and waveforms) were made by Sir H. Jeffreys. The ray series solutions of elastodynamic equation with variable coefficients were first suggested by Babich (1956) and Karal and Keller (1959) for inhomogeneous isotropic media, and by Babich (1961) for inhomogeneous anisotropic media.

The Earth's interior is anisotropic or weakly anisotropic in some of its parts. Seismic anisotropy and its effects on wave propagation play an important role in contemporary seismology and seismic exploration. Consequently, it has also been necessary to develop the ray theory for elastic anisotropic media. It is important to emphasize that, for S waves, the ray theory for anisotropic media does not yield the ray theory for isotropic media in the zero anisotropy limit. For this reason, we describe systematically the ray theory for anisotropic media and also present corresponding formulae for isotropic media, and explain the differences between both of them.

S waves require generally a special attention. Well-understood phenomenon is propagation of two separate shear waves in anisotropic media. An underestimated phenomenon is shear-wave coupling, which occurs in weakly anisotropic media or in vicinities of shear-wave singularities. In such regions, standard ray theories for anisotropic as well as isotropic media do not work properly. Therefore, we also briefly describe the coupling ray theory for S waves, which fills the gap between ray theories for isotropic and anisotropic media.

We give here neither a detailed derivation of ray-theoretical expressions nor a relevant systematic

bibliography. This would extend the text considerably. We refer, however, to several textbooks, in which the ray theory is treated in a considerably greater detail (Červený et al. 1977; Kravtsov and Orlov 1990; Červený 2001; Chapman 2004; Babich and Kiselev 2018). The reader may also find useful information in several review papers devoted to seismic ray theory and its various aspects (Červený et al. 1988, 2007; Virieux 1996; Chapman 2002). Examples of computations based on the ray theory can be found, for example, in Červený et al. (1977) and Gjøystdal et al. (2002). Here we refer only to papers, in which the relevant methods and procedures were first proposed, and/or which give a useful more recent treatment of the subject.

We use the following notation. We denote Cartesian coordinates x_i and time t . The dots above letters denote partial derivatives with respect to time ($\ddot{u}_i = \partial^2 u_i / \partial t^2$) and the index following the comma in the subscript indicates the partial derivative with respect to the relevant Cartesian coordinate ($u_{i,j} = \partial u_i / \partial x_j$). We consider high-frequency time-harmonic seismic body waves, with the exponential factor $\exp(-i\omega t)$, where ω is fixed, positive, real-valued circular frequency. The lower-case Roman indices take the values 1, 2, 3, the upper-case indices 1, 2. Hats over bold symbols indicate 3×3 matrices, bold symbols without hats denote 2×2 matrices. The Einstein summation convention over repeating Roman indices is used, with exception of indices in parentheses.

Basic Equations of the Seismic Ray Method

For smoothly varying elastic media, the source-free *equation of motion* reads

$$\tau_{ij,j} - \rho \ddot{u}_i = 0. \quad (1)$$

Here $\tau_{ij}(x_n, t)$, and $u_i(x_n, t)$ are Cartesian components of stress tensor and displacement vector, respectively, and ρ is the density. In anisotropic media, the stress tensor τ_{ij} and the infinitesimal strain tensor $e_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i})$ are related by Hooke's law:

$$\tau_{ij} = c_{ijkl} e_{kl} = c_{ijkl} \partial u_k / \partial x_l. \quad (2)$$

$c_{ijkl}(x_n)$ is a tensor of elastic moduli (stiffness tensor), satisfying symmetry relations $c_{ijkl} = c_{jikl} = c_{ijlk} = c_{klij}$. There are, at the most, 21 independent elastic moduli. Inserting Eq. 2 into Eq. 1, we get the *elastodynamic equation*

$$(c_{ijkl} u_{k,l})_{,j} - \rho \ddot{u}_i = 0. \quad (3)$$

In the seismic ray method, high-frequency seismic body waves propagating in smoothly varying, isotropic or

anisotropic, media are studied. The formal ray series solution of the elastodynamic equation, see Eq. 3, for the displacement vector $\mathbf{u}(x_n, t)$ is sought in the form of an asymptotic series in inverse powers of circular frequency ω ,

$$\mathbf{u}(x_n, t) = \exp[-i\omega(t - T(x_n))] \left[\mathbf{U}^{(0)}(x_n) + \frac{\mathbf{U}^{(1)}(x_n)}{(-i\omega)} + \frac{\mathbf{U}^{(2)}(x_n)}{(-i\omega)^2} + \dots \right]. \quad (4)$$

Here $T(x_n)$ is the real-valued travel time, $\mathbf{U}^{(k)}$, $k = 0, 1, 2, \dots$ are complex-valued *vectorial amplitude coefficients*. Surfaces $T(x_i) = \text{const.}$ are called *wavefronts* (or phase fronts). In perfectly elastic media, functions $T(x_n)$, and $\mathbf{U}^{(k)}(x_n)$ are frequency independent.

Also other forms of the ray series have been used in the seismic ray method. For example, Chapman (2004) developed the seismic ray method using the ray series for particle velocity and traction. Such a formal ray series has certain advantages with respect to Eq. 4. Here, however, we consider systematically the traditional ray series for the displacement vector in the form of Eq. 4.

Inserting Eq. 4 into elastodynamic equation, see Eq. 3, we obtain a series in inverse powers of ω , which equals zero. Consequently, the coefficients of the individual powers of ω must also equal zero. This yields a system of equations called the basic recurrence system of equations of the ray method. This system can be used to determine the eikonal equation for travel times $T(x_n)$ and, successively, the equations for the amplitude coefficients $\mathbf{U}^{(0)}(x_n)$, $\mathbf{U}^{(1)}(x_n)$, $\mathbf{U}^{(2)}(x_n), \dots$. The equations for $\mathbf{U}^{(k)}(x_n)$ yield, among others, transport equations. For a detailed derivation of the basic system of equations of the ray method see Červený (2001, Sect. 5.7).

The vectorial amplitude coefficients $\mathbf{U}^{(k)}(x_n)$, $k = 1, 2, \dots$ can be expressed as a sum of the *principal component* and *additional component*. The zero-order amplitude coefficient $\mathbf{U}^{(0)}(x_n)$, which has no additional component, is an exception. Its principal component is determined from the transport equation discussed later. The principal component of $\mathbf{U}^{(k)}(x_n)$ for $k > 0$ is the projection of $\mathbf{U}^{(k)}(x_n)$ into the unit vector parallel to the zero-order amplitude coefficient $\mathbf{U}^{(0)}(x_n)$, the additional component of $\mathbf{U}^{(k)}(x_n)$ is the remaining part of $\mathbf{U}^{(k)}(x_n)$. The complexity of the equations for higher-order amplitude coefficients $\mathbf{U}^{(k)}$ increases rapidly with increasing k . Moreover, the higher-order amplitude coefficients are unstable and usually do not increase the accuracy notably. They are very sensitive to fine details of the medium. The instability of the amplitude coefficients increases with increasing k . For these reasons, only the zero-order coefficient $\mathbf{U}^{(0)}(x_n)$, with the additional component of $\mathbf{U}^{(1)}(x_n)$, at the most, has been used in seismological applications. In the following, we shall concentrate on the zero-order ray approximation $\mathbf{U}^{(0)}(x_n)$ only.

The zero-order approximation of the ray method reads:

$$\mathbf{u}(x_n, t) = \mathbf{U}(x_n) \exp[-i\omega(t - T(x_n))]. \quad (5)$$

In Eq. 5, we have dropped the superscript (0) of $\mathbf{U}(x_n)$. We call $\mathbf{U}(x_n)$ the complex-valued *vectorial amplitude*. In smooth, laterally varying media, containing smooth structural interfaces, the zero-order approximation of the ray method in Eq. 5 usually offers sufficiently accurate results, particularly for travel time $T(x_n)$. Its great advantage is that it allows one to work with frequency-independent travel time and amplitude. However, if the medium under consideration becomes more and more complex (less smooth) or if a singularity is close, vectorial amplitude $\mathbf{U}(x_n)$ becomes less accurate. In structures exceeding certain degree of complexity or close to singularities, the ray method may yield inaccurate results or even fail.

The first equation of the basic recurrence system of equations of the ray method reads:

$$(\Gamma_{ik} - \delta_{ik})U_k = 0, \quad i = 1, 2, 3. \quad (6)$$

Here Γ is the 3×3 *generalized Christoffel matrix* with elements given by the relation:

$$\Gamma_{ik} = a_{ijkl}p_j p_l. \quad (7)$$

In Eq. 7, p_i are the Cartesian components of the slowness vector $\mathbf{p}$,

$$p_i = \partial T / \partial x_i \quad (8)$$

and $a_{ijkl} = c_{ijkl}/\rho$ are density-normalized elastic moduli. Note that the classical Christoffel matrix, with elements $a_{ijkl}n_j n_l$, contains components of the real-valued unit vector $\mathbf{n}$ (perpendicular to the wavefront) instead of $\mathbf{p}$. For this reason, we call the matrix in Eq. 7 the “generalized” Christoffel matrix. The relation between p_i and n_i is $p_i = n_i/C$, where C is the phase velocity.

The generalized 3×3 Christoffel matrix in solid elastic media is symmetric ($\Gamma_{ik} = \Gamma_{ki}$), positive definite ($\Gamma_{ik}a_i a_k > 0$, where a_i are components of any non-vanishing real-valued vector), and homogeneous function of the second degree in p_i ($\Gamma_{ik}(x_n, ap_j) = a^2 \Gamma_{ik}(x_n, p_j)$ for any nonvanishing constant a). It has three real-valued positive eigenvalues $G_m(x_n, p_j)$, and three corresponding real-valued unit eigenvectors $\mathbf{g}^{(m)}(x_n, p_j)$, $m = 1, 2, 3$. G_m and $\mathbf{g}^{(m)}$ are solutions of the eigenvalue equations

$$(\Gamma_{ik} - \delta_{ik}G_m)g_k^{(m)} = 0, \quad i = 1, 2, 3. \quad (9)$$

Eigenvectors $\mathbf{g}^{(1)}, \mathbf{g}^{(2)}, \mathbf{g}^{(3)}$ are mutually perpendicular. Eigenvalue G_m and the relevant eigenvector $\mathbf{g}^{(m)}$ are mutually related as follows:

$$G_m = \Gamma_{ik}g_i^{(m)}g_k^{(m)} = a_{ijkl}p_j p_l g_i^{(m)}g_k^{(m)}. \quad (10)$$

For isotropic media, elastic moduli $c_{ijkl}(x_n)$ can be specified in terms of Lamé’s elastic moduli $\lambda(x_n)$ and $\mu(x_n)$, describing isotropic media, as follows:

$$c_{ijkl} = \lambda \delta_{ij} \delta_{kl} + \mu (\delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk}). \quad (11)$$

Elements of the generalized Christoffel matrix are then given by the relation:

$$\Gamma_{ik} = \frac{\lambda + \mu}{\rho} p_i p_k + \frac{\mu}{\rho} \delta_{ik} p_n p_n. \quad (12)$$

In isotropic media, the expressions for eigenvalues and eigenvectors of the generalized Christoffel matrix can be determined analytically:

$$G_1 = G_2 = \beta^2 p_k p_k, \quad G_3 = \alpha^2 p_k p_k. \quad (13)$$

Here

$$\alpha^2 = (\lambda + 2\mu)/\rho, \quad \beta^2 = \mu/\rho. \quad (14)$$

The eigenvector relevant to the eigenvalue G_3 equals $\mathbf{n}$, the unit vector perpendicular to the wavefront. The eigenvectors relevant to coinciding eigenvalues G_1 and G_2 are mutually perpendicular unit vectors situated arbitrarily in the plane perpendicular to $\mathbf{n}$ and tangent to the wavefront.

Eikonal Equation. Polarization Vector

The comparison of Eq. 6 with the eigenvalue equation for the 3×3 generalized Christoffel matrix, see Eq. 9, shows that Eq. 6 is satisfied, if the eigenvalue G_m of the generalized Christoffel matrix satisfies the relation

$$G_m(x_i, p_j) = 1, \quad (15)$$

and if the complex-valued vectorial amplitude $\mathbf{U}$ of the wave under consideration is related to eigenvector $\mathbf{g}^{(m)}$ as follows:

$$\mathbf{U} = A \mathbf{g}^{(m)}. \quad (16)$$

Equation 15 is the important *eikonal equation*. It is a nonlinear, first-order partial differential equation for travel time $T(x_n)$. Equation 16 shows that displacement vector $\mathbf{U}$ is parallel to the appropriate eigenvector $\mathbf{g}^{(m)}$ of the generalized Christoffel matrix. For this reason, we call $\mathbf{g}^{(m)}$ the *polarization vector*. Symbol $A(x_n)$ denotes the complex-valued, frequency-independent, *scalar amplitude*.

Taking into account that G_m is a homogeneous function of the second degree in p_i , where $\mathbf{p} = C^{-1}\mathbf{n}$, we obtain $G_m(x_i, p_j) = C^{-2}G_m(x_i, n_j)$. This and Eqs. 10 and 15 yield

$$C^2(x_i, n_j) = G_m(x_i, n_j) = a_{ijkl}n_j n_l g_i^{(m)} g_k^{(m)}. \quad (17)$$

Phase velocity C is the velocity of the propagation of the wavefront in the direction $\mathbf{n}$. The phase-velocity vector $\mathbf{C} = C(x_i, n_j)\mathbf{n}$ has the direction of $\mathbf{n}$, i.e., it is perpendicular to the wavefront. It follows from Eq. 17 that the squares of phase velocity C are eigenvalues $G_m(x_i, n_j)$ of the classical Christoffel matrix with elements $a_{ijkl}n_j n_l$.

Generally, eigenvalues G_m , $m = 1, 2, 3$, of the generalized Christoffel matrix are mutually different. They correspond to three high-frequency body waves propagating in inhomogeneous anisotropic media. Smaller eigenvalues, G_1 and G_2 , belong usually to S1 and S2 waves, largest, G_3 , to P wave. Such situations are considered here. If the eigenvalues are mutually different, their polarization vectors can be determined uniquely.

If two eigenvalues coincide, we speak of the *degenerate case* of the eigenvalue problem. The corresponding eigenvectors can then be chosen as mutually perpendicular vectors situated arbitrarily in the plane perpendicular to the eigenvector related to the different eigenvalue. Eigenvalues may coincide *locally*, along certain lines or at certain points, which correspond to the so-called *S wave singular directions*, or may be close to one another *globally* in a vicinity of singular directions or in *weakly anisotropic media*. The approximate but unique determination of polarization vectors in the latter situations is possible using perturbation approach (Jech and Pšenčík 1989).

In isotropic media, the S wave eigenvalues G_1 and G_2 coincide *globally*, see Eq. 13. Consequently, in isotropic media, the S waves are controlled by a single eikonal equation and we have thus only two different eikonal equations corresponding to P and S waves. As the equations for the eigenvalues in isotropic media can be determined analytically, see Eq. 13, we can express the eikonal equations, see Eq. 15, for P and S waves explicitly:

$$\alpha^2 p_k p_k = 1 \quad \text{for P waves}, \quad (18)$$

$$\beta^2 p_k p_k = 1 \quad \text{for S waves}. \quad (19)$$

In isotropic media, the generally complex-valued amplitude vector $\mathbf{U}$ can be expressed in the simple form, see Eq. 16, only for P waves. In this case the polarization vector $\mathbf{g}^{(3)} = \mathbf{n}$, i.e., it is perpendicular to the wavefront. For S waves, $\mathbf{U}$ must be considered in the following form:

$$\mathbf{U} = B\mathbf{g}^{(1)} + C\mathbf{g}^{(2)}. \quad (20)$$

Here $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ are two mutually perpendicular unit vectors in the plane tangent to the wavefront, i.e., perpendicular to the vector $\mathbf{n}$. The determination of $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ along the

ray is explained later, see Eq. 38. Symbols $B(x_n)$ and $C(x_n)$ are the corresponding, generally complex-valued scalar amplitudes.

In the seismic ray method, it is common to express the eikonal equation, see Eq. 15, in Hamiltonian form. Hamiltonian $\mathcal{H}(x_i, p_j)$ may be introduced in various ways. We shall consider the Hamiltonian, which is a homogeneous function of the second degree in p_i . For inhomogeneous anisotropic media, we can introduce the Hamiltonian expressed in terms of $G_m(x_i, p_j)$, see Eq. 10:

$$\mathcal{H}(x_i, p_j) = \frac{1}{2}G_m(x_i, p_j) = \frac{1}{2}a_{ijkl}p_j p_l g_i^{(m)} g_k^{(m)}. \quad (21)$$

The eikonal equation, see Eq. 15, then reads:

$$\mathcal{H}(x_i, p_j) = \frac{1}{2}. \quad (22)$$

It holds for anisotropic as well as isotropic media.

From Eqs. 13 and 21, we get for isotropic inhomogeneous media:

$$\mathcal{H}(x_i, p_j) = \frac{1}{2}V^2(x_i)p_k p_k, \quad (23)$$

where $V = \alpha$ for P waves and $V = \beta$ for S waves.

Ray Tracing and Travel-Time Computation

The eikonal equation in Hamiltonian form as shown in Eq. 22, with $p_j = \partial T / \partial x_j$, is a nonlinear partial differential equation of the first order for travel time $T(x_i)$. It can be solved by the method of characteristics. The characteristics of eikonal equation, see Eq. 22, are spatial trajectories, along which Eq. 22 is satisfied, and along which travel time T can be computed by quadratures. The characteristics of the eikonal equation represent *rays*.

The characteristics of the eikonal equation expressed in general Hamiltonian form are described by a system of nonlinear, ordinary differential equations of the first order:

$$\frac{dx_i}{du} = \frac{\partial \mathcal{H}}{\partial p_i}, \quad \frac{dp_i}{du} = -\frac{\partial \mathcal{H}}{\partial x_i}, \quad \frac{dT}{du} = p_k \frac{\partial \mathcal{H}}{\partial p_k}. \quad (24)$$

Here u is a real-valued parameter along the ray. The relation between parameter u and the travel time along the ray depends on the form of the Hamiltonian used; see the last equation in Eq. 24. For Hamiltonians, which are homogeneous functions of the second degree in p_i , the Euler equation for homogeneous functions yields $p_k \partial \mathcal{H} / \partial p_k = 2\mathcal{H}$. If we consider Hamiltonian in the form of Eq. 22, we get $dT/du = 1$ from Eq. 24. For travel time T along the ray, denoted $\tau = T$, Eq. 24 simplifies to:

$$\frac{dx_i}{d\tau} = \frac{\partial \mathcal{H}}{\partial p_i}, \quad \frac{dp_i}{d\tau} = -\frac{\partial \mathcal{H}}{\partial x_i}. \quad (25)$$

This system of equations is usually called the *ray tracing system*. Solution of the ray tracing system, see Eq. 25, with appropriate initial conditions yields $x_i(\tau)$, the coordinates of points along the ray trajectory, and $p_i(\tau)$, the Cartesian components of the slowness vectors along the ray. The travel time T along the ray is obtained automatically, $T = \tau$.

Inserting Eq. 21 to Eq. 25, we obtain the ray tracing system for m -th wave in the inhomogeneous anisotropic medium:

$$\frac{dx_i}{d\tau} = a_{ijkl} p_l g_j^{(m)} g_k^{(m)}, \quad \frac{dp_i}{d\tau} = -\frac{1}{2} \frac{\partial a_{ijkl}}{\partial x_i} p_k p_n g_j^{(m)} g_l^{(m)}. \quad (26)$$

In the derivation of the first equation of Eq. 26 for $\partial \mathcal{H} / \partial p_i$, we took into account that $\Gamma_{ik} \partial (g_i^{(m)} g_k^{(m)}) / \partial p_n = 0$. An alternative version of ray-tracing equations, see Eq. 26, was derived by Červený (1972), in which the eigenvectors $\mathbf{g}^{(m)}$ were not used.

The initial conditions for the ray tracing system, see Eq. 26, are $x_i = x_{0i}$, $p_i = p_{0i}$, where x_{0i} and p_{0i} satisfy the eikonal equation, see Eq. 22, corresponding to the wave we wish to compute (P, S1 or S2). Components p_{0i} of the initial slowness vector $\mathbf{p}_0$ can be expressed as $p_{0i} = n_{0i} / C(x_{0j})$, where C is the relevant phase velocity. The eikonal equation, see Eq. 22, is then satisfied along the whole ray.

In inhomogeneous isotropic media, the ray tracing system, see Eq. 25 with Eq. 23, yields

$$\frac{dx_i}{d\tau} = V^2 p_i, \quad \frac{dp_i}{d\tau} = -\frac{\partial \ln V}{\partial x_i}. \quad (27)$$

The initial conditions for the ray tracing system, see Eq. 27, are again $x_i = x_{0i}$, $p_i = p_{0i}$, where $p_{0i} = n_{0i} / V(x_{0j})$. Here $V = \alpha$ for P waves, and $V = \beta$ for S waves.

As τ is the travel time along the ray, $dx_i / d\tau$ in Eq. 26 represents the Cartesian components $\mathcal{U}_i$ of the *ray-velocity vector* $\mathbf{U}$ of the m -th wave:

$$\mathcal{U}_i = a_{ijkl} p_l g_j^{(m)} g_k^{(m)}. \quad (28)$$

In elastic anisotropic media, the ray-velocity vector $\mathbf{U}$ is also called the group-velocity vector or the energy-velocity vector. As indicated by the name, the energy velocity vector $\mathbf{U}$ represents the velocity of the energy propagation.

In anisotropic media, the ray-velocity vector $\mathbf{U}$ must be strictly distinguished from the phase-velocity vector $\mathbf{C}$. In inhomogeneous anisotropic media, the ray-velocity and phase-velocity vectors $\mathbf{U}$ and $\mathbf{C}$ are generally different, both in size and direction. Vector $\mathbf{U}$ is always greater than $\mathbf{C}$. The two vectors are equal (in size and direction) only in special directions, called *longitudinal directions*.

In inhomogeneous isotropic media, Eq. 28 for the ray-velocity vector yields $\mathbf{U} = V^2 \mathbf{p}$. For the phase-velocity vector, using Eq. 17, we get $\mathbf{C} = V^2 \mathbf{p}$, where $V = \alpha$ for P waves, and $V = \beta$ for S waves. Thus, the ray-velocity and phase-velocity vectors are identical in isotropic media.

Figure 1 shows mutual orientation of ray-velocity vector $\mathbf{U}$, phase-velocity vector $\mathbf{C}$ (parallel to slowness vector $\mathbf{p}$), and polarization vector $\mathbf{g}$ of a P wave propagating in an isotropic (left) and anisotropic (right) medium. While $\mathbf{U}$, $\mathbf{C}$, and $\mathbf{g}$ are parallel in isotropic media, they generally differ in anisotropic media. For S waves, the vectors $\mathbf{U}$ and $\mathbf{C}$ have similar orientation as in the case of P waves. The polarization vectors $\mathbf{g}$ are, however, perpendicular (isotropic medium) or nearly perpendicular (anisotropic medium) to the ray.

Ray tracing systems in Eqs. 26 and 27 can be simply solved if the initial values x_{0i} and p_{0i} are specified at some point S of the ray. We then speak of *initial-value ray tracing*. The standard numerical procedures of solving the system of ordinary differential equations of the first order with specified initial conditions can then be used (for example, Runge-Kutta). A very important role in seismology is played by *boundary-value ray tracing*, in which we seek the ray, satisfying prescribed boundary conditions. The typical boundary value problem is *two-point ray tracing*, in which we seek the ray connecting two specified points. Mostly, the controlled initial-value ray tracing (controlled shooting method) is used to solve this problem (Červený et al. 2007). Boundary-value ray tracing is considerably more complicated than initial-value ray tracing.

There are four important differences between initial value ray tracing in isotropic and anisotropic media. First: In anisotropic media, we deal with three waves, P, S1, and S2, in isotropic media with two waves, P and S, only. Second: In inhomogeneous anisotropic media, ray tracing system, see Eq. 26, is the same for all three waves. The wave under consideration is specified by the initial conditions, which must satisfy the eikonal equation of the considered wave. In isotropic inhomogeneous media, the ray tracing systems are different for P and S waves, see Eq. 27 with $V = \alpha$ and $V = \beta$,

Seismic Ray Theory, Fig. 1 Slowness vector $\mathbf{p}$ (perpendicular to the wavefront), ray-velocity vector $\mathbf{U}$ (tangent to the ray), and polarization vector $\mathbf{g}$ of a P wave propagating in an isotropic (left) and anisotropic (right) medium. For simplicity, the three vectors in the right-hand plot are shown in one plane. In general, this is not the case in anisotropic media

respectively. Third: In isotropic media, the initial direction of the slowness vector specifies directly the initial direction of the ray (as the tangents to the ray and the slowness vector have the same directions). In anisotropic media, the direction of the ray is, generally, different from the direction of the slowness vector. Nevertheless, we have to use p_{0i} as the initial values for the ray tracing system. The ray-velocity vector $\mathbf{U}$ can be simply calculated from slowness vector $\mathbf{p}$ at any point of the ray, including the initial point, however, not vice versa. Fourth: Ray tracing for P and S waves is regular everywhere in inhomogeneous isotropic media. In anisotropic media, problems arise with tracing S-wave rays in vicinities of singular directions, or if medium is nearly isotropic (quasi-isotropic).

The problem of ray tracing and travel-time computation in inhomogeneous media has been broadly discussed in the seismological literature, particularly for inhomogeneous isotropic media. Many ray tracing systems and many suitable numerical procedures for performing ray tracing have been proposed. For 1-D isotropic media (vertically inhomogeneous, radially symmetric), the ray tracing systems may be simplified so that they reduce to simple quadratures, well-known from classical seismological textbooks. For P-wave travel time T and angular distance Δ , they read:

$$T(p) = \int \left(1 - \frac{p^2 \alpha^2}{r^2} \right)^{-1/2} \frac{dr}{\alpha},$$

$$\Delta(p) = \int \frac{p\alpha}{r^2} \left(1 - \frac{p^2 \alpha^2}{r^2} \right)^{-1/2} dr. \quad (29)$$

Here, $\alpha = \alpha(r)$ is the P wave velocity as the function of the radius r , and p is the ray parameter, $p = (r \sin i)/\alpha$, where i is the angle made by the ray and the radius, see Eq. (9.21) of Aki and Richards (2002), where additional details can be found.

Standard programs for ray tracing and travel-time computations in laterally varying isotropic and anisotropic structures are available, see, for example, program packages SEIS (2D isotropic models), CRT, and ANRAY (3D isotropic/anisotropic models) available at <http://sw3d.cz/>. Programs for anisotropic media have, however, problems with S wave computations in weakly anisotropic media and in the vicinities of shear-wave singularities. In such cases, the standard ray theory should be replaced by the coupling ray theory.

Ray tracing may also serve as a basis for the so-called *wavefront construction method* (Gjøystdal et al. 2002). In this case, for a selected wave, wavefronts with travel times $T = T_0 + k\Delta T$ are computed successively from the previous wavefronts with travel times $T = T_0 + (k - 1)\Delta T$. The wavefront construction method has found broad applications in seismic exploration.

Let us consider a two-parametric system of rays, call it the *ray field*, and specify the individual rays in the ray field by *ray parameters* γ_1, γ_2 . Ray parameters γ_1, γ_2 may represent,

e.g., the take-off angles at a point source or the curvilinear Gaussian coordinates of initial ray points along the initial surface. The family of rays with ray parameters within the limit $[\gamma_1, \gamma_1 + d\gamma_1], [\gamma_2, \gamma_2 + d\gamma_2]$, is called the *elementary ray tube* or briefly the ray tube. We further introduce *ray coordinates* $\gamma_1, \gamma_2, \gamma_3$ in such a way that γ_1, γ_2 are ray parameters, and γ_3 is some monotonic parameter along a ray (arclength s , travel time τ , etc.). Here we consider $\gamma_3 = \tau$, but our results may be simply modified for any other monotonic parameter γ_3 . We further introduce the 3×3 transformation matrix $\hat{\mathbf{Q}}$ from ray to Cartesian coordinates with elements $Q_{ij} = \partial x_i / \partial \gamma_j$. The Jacobian of transformation from ray to Cartesian coordinates, $\det \hat{\mathbf{Q}}$, can be expressed as follows:

$$\det \hat{\mathbf{Q}}(\tau) = (\partial \mathbf{x}(\tau) / \partial \gamma_1 \times \partial \mathbf{x}(\tau) / \partial \gamma_2)^T \mathbf{U}(\tau). \quad (30)$$

The vectorial product in Eq. 30 has the direction of the normal to the wavefront, specified by $\mathbf{n} = C \mathbf{p}$. As $\mathbf{p}(\tau) \cdot \mathbf{U}(\tau) = 1$, see Eqs. 10, 15, and 28, we also obtain

$$\det \hat{\mathbf{Q}}(\tau) = \pm C(\tau) |(\partial \mathbf{x}(\tau) / \partial \gamma_1 \times \partial \mathbf{x}(\tau) / \partial \gamma_2)|. \quad (31)$$

Thus the Jacobian $\det \hat{\mathbf{Q}}(\tau)$ equals $\pm C(\tau) d\Omega(\tau)$, where $d\Omega(\tau) = |(\partial \mathbf{x}(\tau) / \partial \gamma_1 \times \partial \mathbf{x}(\tau) / \partial \gamma_2)|$ is the scalar surface element cut out of the wavefront by the ray tube. It measures the expansion or contraction of the ray tube, see Fig. 2. For this reason, the 3×3 matrix $\hat{\mathbf{Q}}(\tau)$ is also often called the *geometrical spreading matrix* and various quantities related to $\det \hat{\mathbf{Q}}(\tau)$ are called *geometrical spreading*. It plays an important role in the computation of the ray-theory amplitudes.

Transport Equation. Computation of Ray-Theory Amplitudes

The second equation of the basic recurrence system of equations of the ray method yields the transport equation for the

Seismic Ray Theory, Fig. 2 Elementary ray tube. $d\Omega_0$ and $d\Omega$ are scalar surface elements cut out of the wavefront by the ray tube. This means that in isotropic media, the normals to $d\Omega_0$ and $d\Omega$ are parallel to rays. In anisotropic media, they are not

scalar ray-theory amplitude $A(x_i)$ specifying the zero-order vectorial amplitude $\mathbf{U}(x_n)$, see Eq. 16. The transport equation is a partial differential equation of the first order. It can be expressed in several forms. One of them, valid for isotropic and anisotropic media, and for any wave, reads

$$\nabla \cdot (\rho A^2 \mathbf{U}) = 0. \quad (32)$$

It is common to solve the transport equation along the ray. $\nabla \cdot \mathbf{U}$ can then be expressed as follows:

$$\nabla \cdot \mathbf{U} = d \left[\ln (\det \hat{\mathbf{Q}}) \right] / d\tau \quad (33)$$

(Červený 2001, Eq. 3.10.24). Inserting Eq. 33 into Eq. 32 yields the transport equation in the form of the first-order ordinary differential equation along the ray:

$$d \left(\rho(\tau) A^2(\tau) \det \hat{\mathbf{Q}}(\tau) \right) / d\tau = 0. \quad (34)$$

This yields a simple form of the continuation relation for $A(\tau)$ along the ray:

$$A(\tau) = \left[\frac{\rho(\tau_0) \det \hat{\mathbf{Q}}(\tau_0)}{\rho(\tau) \det \hat{\mathbf{Q}}(\tau)} \right]^{1/2} A(\tau_0). \quad (35)$$

We obtain another suitable continuation relation for amplitudes along the ray by introducing a special local Cartesian coordinate system y_1, y_2, y_3 , varying along the ray. We call it the *wavefront orthonormal coordinate system*. At any point of the ray specified by $y_3 = \tau$, the y_3 axis is parallel to slowness vector $\mathbf{p}$, and the y_1, y_2 axes are confined to the plane tangential to the wavefront at $y_3 = \tau$. Axes y_1 and y_2 are mutually perpendicular. If we denote the 3×3 transformation matrix from ray coordinates to wavefront orthonormal coordinates by $\hat{\mathbf{Q}}^{(y)}$, then

$$\det \hat{\mathbf{Q}}(\tau) = \det \hat{\mathbf{Q}}^{(y)}(\tau) = C(\tau) \det \mathbf{Q}^{(y)}(\tau). \quad (36)$$

Here $C(\tau)$ is the phase velocity, and $\mathbf{Q}^{(y)}(\tau)$ is the 2×2 upper-left submatrix of $\hat{\mathbf{Q}}^{(y)}(\tau)$. Using Eq. 36 in Eq. 35, we obtain the continuation relation in an alternative form:

$$A(\tau) = \left[\frac{\rho(\tau_0) C(\tau_0) \det \mathbf{Q}^{(y)}(\tau_0)}{\rho(\tau) C(\tau) \det \mathbf{Q}^{(y)}(\tau)} \right]^{1/2} A(\tau_0). \quad (37)$$

An important property of the continuation relation presented in Eq. 37 is that $\det \mathbf{Q}^{(y)}(\tau)$ is uniquely determined by coordinates y_1 and y_2 , confined to the plane tangential to the wavefront at τ . Thus, Eq. 37 remains valid for any coordinate systems q_i (even nonorthogonal), in which the coordinate axes q_1 and q_2 are orthogonal in the plane tangential to the

wavefront, but the axis q_3 is taken in a different way than y_3 , for example, along the ray. This is, e.g., the case of the well-known *ray-centered coordinate system* q_1, q_2, q_3 . We have $\det \mathbf{Q}^{(q)}(\tau) = \det \mathbf{Q}^{(y)}(\tau)$, where $\mathbf{Q}^{(q)}$ is the 2×2 transformation matrix from ray (y_1, y_2) to ray-centered (q_1, q_2) coordinates.

Transport equations for P and S waves in isotropic media may be also expressed in the form of Eq. 32. The expression is straightforward for P waves. For S waves, transport equations for scalar amplitudes B and C in Eq. 20 are generally coupled. They decouple only if the unit vectors $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ in Eq. 20 satisfy the following relation along the ray:

$$d\mathbf{g}^{(M)} / d\tau = (\mathbf{g}^{(M)} \cdot \nabla \beta) \mathbf{n}, \quad M = 1, 2. \quad (38)$$

In the terminology of the Riemannian geometry, vector $\mathbf{g}^{(M)}$ satisfying Eq. 38 is transported parallelly along the ray. If $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ are chosen as mutually perpendicular and perpendicular to $\mathbf{n}$ at one point of the ray, Eq. 38 guarantees that they have these properties at any point of the ray. Consequently, $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ are always perpendicular to the ray and do not rotate around it as the S wave progresses. As $\mathbf{g}^{(1)}$, $\mathbf{g}^{(2)}$, and $\mathbf{n}$ are always orthonormal, and $\mathbf{n}$ is known at any point of the ray, it is not necessary to use Eq. 38 to compute both vectors $\mathbf{g}^{(M)}$. One of them can be determined from the orthonormality condition, once the other has been computed using Eq. 38.

Quantity $\det \hat{\mathbf{Q}}(\tau)$ in Eq. 35 may become zero at some point $\tau = \tau^C$. This means that the cross-sectional area of the ray tube shrinks to zero at $\tau = \tau^C$. The relevant point $\tau = \tau^C$ of the ray is called the *caustic point*. At the caustic point, the ray solution is singular and yields an infinite amplitude there. In passing through the caustic point τ^C along the ray, the argument of $[\det \hat{\mathbf{Q}}(\tau)]^{1/2}$ may change by $\pm\pi/2$ or $\pm\pi$ (Kravtsov and Orlov 1999). The former case corresponds to the caustic point of the first order, see Fig. 3a, during which the ray tube shrinks to an elementary arc, the latter case corresponds to the caustic point of the second order, see Fig. 3b, during which the ray tube shrinks to a point. If the caustic point τ^C is situated between τ_0 and τ , it is common to introduce the *phase shift* $T^C(\tau, \tau_0)$ due to caustic using the relation:

$$\left[\frac{\det \hat{\mathbf{Q}}(\tau_0)}{\det \hat{\mathbf{Q}}(\tau)} \right]^{1/2} = \left| \frac{\det \hat{\mathbf{Q}}(\tau_0)}{\det \hat{\mathbf{Q}}(\tau)} \right|^{1/2} \exp [iT^C(\tau, \tau_0)]. \quad (39)$$

The phase shift due to the caustic is cumulative. If the ray passes through several caustic points along the ray between τ_0 and τ , the phase shift due to caustics is the sum of the individual phase shifts. For the choice of the exponential factor $\exp(-i\omega t)$ in Eq. 4, it has the form $T^C(\tau, \tau_0) = -\frac{1}{2}\pi k(\tau, \tau_0)$, where $k(\tau, \tau_0)$ is an integer, called the KMAH index (to acknowledge the work by Keller, Maslov, Arnold and Hörmander in this field). The continuation relation for ray-theory amplitudes given in Eq. 35 can then be modified to read:

Seismic Ray Theory,**Fig. 3** Caustic points of (a) the first order and (b) second order (Fig. 3.13 of Červený 2001)

$$A(\tau) = \left[\frac{\rho(\tau_0) |\det \hat{\mathbf{Q}}(\tau_0)|}{\rho(\tau) |\det \hat{\mathbf{Q}}(\tau)|} \right]^{1/2} \exp [iT^C(\tau, \tau_0)] A(\tau_0). \quad (40)$$

Equation 37 can be transformed to the form analogous to Eq. 40 as the zeros of $\det \hat{\mathbf{Q}}^{(v)}(\tau)$ are situated at the same points τ^C on the ray as the zeros of $\det \hat{\mathbf{Q}}(\tau)$.

The KMAH index can be calculated along the ray as a byproduct of dynamic ray tracing. For detailed derivations and discussion see Bakker (1998) and Klimeš (2010).

There are some differences between the KMAH indices along the rays in isotropic and anisotropic media. In isotropic media, the KMAH index always increases when the ray passes through a new caustic point, either by one or two. In anisotropic media, however, it may also decrease by one or two at some caustic points. This happens only for S waves as a consequence of the concave form of the slowness surface of the corresponding S wave.

Alternative expressions for ray-theory amplitudes and their mutual relations can be found in Klimeš (2019).

Dynamic Ray Tracing. Paraxial Approximations

As we can see in Eq. 35, the computation of the ray-theory amplitudes requires knowledge of $\det \hat{\mathbf{Q}}$, where $\hat{\mathbf{Q}}(\tau)$ characterizes the properties of the ray field in the vicinity of the ray under consideration. $\hat{\mathbf{Q}}(\tau)$ can be computed by the procedure called *dynamic* (or *paraxial*) *ray tracing*. In addition to $\hat{\mathbf{Q}}(\tau)$

with elements $Q_{ij}(\tau) = \partial x_i / \partial \gamma_j$, we also have to introduce a new 3×3 matrix $\hat{\mathbf{P}}(\tau)$ with elements $P_{ij}(\tau) = \partial p_i / \partial \gamma_j$. The equation for P_{ij} must be included to obtain the linear dynamic ray tracing system. Differentiating ray tracing system shown in Eq. 25 with respect to γ_j , we can easily obtain a system of linear ordinary differential equations of the first order for Q_{ij} and P_{ij} ,

$$\begin{aligned} \frac{dQ_{ij}}{d\tau} &= \frac{\partial^2 \mathcal{H}}{\partial p_i \partial x_k} Q_{kj} + \frac{\partial^2 \mathcal{H}}{\partial p_i \partial p_k} P_{kj}, \\ \frac{dP_{ij}}{d\tau} &= -\frac{\partial^2 \mathcal{H}}{\partial x_i \partial x_k} Q_{kj} - \frac{\partial^2 \mathcal{H}}{\partial x_i \partial p_k} P_{kj}, \end{aligned} \quad (41)$$

see Červený (1972). This system is usually called the *dynamic ray tracing system*, and the relevant procedure dynamic ray tracing. It can be solved along a given ray Ω , or together with ray tracing system, see Eq. 25.

The dynamic ray tracing system shown in Eq. 41 may be expressed in various forms. Instead of Cartesian coordinates x_i , we can use the wavefront orthonormal coordinates y_i , or the ray-centered coordinates q_i . Then, instead of the 3×3 matrices $\hat{\mathbf{Q}}$ and $\hat{\mathbf{P}}$, it is sufficient to seek the 2×2 matrices $\mathbf{Q}^{(v)}$, $\mathbf{P}^{(v)}$, or $\mathbf{Q}^{(q)}$, $\mathbf{P}^{(q)}$. This reduces the number of DRT equations, but complicates their right-hand sides (Červený 2001, Sect. 4.2).

As the dynamic ray tracing system presented in Eq. 41 is of the first order and linear, we can compute its fundamental matrix consisting of six linearly independent solutions. The 6×6 fundamental matrix of the dynamic ray tracing system in Eq. 41, specified by the 6×6 identity matrix at an arbitrary

point $\tau = \tau_0$ of the ray is called the *ray propagator matrix* and denoted by $\mathbf{\Pi}(\tau, \tau_0)$.

The 6×6 ray propagator matrix $\mathbf{\Pi}(\tau, \tau_0)$ is symplectic:

$$\mathbf{\Pi}^T(\tau, \tau_0) \mathbf{J} \mathbf{\Pi}(\tau, \tau_0) = \mathbf{J}, \quad \text{with} \quad \mathbf{J} = \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{I} & \mathbf{0} \end{pmatrix}. \quad (42)$$

If we know the matrices $\hat{\mathbf{Q}}(\tau_0)$, $\hat{\mathbf{P}}(\tau_0)$, we can compute $\hat{\mathbf{Q}}(\tau)$, $\hat{\mathbf{P}}(\tau)$ at any point τ of the ray by a simple matrix multiplication

$$\begin{pmatrix} \hat{\mathbf{Q}}(\tau) \\ \hat{\mathbf{P}}(\tau) \end{pmatrix} = \mathbf{\Pi}(\tau, \tau_0) \begin{pmatrix} \hat{\mathbf{Q}}(\tau_0) \\ \hat{\mathbf{P}}(\tau_0) \end{pmatrix}. \quad (43)$$

The ray propagator matrix $\mathbf{\Pi}(\tau, \tau_0)$ satisfies the chain rule, $\mathbf{\Pi}(\tau, \tau_0) = \mathbf{\Pi}(\tau, \tau_1) \mathbf{\Pi}(\tau_1, \tau_0)$, where point τ_1 is situated arbitrarily on the ray. It is simple to compute the inverse of $\mathbf{\Pi}(\tau, \tau_0)$: $\mathbf{\Pi}^{-1}(\tau, \tau_0) = \mathbf{\Pi}(\tau_0, \tau)$. We can express $\mathbf{\Pi}(\tau, \tau_0)$ in the following way:

$$\mathbf{\Pi}(\tau, \tau_0) = \begin{pmatrix} \hat{\mathbf{Q}}_1(\tau, \tau_0) & \hat{\mathbf{Q}}_2(\tau, \tau_0) \\ \hat{\mathbf{P}}_1(\tau, \tau_0) & \hat{\mathbf{P}}_2(\tau, \tau_0) \end{pmatrix}, \quad (44)$$

where $\hat{\mathbf{Q}}_1(\tau, \tau_0)$, $\hat{\mathbf{Q}}_2(\tau, \tau_0)$, $\hat{\mathbf{P}}_1(\tau, \tau_0)$, and $\hat{\mathbf{P}}_2(\tau, \tau_0)$ are 3×3 matrices.

Equation 43 can be used to obtain a very important quantity – the 3×3 matrix $\hat{\mathbf{M}}(\tau)$ of second derivatives of the travel-time field with respect to Cartesian coordinates, with elements $M_{ij} = \partial^2 T / \partial x_i \partial x_j$:

$$\hat{\mathbf{M}}(\tau) = \hat{\mathbf{P}}(\tau) (\hat{\mathbf{Q}}(\tau))^{-1}. \quad (45)$$

Matrix $\hat{\mathbf{M}}(\tau)$ plays an important role in the computation of travel time not only along the ray Ω but also in its “quadratic” paraxial vicinity:

$$T(\mathbf{x}) = T(\mathbf{x}^\Omega) + (\mathbf{x} - \mathbf{x}^\Omega)^T \mathbf{p}(\tau) + \frac{1}{2} (\mathbf{x} - \mathbf{x}^\Omega)^T \hat{\mathbf{M}}(\tau) (\mathbf{x} - \mathbf{x}^\Omega). \quad (46)$$

In Eq. 46, $\mathbf{x}$ denotes an arbitrary point in the paraxial vicinity of the ray Ω , close to point $\mathbf{x}^\Omega = \mathbf{x}^\Omega(\tau)$ on the ray Ω ; slowness vector $\mathbf{p}(\tau)$ and the matrix $\hat{\mathbf{M}}(\tau)$ are given at $\mathbf{x}^\Omega$. The possibility of computing the travel time in the paraxial vicinity of the ray has many important applications.

The properties of the 6×6 ray propagator matrix $\mathbf{\Pi}(\tau, \tau_0)$ described above are also valid for the 4×4 ray propagator matrices $\mathbf{\Pi}^{(v)}(\tau, \tau_0)$ or $\mathbf{\Pi}^{(q)}(\tau, \tau_0)$ expressed in wavefront orthonormal coordinates y_i or ray-centered coordinates q_i . The ray propagator matrices $\mathbf{\Pi}^{(v)}(\tau, \tau_0)$ and $\mathbf{\Pi}^{(q)}(\tau, \tau_0)$

are identical, therefore, they can be expressed in terms of the same 2×2 matrices $\mathbf{Q}_1(\tau, \tau_0)$, $\mathbf{Q}_2(\tau, \tau_0)$, $\mathbf{P}_1(\tau, \tau_0)$, and $\mathbf{P}_2(\tau, \tau_0)$. Matrices $\mathbf{Q}_1(\tau, \tau_0)$, $\mathbf{P}_1(\tau, \tau_0)$ correspond to the plane-wavefront initial conditions at τ_0 , and matrices $\mathbf{Q}_2(\tau, \tau_0)$, $\mathbf{P}_2(\tau, \tau_0)$ to the point-source initial conditions at τ_0 , see Fig. 4. The 2×2 matrix $\mathbf{Q}_2(\tau, \tau_0)$ plays an important role in computing the ray-theory Green function. The quantity

$$\mathcal{L}(\tau, \tau_0) = |\det \mathbf{Q}_2(\tau, \tau_0)|^{1/2} \quad (47)$$

is called the *relative geometrical spreading*.

As in Eq. 45, we can define the 2×2 matrix of the second derivatives of the travel-time field with respect to y_1, y_2 or q_1, q_2 as follows:

$$\mathbf{M}(\tau) = \mathbf{P}(\tau) (\mathbf{Q}(\tau))^{-1}. \quad (48)$$

Let us briefly summarize several useful ray-theory quantities and applications, which rely fully or partly on dynamic ray tracing. For derivations and more detailed explanations, see Červený (2001, Chap. 4), where also many other applications and references can be found: (1) Paraxial travel times. (2) Paraxial slowness vectors. (3) Paraxial rays. (4) Curvature of the wavefront. (5) Matrix of geometrical spreading $\hat{\mathbf{Q}}$ and the relevant matrix $\hat{\mathbf{P}}$. (6) Continuation relations for ray-theory amplitudes along the ray. (7) Relative geometrical spreading. (8) Phase shift due to caustics. (9) Ray-theory elastodynamic Green function. (10) Higher-order spatial derivatives of the travel-time field. (11) Fresnel volumes and Fresnel zones. (12) Surface-to-surface propagator matrix. (13) Boundary-value problems in four-parametric system of paraxial rays, including two-point ray tracing. (14) Factorization of the geometrical spreading.

Dynamic ray tracing is also required in the computation of the two-point paraxial travel times in inhomogeneous, isotropic or anisotropic media (bin Waheed et al. 2013). This approach offers an efficient way of the determination of travel times between sources and receivers situated close to a known

Seismic Ray Theory, Fig. 4 Plane-wavefront and point-source initial conditions for dynamic ray tracing. In anisotropic media, rays are not perpendicular to the wavefront

reference ray and specified in Cartesian coordinates. Dynamic ray tracing is also needed in the investigation of chaotic rays and in computations of Lyapunov exponents (Červený et al. 2007), in ray perturbation methods and in modifications and extensions of the ray method such as coupling ray method, Maslov method, Gaussian beam and Gaussian packet summation methods, in Kirchhoff-Helmholtz method, and in various diffraction problems.

Coupling Ray Theory for S Waves in Anisotropic Media

In inhomogeneous weakly anisotropic media, the standard ray theory described above yields distorted results since it is unable to describe the coupling of S1 and S2 waves propagating with approximately equal phase velocities. This problem can be removed by using the coupling ray theory. In the coupling ray theory, the amplitudes of the two S waves can be computed along a trajectory called the *common ray* (Bakker 2002; Klimeš 2006). The closer the common ray approximates actual S wave rays, the more accurate results the coupling ray theory yields. The common rays can be constructed in a reference isotropic medium or in the actual anisotropic medium. A convenient option is to compute common rays using ray-tracing equations given in Eq. 25 with the Hamiltonian given as

$$\mathcal{H}(x_i, p_j) = \frac{1}{4} [G_1(x_i, p_j) + G_2(x_i, p_j)]. \quad (49)$$

In Eq. 49, G_1 and G_2 are eigenvalues of the generalized Christoffel matrix given in Eq. 7, corresponding to S1 and S2 waves.

The coupling ray theory solution is sought in the form (Coates and Chapman 1990; Bulant and Klimeš 2002):

$$\mathbf{u}(\tau, t) = A(\tau) \left[r_1(\tau) \mathbf{g}^{(1)}(\tau) \exp(i\omega\tau_1) + r_2(\tau) \mathbf{g}^{(2)}(\tau) \exp(i\omega\tau_2) \right] \exp(-i\omega t). \quad (50)$$

Here, $A(\tau)$ is the scalar amplitude given in Eqs. 35 or 37 calculated along the common ray. The symbols $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ denote the S wave eigenvectors of the generalized Christoffel matrix $\Gamma(x_i, p_j)$ calculated along the common ray. The travel times τ_1 and τ_2 are travel times corresponding to the above vectors $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$. They can be obtained by quadratures along the common ray:

$$d\tau_1/d\tau = \left[\Gamma_{ik} g_i^{(1)} g_k^{(1)} \right]^{-1/2}, \quad d\tau_2/d\tau = \left[\Gamma_{ik} g_i^{(2)} g_k^{(2)} \right]^{-1/2}. \quad (51)$$

The amplitude factors r_1 and r_2 are solutions of two coupled ordinary differential equations (Coates and Chapman 1990):

$$\begin{pmatrix} dr_1/d\tau \\ dr_2/d\tau \end{pmatrix} = \begin{pmatrix} 0 & \exp(i\omega[\tau_2(\tau) - \tau_1(\tau)]) \\ -\exp(i\omega[\tau_1(\tau) - \tau_2(\tau)]) & 0 \end{pmatrix} \begin{pmatrix} r_1 \\ r_2 \end{pmatrix}, \quad (52)$$

where the angular velocity $d\varphi/d\tau$ of the rotation of the eigenvectors $\mathbf{g}^{(1)}$ and $\mathbf{g}^{(2)}$ is given by

$$\frac{d\varphi}{d\tau} = \mathbf{g}^{(2)} \frac{d\mathbf{g}^{(1)}}{d\tau} = -\mathbf{g}^{(1)} \frac{d\mathbf{g}^{(2)}}{d\tau}. \quad (53)$$

For detailed description of the algorithm, see Bulant and Klimeš (2002), for its generalization to the prevailing-frequency approximation of the coupling ray theory, which is effectively independent of frequency, see Klimeš and Bulant (2016). It allows to treat the coupling ray-theory results as standard ray-theory results because it avoids repeated calculations for varying frequencies.

There are many possible modifications and approximations of the coupling ray theory. In some of them, the amplitude vector $\mathbf{U}$ of coupled S waves is sought along the common ray in the form presented in Eq. 20, in which the amplitude factors B and C can be expressed as

$$B(\tau) = A(\tau) \mathcal{B}(\tau) \quad C(\tau) = A(\tau) \mathcal{C}(\tau). \quad (54)$$

In Eq. 54, $A(\tau)$ is again the scalar ray amplitude given in Eqs. 35 or 37 calculated along the common S-wave ray. There are many ways how to evaluate factors $\mathcal{B}$ and $\mathcal{C}$ (Kravtsov 1968; Červený et al. 2007). Here we present a combination of coupling ray theory and of the first-order ray tracing (Farra and Pšenčík 2010, see also section on “[Ray Perturbation Methods](#)”). In the approximation of Farra and Pšenčík (2010), the common ray is obtained as the first-order ray, see section on “[Ray Perturbation Methods](#)”. The vectors $\mathbf{g}^{(K)}$, appearing in Eq. 20, specify the first-order approximation of the S wave polarization plane. The factors $\mathcal{B}$ and $\mathcal{C}$ in Eq. 54 are then obtained as a solution of two coupled ordinary differential equations, which result from the corresponding two coupled transport equations:

$$\begin{pmatrix} d\mathcal{B}/d\tau \\ d\mathcal{C}/d\tau \end{pmatrix} = -\frac{i\omega}{2} \begin{pmatrix} \mathcal{M}_{11} - 1 & \mathcal{M}_{12} \\ \mathcal{M}_{12} & \mathcal{M}_{22} - 1 \end{pmatrix} \begin{pmatrix} \mathcal{B} \\ \mathcal{C} \end{pmatrix}. \quad (55)$$

Evaluation of the matrix $\mathcal{M}$ with elements $\mathcal{M}_{IJ}$ is simple, see Eqs. 7 and 20 of Farra and Pšenčík (2010).

The resulting equations reduce to standard ray-theory equations in inhomogeneous isotropic media, they describe properly S wave coupling in inhomogeneous weakly anisotropic media and even yield separate S waves when anisotropy is stronger. Common S wave rays are regular

everywhere. They do not suffer from problems well known from tracing rays of individual S waves in anisotropic media and are suitable for investigating shear-wave splitting, see Pšenčík et al. (2012).

Effects of Structural Interfaces

Assume that the ray is incident on a curved structural interface. If we wish to continue the ray computations for the reflected, transmitted, monotypic, or converted waves, see Fig. 5, we have to use relevant transformation relations for the ray tracing system, dynamic ray tracing system, and for the ray theory amplitudes at the interface.

The transformation relations for ray tracing and dynamic ray tracing systems at interfaces are well known (Červený 2001). For the sake of brevity, we do not present them here. We shall, however, discuss the transformation of amplitudes. In the zero-order ray approximation, the transformation of ray-theory amplitudes across an interface is described by plane-wave reflection/transmission coefficients. In other words, amplitudes of generated waves do not depend on the curvature of the wavefront of the incident wave and the curvature of the interface at the point of incidence Q . Neither do they depend on the gradients of the density and on gradients of the density-normalized elastic moduli at Q , on both sides of the interface. They depend only on the local values of the density and density-normalized elastic moduli at Q (on both sides of the interface) and on the angle of incidence (the acute angle between the slowness vector of the incident wave and the normal $\mathbf{N}$ to the interface at the point of incidence Q).

Seismic Ray Theory, Fig. 5 Slowness vectors of P, S1, and S2 waves generated at the point of incidence Q of a curved interface separating two inhomogeneous anisotropic media. All slowness vectors at Q are situated in the plane of incidence specified by the slowness vector of the incident wave and the normal to the interface $\mathbf{N}$ at Q . Ray-velocity vectors (tangent to rays) of individual waves at Q are, in general, not confined to the plane of incidence. In isotropic media, instead of reflected and transmitted S1 and S2 waves, single reflected and transmitted S waves are generated. Ray-velocity vectors of individual waves at Q are situated in the plane of incidence

Various types of R/T coefficients may be used. The displacement R/T coefficients are used most frequently (Aki and Richards 2002; Červený et al. 1977 for isotropic media; Fedorov 1968 for anisotropic media). Very useful are the energy R/T coefficients, as they are reciprocal. The relation between the energy R/T coefficient $\mathcal{R}(Q)$ and the displacement R/T coefficient $R(Q)$ is as follows:

$$\mathcal{R}(Q) = R(Q) \left[\frac{\rho(\tilde{Q}) u_n(\tilde{Q})}{\rho(Q) u_n(Q)} \right]^{1/2} \quad (56)$$

(Červený 2001, Sect. 5.4.3). Here Q is the point of incidence, and $\tilde{Q}$ the relevant initial point of the R/T wave, both points being, of course, identical. u_n is the normal component (perpendicular to the interface) of the ray-velocity vector. We further introduce the complete energy R/T coefficients $\mathcal{R}^C$ along the ray using the relation

$$\mathcal{R}^C = \prod_{k=1}^N \mathcal{R}(Q_k). \quad (57)$$

The complete energy R/T coefficient $\mathcal{R}^C$ corresponds to the ray, which interacts N -times with interfaces (at points of incidence $Q_1, Q_2, \dots, Q_N$) between the initial and end point of the ray.

Generalization of the continuation relation presented in Eq. 37 for the ray-theory amplitudes along the ray situated in a laterally varying anisotropic medium containing curved interfaces then reads:

$$A(\tau) = \left[\frac{\rho(\tau_0) C(\tau_0) |\det \mathbf{Q}^{(y)}(\tau_0)|}{\rho(\tau) C(\tau) |\det \mathbf{Q}^{(y)}(\tau)|} \right]^{1/2} \times \mathcal{R}^C \exp [i\Gamma^C(\tau, \tau_0)] A(\tau_0). \quad (58)$$

In seismic prospecting, in the technique called *amplitude variation with offset* (AVO), it is common to work with the so-called *weak-contrast R/T coefficients*. They are linearized versions of exact R/T displacement coefficients. Linearization is mostly made with respect to the contrasts of the density and elastic moduli across the interface, often also under the assumption of weak anisotropy. There is a great variety of linearized formulae depending on the type of media surrounding the interface (isotropic, anisotropic), strength of anisotropy (weak, strong), etc. The coefficients yield reasonable approximation in the vicinity of normal incidence. For increasing incidence angles, their accuracy decreases. The advantage of the weak-contrast coefficients is their simplicity and the possibility of expressing them in explicit form. The effects of the individual medium parameters on the coefficients can then be easily evaluated.

Ray-Theory Elastodynamic Green Function

The elastodynamic Green function $G_{in}(R, t, S, t_0)$ represents the i -th Cartesian component of the displacement vector at location R and time t , due to a single-force point source situated at location S and oriented along the n -th Cartesian axis, with the time dependence $\delta(t - t_0)$. We introduce quite analogously the ray-theory elastodynamic Green function, with only two differences. The first difference is that ray-theory Green function is defined as a sum of *elementary ray-theory Green functions* computed along rays of selected elementary waves (direct, multiply reflected/transmitted, etc.). The second difference is that the elementary ray-theory Green functions are not exact, but only zero-order ray approximations.

In the frequency domain, the elementary ray-theory elastodynamic Green function $G_{in}(R, S, \omega)$ for $t_0 = 0$ reads:

$$G_{in}(R, S, \omega) = \frac{g_n(S)g_i(R) \exp [iT^C(R, S) + i\omega T(R, S)]}{4\pi[\rho(S)\rho(R)C(S)C(R)]^{1/2}\mathcal{L}(R, S)} \mathcal{R}^C. \quad (59)$$

Here $\mathcal{L}(R, S)$ is the relative geometrical spreading, given in Eq. 47, $g_i(R)$ and $g_n(S)$ are the eigenvectors of the generalized Christoffel matrix at R and S (polarization vectors corresponding to the considered elementary wave), $T(R, S)$ is the travel time along the ray from S to R , $\mathcal{R}^C$ is the complete energy R/T coefficient resulting from interactions of the wave under consideration with interfaces between S and R , and $T^C(R, S)$ is the complete phase shift due to caustics along the ray between S and R . The relevant KMAH index in anisotropic media may also include a contribution at a point source S (if the slowness surface of the considered wave is concave at S). In isotropic media, this contribution is always zero.

The complete energy R/T coefficient $\mathcal{R}^C$, the travel time $T(R, S)$, the relative geometrical spreading $\mathcal{L}(R, S)$, and the complete phase shift due to caustics are always reciprocal. Consequently, the elementary ray-theory elastodynamic Green function satisfies a very important property of reciprocity:

$$G_{in}(R, S, \omega) = G_{ni}(S, R, \omega). \quad (60)$$

This relation is valid for any elementary seismic body wave generated by a point source.

Chaotic Rays. Lyapunov Exponents

In homogeneous media, geometrical spreading increases linearly with increasing length of the ray. In heterogeneous

media, behavior of geometrical spreading is more complicated and depends considerably on the degree of heterogeneity of the medium. In models, in which the heterogeneity exceeds certain degree, average geometrical spreading increases exponentially with increasing length of the ray. Rays in such a medium often exhibit chaotic behavior, which is characterized by a strong sensitivity of rays to the initial values (for example, to ray parameters). The rays with only slightly differing specification of their initial values tend to diverge *exponentially* at large distances from the initial point. Consequently, the rays intersect many times and many rays pass through the same point. With such *chaotic rays*, two-point ray tracing is practically impossible, and the ray tubes are not narrow enough for travel time interpolation. The chaotic behavior of rays increases with increasing length of rays and prevents applicability of the ray theory.

The exponential divergence of chaotic rays in the phase space (the space formed by spatial coordinates x_i and slowness-vector components p_j) can be quantified by the so-called *Lyapunov exponents*. They may be introduced in several ways. It is common to express them in terms of characteristic values of the ray propagator matrix. The relevant expressions for the Lyapunov exponents and several numerical examples for 2D models without interfaces can be found in Klimeš (2002a). See also Červený et al. (2007), where other references can be found.

The estimate of the Lyapunov exponent of a single finite ray depends on its position and direction. The Lyapunov exponents associated with rays of different positions and directions can be used to calculate *average Lyapunov exponents* for the model. The average Lyapunov exponents play a very important role in smoothing the models to make them suitable for ray tracing (Červený et al. 2007).

Ray Perturbation Methods

Ray perturbation methods represent an important part of the ray theory. They can be used for approximate but fast and transparent solutions of forward problems in complicated models. They play even more important role in the inverse problems.

Ray perturbation methods are useful everywhere, where we wish to compute the wavefield or its constituents (travel times, amplitudes, and polarization) in complicated models, which deviate only little from *reference models*, for which computations are simpler. The solutions for complicated models are then sought as perturbations of simple solutions for the reference models. Examples are computations in weakly anisotropic media, which use an isotropic medium as a reference, or in weakly dissipative media, which use a perfectly elastic medium as a reference. Basic role in these approaches is played by *reference rays* traced in reference

media. Solutions in perturbed media can be given in the form of a power series in the deviations of the perturbed and reference models. Mostly, the *first-order approximation*, i.e., the first term of the power series, is used.

The most frequent application of ray perturbation methods is in travel-time computations. First-order travel-time perturbation formulae for isotropic media are known and have been used (mostly in tomography) for several decades. Well known and broadly applied are also first-order travel-time formulae for anisotropic media (Hanyga 1982; Červený 2001, Sect. 3.9). Travel-time perturbations are obtained by quadratures along reference rays. As integration parameters, the parameters along reference rays are used.

Another application of the perturbation method to the computation of travel times is the use of the so-called weak-anisotropy approximation to evaluate approximately reflection moveout. Reflection moveout is commonly calculated as a Taylor series expansion of the squared reflection travel time (for example, Tsvankin and Grechka 2011), which loses rapidly accuracy with increasing offset. Weak-anisotropy approximation of the moveout formulae is free of this limitation. The moveout formulae are available for unconverted or converted waves, for horizontal or dipping reflectors, for anisotropy of arbitrary symmetry. For example, formula for P wave reflection moveout in a homogeneous layer of tilted orthorhombic symmetry can be found in Farra and Pšenčík (2017).

Several procedures for computation of higher-order travel-time perturbations for weakly anisotropic media (note that anisotropy of the Earth is mostly weak) also exist. The procedure based on the so-called perturbation Hamiltonians (Klimeš 2002b; Červený et al. 2007) allows computation of highly accurate travel times along a fixed reference ray in a reference medium. Another procedure is based on the so-called first-order ray tracing described briefly below. In the latter method, second-order travel-time perturbations can be calculated along first-order rays.

Perturbation methods are also used in *first-order ray tracing* and *first-order dynamic ray tracing* for P and S waves in inhomogeneous, weakly anisotropic media (Pšenčík and Farra 2007; Farra and Pšenčík 2010). They allow to compute, approximately, not only rays and travel times but whole wavefields. To derive first-order ray tracing and dynamic ray tracing, the perturbation approach is used, in which deviations of anisotropy from isotropy are considered to be small. Then it is just sufficient to use Eqs. 25 and 41 with Eqs. 21 or 49, in which the exact eigenvalues G_m are replaced by their first-order approximations. The resulting ray tracing provides first-order rays, first-order travel times, and the first-order geometrical spreading. By simple quadratures along first-order rays, second-order travel-time corrections can be computed. This approach is applicable to P and S waves. In case of S waves, it can include the computation of coupling effects. First-order ray tracing and dynamic ray tracing are used in this

case for computing common S wave rays, first-order travel times and geometrical spreading along them. The wavefield of S waves is obtained by solving second-order coupling equations along the S wave common rays. The procedure yields standard ray-theory results for S waves propagating in isotropic media, and approximate results in anisotropic media when the S waves are coupled or even decoupled.

Ray Perturbation Method for Weakly Dissipative Media

Study of wave propagation in dissipative media can be often simplified by the use of the *correspondence principle* (Borchardt 2009; Carcione 2014). When applicable, it allows to obtain solutions for viscoelastic waves from solutions for elastic waves by replacing real-valued elastic parameters by their complex-valued, frequency-dependent counterparts. The density-normalized stiffness tensor $a_{ijkl}(x, \omega)$ then reads:

$$a_{ijkl} = a_{ijkl}^R - i a_{ijkl}^I. \quad (61)$$

If a_{ijkl}^I is small, the dissipative medium can be considered as a perturbation of an elastic medium (Gajewski and Pšenčík 1992; Červený 2001, Sect. 5.5.3), which has a form of the imaginary-valued term $-i a_{ijkl}^I$. Reference ray in the reference elastic medium and corresponding real-valued travel time T along the reference ray between points S and R can be obtained by standard ray tracing in the elastic medium. The travel-time perturbation ΔT (the perturbation due to the perturbation of the reference elastic medium $-i a_{ijkl}^I$), responsible for the exponential amplitude decay along the reference ray, can be obtained by quadratures along this ray:

$$\Delta T = \frac{i}{2} \int_S^R Q^{-1}(\tau) d\tau. \quad (62)$$

The quantity Q in Eq. 62 is a direction-dependent *quality factor* for anisotropic media, corresponding to the Hamiltonian given in Eq. 21:

$$Q^{-1} = a_{ijkl}^I p_j p_l g_i g_k. \quad (63)$$

For general Hamiltonians, the quality factor Q is given by the relation $Q^{-1} = -\text{Im} \mathcal{H}(x_i, p_j)$.

For causal dissipation, the stiffness tensor given in Eq. 61 is frequency dependent. The above-described perturbation approach is then equivalent to the perturbation scheme, in which $a_{ijkl}^I(x_m, \omega)$ is considered to be of the order of ω^{-1} for $\omega \rightarrow \infty$ (Kravtsov and Orlov 1990; Gajewski and Pšenčík 1992).

In an inhomogeneous isotropic, weakly dissipative medium, the expression shown in Eq. 63 reduces to the well-known formula

$$Q^{-1} = -\text{Im}V^2 / \text{Re} V^2 \doteq -2\text{Im}V / \text{Re} V, \quad (64)$$

in which V is the complex-valued velocity, $V = \alpha$ for P waves and $V = \beta$ for S waves. Complex-valued quantities α and β are generalizations (to the complex space) of real-valued α and β from Eq. 14.

The perturbation method described above uses the real ray tracing in a reference elastic medium. Vavryčuk (2012) shows that more accurate results are obtained by the procedure, which he calls the real viscoelastic ray tracing. Vavryčuk (2012) illustrates it on examples of isotropic dissipative media. Klimeš and Klimeš (2011) extend Vavryčuk's (2012) work to anisotropic dissipative media. They construct the reference Hamiltonian function using the Hamiltonian function corresponding to a given complex-valued eikonal equation. They show that the reference Hamiltonians can be constructed in various ways leading to travel time perturbations of varying accuracy.

Continuing attention is devoted to the study of effects of attenuation on reflection/transmission coefficients (Krebes and Daley 2007; Borchardt 2009; Ursin et al. 2017). There are still some open questions, mostly concerning the applicability of the correspondence principle to the reflection/transmission coefficients of overcritically reflected waves.

Concluding Remarks. Applications, Modifications, and Extensions of the Ray Method

Seismic ray method has found many applications both in global seismology and in seismic exploration. The advantages of the seismic ray method consist in its numerical efficiency, universality, conceptual clarity, and in its ability to treat various seismic body waves independently of other waves. Although its accuracy is only limited, the seismic ray method is the only method which is able to give an approximate answer to many problems of high-frequency seismic body wave propagation in laterally varying, isotropic or anisotropic, perfectly elastic or dissipative, layered and block structures.

In classical global seismology, the seismic ray method has been traditionally used to study the internal structure of the whole Earth, assuming that the Earth is radially symmetric. The standard Earth's model, obtained in this way, is expressed in terms of distribution of elastic parameters varying with depth.

At present, the applications of the seismic ray method are considerably broader. It is used to study the 3-D local laterally inhomogeneous structures, their anisotropy and attenuation,

and the form and physical properties of structural interfaces. In addition to forward modelling, the ray perturbation methods are also broadly used in inversions using observed travel times or whole waveforms. In lithospheric structural studies, particularly in crustal seismology, the ray-synthetic seismograms have been also often used for ultimate comparison with observed seismograms. The computation of ray-synthetic seismograms requires determination of not only travel times but also ray-theory amplitudes and polarizations of individual waves. Seismic ray method has also found applications in other branches of seismology. Important examples are the localization of seismic sources either in a known structure or simultaneously with structural inversion.

In most applications of the ray method in seismic exploration for oil, the use of local 3-D structures with structural curved interfaces is a necessity. Sophisticated algorithms have been developed and used to image the structures under consideration. At present, the most important role is played by migration algorithms. Seismic ray theory and its extensions have found important applications in these algorithms.

The ray method is not valid universally. We have briefly described three serious limitations of the ray method: (a) The ray method can be used only for high-frequency signals. (b) In models, in which heterogeneity of the medium exceeds certain degree, the ray field has chaotic character, particularly at large distances from the source. (c) The standard ray method cannot be used for computing S waves propagating in inhomogeneous, weakly anisotropic media. It must be replaced by the coupling ray theory. The coupling ray theory must be used in the vicinity of shear-wave singular directions.

The ray method fails, however, even in other singular situations. In smooth isotropic or anisotropic media, the most important types of singularity are *caustics*. Caustics may attain various forms. Various extensions of the ray method can be used to compute wavefields in caustic regions. These extensions are frequency dependent. See a detailed treatment of wavefields in caustic regions in Kravtsov and Orlov (1999), and also in Stamnes (1986). In models with smooth structural interfaces, other singularities often appear. For edge and vertex points, see Ayzenberg et al. (2007). For critical singular regions, at which head waves separate from reflected waves, see Červený and Ravindra (1971). For the waves, whose rays are tangential to interfaces, see Thomson (1989).

Specific methods, designed for different types of singularities may be used for computing wavefields in singular regions. Disadvantage of these methods is that they are different for different singularities. Moreover, singular regions often overlap, and the wavefield in the overlapping region requires again different treatment. It is desirable to have available a more general extension of the ray method, applicable uniformly in any of the mentioned singular regions, or, at least, in most of them. Such an extension

would simplify ray computations considerably and could even lead to more accurate results.

Several such extensions of the ray method have been proposed. We do not describe them here in detail. Instead, we merely present references, in which more details and further references can be found. Let us mention the Maslov asymptotic ray theory introduced to seismology by Chapman and Drummond (1982); see also Thomson and Chapman (1985) and Chapman (2004). Another extension of the ray method is based on the summation of Gaussian beams (Popov 1982; Červený et al. 1982; Klimeš 2018). For the relation of this method with the Maslov method see Klimeš (1984). The Gaussian beam summation method has found applications both in the forward modelling of seismic wavefields and in migrations in seismic exploration. It is closely related to the method of summation of Gaussian packets (Červený et al. 2007). Ray theory can be also used in the Born scattering theory (Chapman and Coates 1994; Chapman 2004). For waves reflected from a smooth structural interface separating two heterogeneous, isotropic or anisotropic media, the Kirchhoff surface integral method can be used. For details and many references see Chapman (2004, Sect. 10.4). Another useful extension of the ray method is the one-way wave equation approach (Thomson 1999).

Seismic Reservoir Characterization

Dhananjay Kumar

Chevron, Houston, TX, USA

BP, Houston, TX, USA

Definition

Reservoir

A petroleum reservoir is a column of layers of sedimentary rocks in the subsurface containing oil and gas.

Reservoir properties

In petroleum exploration, some of the common reservoir properties of interest are thickness, rock type, porosity, permeability, fluid type, and saturation.

Reservoir

characterization

It is a method to describe the reservoir in terms of its structure and in situ rock and fluid properties in the subsurface.

Seismic

reservoir

characterization

It is the use of seismic data for 3D reservoir characterization away from the well locations.

Well tie

It is the comparison of a measured seismic response with a well log-based synthetic seismic response at a well location. Also, it is a comparison of a seismically derived property with a well log property at well locations.

Seismic

amplitude

calibration

It is a process to relate seismic amplitude to geology (often based on well log synthetics) for quantitative estimation of reservoir properties from seismic.

Introduction

In petroleum exploration, geoscientists want to locate and characterize reservoirs that may be a few kilometers deep in the subsurface. Seismic imaging is a noninvasive method that uses seismic data to produce three-dimensional (3D) images of the subsurface in terms of its structure, layered earth stratigraphy, and elastic properties of the rock formations – all the way from the top surface to deeper zones. However, a reservoir characterization study generally focusses on the hydrocarbon-bearing reservoir intervals of interest. To help understand how best to produce hydrocarbons from a reservoir, we want to understand the reservoir in terms of its size, shape, depth, thickness, rock type, rock strength, porosity, permeability, fluid type, saturation, pore pressure, and connectivity. Wells, including well log data, provide abundant information about the reservoir. However, wells usually must be drilled at sparse locations due to cost and safety

practicalities. Seismic data can be acquired on the surface, and the role of seismic reservoir characterization is to define the structure and interpret reservoir properties away from and between the well locations.

Seismic data is a time series representation of the earth's subsurface that contains information about the reservoir properties filtered with the source wavelet and wave propagation effects. The seismic response is a cumulative effect of wave propagation in the overburden and reservoir. Figure 1 shows a schematic plot of wave energy propagation in a subsurface model highlighting that the wave, represented by ray paths, spends most of the time in the overburden and only a short time in the reservoir. Data processing is carried out to attenuate unwanted seismic noise and enhance spatial and temporal resolution to detect finer details of the reservoir. Processed seismic volumes can be interpreted to map geological boundaries (horizons) and generate a variety of attributes for geological interpretation. For quantitative interpretation, the

seismic amplitudes are first calibrated to well log-based synthetic responses to establish relationships between the seismic waveform response and geology (reservoir properties) at well locations. While seismic reflectivity (amplitude) images have been used for decades in seismic interpretation, seismic inversion is now a standard technique used for quantitative reservoir characterization. Seismic inversion can be undertaken in two ways, either by inverting for elastic rock properties (P-wave velocity V_p , S-wave velocity V_s , impedance), from which reservoir properties (lithology, porosity, fluid saturation) can be estimated using rock physics relationships, or by inverting directly for reservoir properties. The properties estimated from both approaches are used to further estimate reservoir quality (net sand, porosity) and quantity (volumetric hydrocarbon in place), impact well-drilling decisions, and optimize hydrocarbon production and recovery. Figure 2 shows a seismic reservoir characterization workflow.

Seismic Reservoir Characterization, Fig. 1 Schematic subsurface model. An example of seismic wave propagation in the subsurface layers represented by three rays emitting from a source on the surface. Seismic receivers are placed on the top surface and record reflected waveforms in certain time-sampling intervals (i.e., 1 millisecond). Seismic wave propagates in all directions following physics (Snell's law). At each reflective interface (where contrasts in elastic properties and density are present), part of the energy is reflected, and part of the energy is transmitted, and

with each reflection and transmission, the wave may undergo a change in mode to other wave types. Here, only the primary P-P wave reflection and transmission are shown using three rays: (i) dash-dot red lines, (ii) dotted green lines, and (iii) dashed blue lines. Only the dashed blue color ray is reflecting from the base of the target reservoir, and note that this ray is spending most of the time in the overburden, and therefore its seismic response will be dominated by overburden geology and propagation effects

Seismic Data Processing

Seismic data are processed, including migration, to attenuate noise and remove 3D wave propagation effects (Yilmaz 2001). After processing, an ideal seismic response is the one responding to P-wave primary reflections only (without converted waves and multiple reflected waves) and without 3D propagation effects. Processing for the P-wave response is common, because our conventional models for interpretation are based on 1D earth models and P-P wave reflections. Advanced methods are being occasionally used (and studied) to consider the 3D and mode conversion effects. In practice, even after careful processing, seismic amplitudes can still be affected by various overburden geologic and wave propagation effects superimposed on those caused by reservoir layer properties (Sheriff 1975). All unwanted seismic responses are termed “seismic noise.” After processing, we use zero-phase seismic data and generate angle gathers, angle stacks, amplitude variation with angle (AVA) attributes, and other attributes to facilitate reservoir characterization (Chopra and Marfurt 2007).

Seismic-Well Tie

Calibration of a seismic data with synthetic data (generated using well logs) is referred to as the seismic-well tie process. Figure 3 shows an example. A seismic-well tie offers many benefits:

- (i) Provides a basis for interpreting seismic events in geologic terms
- (ii) Helps to establish a time-depth relationship between seismic data and the well depths, respectively
- (iii) Helps to estimate the phase of the data
- (iv) Helps to estimate the wavelet for use in synthetic seismogram computation and in seismic inversion
- (v) Enables general quality control of both seismic and well logs
- (vi) Enables the understanding of seismic resolution and tuning effects

Seismic Rock Physics

Well logs are used to establish relationships between reservoir properties of interest and elastic properties that can be estimated from seismic data (Mavko et al. 1998). For example, relationships can be established to show how seismic impedance (product of velocity and density) can be used to predict reservoir porosity, or how multiple reservoir properties such as lithology and hydrocarbon saturation can be distinguished

using impedance and V_p/V_s ratio simultaneously. If reservoir properties and elastic properties are strongly related, then we have a better chance of successful reservoir characterization in the presence of good-quality seismic data. But if rock physics relationships are non-favorable, then even in the presence of good-quality seismic data, reservoir characterization will be ambiguous.

Seismic Inversion for Reservoir Properties

Seismic reflection data respond to changes in elastic properties and bulk density across interfaces between layered geologic formations. Therefore, the seismic reflectivity response must be inverted for layer properties, as they are better suited for reservoir characterization. Seismic inversion (Menke 1984; Tarantola 1986) is used either to estimate reservoir properties directly or first to estimate elastic properties followed by the application of rock physics models to estimate reservoir properties. Figure 2 shows both methods. The main objective in inversion is to estimate earth model parameters such that the difference between real seismic data and the synthetic seismic data (based on the estimated earth model, the forward modeling method, and the wavelet) is minimum. For the direct estimation of reservoir properties from seismic, rock physics models are included as part of the inversion algorithm and formulate inversion in terms of reservoir properties as model parameters. In this approach, rock physics models are used to compute elastic properties and density for the given reservoir properties (Mavko et al. 1998). Because seismic reflection data is bandlimited in temporal frequency (about 6–60 Hz), inversion using seismic data alone provides relative values of desired properties in seismic frequencies; one such method is colored inversion (Lancaster and Whitcombe 2000). Often, we want to estimate absolute values of reservoir properties, and for that, we use low-frequency (smooth) models based on available well logs and other geologic understanding including 3D seismic structural maps (Simm and Bacon 2014). Seismic models with relative values will have both negative and positive numbers, and models with absolute values will only have positive numbers. Figure 4 compares porosity predictions using two types of seismic inverted acoustic impedance (V_p times density): (i) relative impedance and (ii) absolute impedance. Various sources of noise in seismic data and our use of various models and approximations give rise to uncertainties in the estimated reservoir properties. Two main areas of research are being undertaken to help deal with uncertainties, as well as the increasing abundance of seismic data. One current focus for research is to estimate uncertainties in seismic predictions, for example, through a Bayesian framework, and consider these in the decision-making for petroleum exploration. Another focus area is machine learning methods.

Seismic Reservoir Characterization, Fig. 2 Seismic reservoir characterization workflow. Characterization starts with quality control of both seismic and well log data. Seismic data are conditioned, and desired angle gathers, stacks, or AVA attributes are generated. Well logs are used to generate similar synthetic gathers and stacks, followed by well tie analysis (Fig. 3) to calibrate seismic amplitude with synthetics generated using the estimated wavelet. The seismic reflectivity data can be interpreted for reservoir characterization. Also, we can perform seismic inversion to either directly invert for reservoir properties or first invert for

elastic properties and then estimate reservoir properties. These interpretations and inversions require information and calibration from geology (often using well logs). Common practices in terms of seismic inversion for elastic properties includes (i) pre-stack seismic inversion for V_p , V_s , and density; (ii) limited angle stack inversion for elastic impedance (EI); (iii) inversion of AVO intercept and gradient for acoustic impedance (AI) and gradient impedance (GI), respectively; and (iv) inversion of AVO attributes for V_p , V_s , and density. Refer to Whitcombe et al. (2002) for EI and GI

Applications of Machine Learning Methods in Reservoir Characterization

Machine learning (ML) methods take a numerical approach to estimate reservoir properties (labels in ML), recognizing the inherent imperfection between physics-based models and seismic amplitudes (data). This is possible because of the advancements in computer algorithms and speed and is done by first deriving abstract numerical relationships between data and desired properties using known data and label combinations, followed by predictions of labels for new datasets. In the absence of the availability of labeled data combination, synthetic models can be used to train the algorithms. This approach of ML is known as supervised learning. ML is becoming an alternative method for geophysical inversion in the presence of a large amount of data and a poor understanding of physics (Russell 2019). Structural (fault, horizon) mapping using ML is becoming a routine (Zheng et al. 2019), but reservoir properties prediction is still not fully developed and accepted. However, physics-guided ML takes the unsupervised approach, where a labeled data is not

required. It has been used for reservoir property prediction as one way to improve the validity and acceptable geological interpretations (Biswas et al. 2019b). Most ML algorithms are based on a type of statistical learning (Gareth et al. 2014). Note that conventional reservoir characterization is done using the processed seismic data to make sure seismic data contain only the P-wave primary reflection response that can be explained with known physics (e.g., Zoeppritz AVA equation-based convolutional synthetics). One should think about using the raw seismic data in ML methods for reservoir characterization. Although ML methods have potential to provide fast turnaround of a project and reduce human bias, human interactions will be needed to come up with physically interpretable reservoir properties.

Summary

Seismic data provides images of the subsurface in terms of the 3D structure, where there are changes in elastic properties and density. Various seismic reflectivity attributes are generated to

Seismic Reservoir Characterization, Fig. 3 Seismic-well tie (Biswas et al. 2019a). The first column shows VSH curve to highlight lithology, second column shows V_p (red) and V_s (blue), and third column shows bulk density (red) and porosity (blue). The fourth column evaluates seismic inverted density (blue) with smooth well log density (red), and

the two compare nicely here. The fifth column shows seismic-well tie as synthetic (blue) and seismic (red) reflectivity comparison, and the last column shows another view of seismic-well tie as seismic section along a well and synthetic (blue) displayed along well trajectory

Seismic Reservoir Characterization, Fig. 4

Seismic-derived porosity section views along a well (Kumar et al. 2014). Log porosity along the wellbore is compared with porosity predicted from two seismic acoustic impedance (AI) models: relative seismic AI (a) and absolute seismic AI (b). The two seismic porosities are comparable in the Eagle Ford (EF) shale, and they also match well with log porosity. The same color scale is used for both seismic and log porosities. Seismic formations (upper EF, lower EF, and Buda) are labelled

enhance seismic sensitivity to reservoir properties. Seismic inversion is utilized further to estimate layer properties for geological interpretation. The two critical ingredients for a successful seismic reservoir characterization are (i) favorable rock physics showing a strong sensitivity of seismic amplitude to reservoir properties and (ii) good-quality seismic data. Uncertainties in estimated reservoir properties exist due to low-quality seismic data, bandlimited resolution of seismic, poor calibration of seismic data to well logs, and approximate seismic physics used in the analysis. Future emphasis is on probabilistic seismic analysis and machine learning methods to estimate reservoir properties from seismic.

Seismic Seiches

Art McGarr

Earthquake Science Center, U.S. Geological Survey, Menlo Park, CA, USA

Definition

Seismic seiche is a term first used by Kvale (1955) to discuss oscillations of lake levels in Norway and England caused by the Assam earthquake of August 15, 1950. This definition has since been generalized to apply to standing waves set up in closed, or partially closed, bodies of water including rivers, shipping channels, lakes, swimming pools, and tanks due to the passage of seismic waves from an earthquake.

The first published mention of seismic seiches is thought to be reports of those observed throughout much of Europe due to the great earthquake at Lisbon, Portugal, in 1755 (Wilson 1953; Richter 1958). In addition to the Lisbon and Assam earthquakes, seismic seiches at teleseismic distances have been observed for many other large earthquakes including the 1964 Alaska (McGarr and Vorhis 1968) and the 2002 Denali, Alaska, an earthquake that caused damaging seiches in Lake Union, Seattle, Washington, at an epicentral distance of 2400 km (Barberopoulou et al. 2004). Most recently, Bondevik et al. reported observations of seiches in Norwegian fjords caused by S waves and surface waves from the 2011 M9 Tohoku, Japan, earthquake. Based on evidence from eyewitnesses and surveillance and cell phone cameras, the seiches began about 30 min after the origin time of the earthquake.

Kvale (1955) showed that seismic surface waves from the Assam earthquake were the most probable cause of the seiches observed in Norway and England at that time. Moreover, he concluded that the natural period of a basin must be matched by the periods of the passing seismic surface waves. Motivated by observations reported by Donn (1964) of a seiche generated in a channel near Freeport, Texas, at an epicentral distance of about 5040 km from the 1964 Alaska earthquake, McGarr (1965) developed a relation between the ground motion of seismic waves and the resulting seiche. The passing seismic

wave exerts a horizontal acceleration on a closed, or partially closed, body of water, which can be idealized as a long channel of uniform depth. This causes a seiche, composed of standing water waves whose periods depend on the dimensions of the channel. The amplitude of the seiche depends on channel depth, the amplitudes of the horizontal accelerations of the seismic waves, and the extent to which the periods of the seismic waves match those of standing water waves. The gravest mode of the standing waves has a period given by $T = 2L/\sqrt{gH}$, where T is the period in seconds, L is the channel width in meters, H is the channel depth in meters, and g is gravity. For instance, if $L = 100$ m and $H = 10$ m, then the period of the gravest seiche mode is 20 s, which tends to be the period where surface waves show maximum amplitudes at teleseismic distances. Any factor that enhances the amplitudes of seismic waves, such as basins containing low-velocity sediments, tends to result in greater production of observed seiches from a given earthquake (McGarr and Vorhis 1968; Barberopoulou et al. 2004).

Seismic Signals in Well Water Observations

R. K. Chadha

CSIR:National Geophysical Research Institute, Hyderabad, India

Synonyms

Anomalous water level changes; Groundwater anomalies; Hydrological earthquake precursor

Definition

Seismic signals in well water observations – temporal rise or fall in well water level fluctuations induced by earthquakes.

Introduction

Seismic waves generated during an earthquake cause oscillations and permanent offsets in well water levels. Liu et al. (1989) explained the oscillations in terms of expansion and contraction of pore pressure changes induced by seismic waves. Systematic monitoring of well water levels has led to identification of anomalous pre-, co-, post-, and transient changes in well water levels related to earthquakes (Roeloffs 1996). These signals are believed to reflect pore pressure changes related to the redistribution of stress in the near and far fields of dislocation sources. The co-, post-, and transient seismic changes appear as a step or spikelike anomaly in well water oscillations and recover post-earthquake depending on the transmissivity of the medium. While the co- and post-seismic signals are attributed to local and regional earthquakes, the transient changes are in response to teleseismic (>1000 km) earthquakes. Several attempts have been made, in hindsight, to interpret preseismic well water levels changes as earthquake precursor.

Co- and Post-seismic Signals

The coseismic signals generally coincide with earthquake time and are observed mostly in wells which respond to earth tides. Earth tides are very small deformations in the earth's surface caused by the gravitational fields of the sun and moon as the earth rotates within their fields. The presence of tidal signals in well level recordings indicates that they are connected to confined, that is, hydraulically locked and fully water-saturated aquifers. This is favorable for the detection of weak pore pressure anomalies induced in crustal stress and hence can be considered as volume strainmeter of resolution of the order of 10 nanostrain (1 in 10^{-8}) or better. As an alternate mechanism, Rojstaczer et al. (1995) stressed the role of earthquake-induced enhancement of permeability in the shallow crust to explain the co- and post-hydrological changes observed in springs and groundwater flows after the 1989 Loma Prieta earthquake in California.

The 1999 Chi-Chi earthquake of $M_w 7.6$ in Taiwan is one of the well-documented events for water level changes in wells. Chia et al. (2001) reported the coseismic changes and compared them to the distances between the earthquake fault and the observations wells. Lee et al. (2002) reported coseismic hydrological changes associated with dislocation caused due to Chi-Chi earthquake, and Lai et al. (2004) compared these changes with the regional geological setting

and seismic ground motions. They showed that in the nearby Choshui River alluvial fan area, the groundwater levels rose coseismically, and amplitudes increased with increase in ground acceleration and hydraulic conductivity, whereas in the slope regions near the earthquake fault, the water levels dropped with increasing intensity as the ground accelerations increased. In a recent study, Anhua He and Singh (2019) reported coseismic step changes in 138 wells in China associated with the M_w 7.9 Wenchuan earthquake of 2008. Earlier, Zheng et al. (2012) analyzed the coseismic responses of the fluid well pattern system in Jiangsu Province to the 2008 Wenchuan and 2011 Tohoku earthquakes. Shi et al. (2013) studied coseismic response of groundwater level in the three gorges well network and its relationship to aquifer parameters.

Akita and Matsumoto (2004) showed coseismic changes induced by M 8.0 Tokachi-oki earthquake in 2003 in Japan. These coseismic changes were observed in 29 wells with increases in wells located in southeast part of Hokkaido and decreases in other areas. Matsumoto et al. (2003) studied 28 cases of coseismic changes during 1981 to 1997 at Haibara well in central Japan and obtained an empirical relation between earthquake magnitudes and distances. They attributed these changes to the strong ground motions due to passing of seismic waves. Koizumi et al. (1996) reported groundwater anomalies associated with the 1995 Hyogoken Nanbu earthquake, in Japan.

Chadha et al. (2003) reported four cases of coseismic changes in wells in the Koyna region, India. To comprehend the cause-and-effect relationship between local earthquakes and water level changes, they drilled 21 bore holes surrounding a well-constrained seismic source volume of $30 \times 15 \times 10 \text{ km}^3$ dimension. Analysis of data from these wells from 1997 to 2003 revealed four cases of coseismic step changes associated with local earthquakes of $5.3 \leq M \leq 4.2$ within a 50 km radius. Rudnicki et al. (1993) observed water levels at 17 wells in the Parkfield area along the San Andreas fault during January 1989 to 1990 as a part of the Parkfield earthquake prediction experiment. Using the recovery rates of water level changes due to fault creep or slow slip, they inferred the position of the fault zone. Later, Roeloffs (1998) analyzed persistent water level changes at a well near Parkfield caused by local and distant earthquakes.

Gavrinlenko et al. (2000) reported permanent water level drop associated with Spitak earthquake of 1988 at a well located 110 km from the epicenter. This drop occurred post-earthquake and might have been influenced by closeness of the fault zone. Following a sequence of nine M_w 5.0–5.9 earthquakes in central Italy, changes in water table and spring discharge were reported for several months (Petitta et al. 2018). Data from 22 measurement sites, located within 100 km of the epicentral zones, were analyzed. The intensity of the induced changes was correlated with earthquake magnitude and distance to epicenters.

Transient Signals

Transient changes in well water levels due to teleseismic earthquakes were reported for earthquakes of $M > 7.5$. Chadha et al. (2008) reported transient and persistent water level changes at few wells in Koyna, India, following M_w 9.3 Sumatra earthquakes in 2004 (Fig. 1). The transient changes were either a spike- or a steplike signal. They attributed these changes to the dynamic strain induced by the passage of seismic waves, most probably long period surface waves. Sil and Freymueller (2006) reported anomalous well water level changes in Fairbanks, Alaska, with the passing of seismic waves due to the Sumatra earthquake of 2004 in the Indian Ocean. Kitagawa et al. (2006) reported well water level changes in 38 observation wells due to Sumatra earthquake at a distance of more than 5000 km in Japan. Ishii-type borehole strainmeters installed in 10 of the observation wells also recorded changes in crustal strains.

Sun et al. (2015) showed water level changes at Changping well in China related to M_w 9.0 Tohoku earthquake in Japan. They termed these changes as coseismic induced mostly by the surface waves of this distant earthquake. Similarly, He et al. (2017) reported coseismic response of water levels in the Jingle well in China associated with the Gorkha Nepal (M_w 7.8) earthquake in 2015 in the Himalaya. Several reports of earthquake-induced well water level changes at distant locations came out after the M_w 7.9 Denali earthquake in 2002 in Alaska (Cassidy and Rogers 2004). In the Korean Peninsula, Yun et al. (2019) analyzed groundwater level changes in a monitoring well close to Yangsan fault zone, induced by local and offshore earthquakes around the world.

Preseismic Signals

During 1970s there was a great optimism to study hydrological and geochemical signals for predicting earthquakes after the success of 1975 Haicheng earthquake in China. Wakita et al. (1988) presented preseismic changes in water level, temperature, radon, and strain associated with the 1978 Izu Oshima earthquake of M 7.0 in Japan. Later, Tsunogai and Wakita (1996) reported preseismic data on radon, chlorine, and strain prior to the 1995 Kobe earthquake of M 7.2 in Japan and showed the remarkable similarity in the precursory pattern 1 month prior to the earthquakes. Roeloffs (1996) reported preseismic changes at the observation stations located within 35 km from the epicenter of the 1985 M 6.1 Kettleman Hills earthquake along the San Andreas fault system. Two of the four water level sites and two of three volumetric strain sites showed covarying precursory signals beginning 3 days before the event. King et al. (1999) studied the water level drops observed at 16 wells in Tono mines in central Japan, prior to a M 5.8 local earthquake, and suggested

Seismic Signals in Well Water

Observations, Fig. 1 Transient changes in water levels at UKA, TAL, and GOV wells in the Koyna region, western India, induced by $M_w 9.3$ Sumatra earthquake 2000 km away in the Indian Ocean. Arrow shows the arrival of surface waves at the well location

that these changes were premonitory in nature. Chadha et al. (2003) reported preseismic water level drops prior to a coseismic step associated with a $M 4.4$ local earthquake in the Koyna region (Fig. 2). Igarashi et al. (1992) explained the preseismic water level drop as a “rebound anomaly” related to an increase of porosity and permeability due to fracturing, with subsequent recovery attributable either to influx of fluid or to compression.

Mechanisms

Three mechanisms have been put forward to explain the seismic signals in the wells.

Fault dislocation and static poroelastic strain mechanism states that coseismic water level changes can be explained by the coseismic static strain and the change in pore pressure predicted by the poroelastic theory (Wakita 1975; Ge and Stover 2000). Chadha et al. (2005) computed static volumetric strain change to explain the coseismic steps observed in four cases associated with $M \geq 4.2$ local earthquakes in the Koyna region, India. They showed a good correlation between steplike increases in wells located in compression and decrease in dilatational zones but reported a misfit in amplitudes of the anomalies. Based on this study, they concluded that coseismic strains may be a function of site effects controlled by local heterogeneity in geological structures. Thus, simple elastic models cannot wholly explain the

amplitudes of the hydrological anomalies. Huang et al. (1995) and Grecksch et al. (1999) have suggested a nonlinear response of water levels to coseismic strain changes due to local heterogeneities. King et al. (1999) computed strain from dislocation of seismic faults in Japan and showed a good quantitative agreement with the strain inferred from the water level changes around the epicenter. Quilty and Roeloffs (1997) showed good agreement between predicted strain and observed water level changes due to 1994 earthquake in Parkfield, California. Lee et al. (2002) found a similar pattern using the 178 auto-recording monitoring wells associated with the 1999 Chi-Chi earthquake.

Consolidation hypothesis proposes that seismic shaking causes sediments to consolidate or dilate under undrained conditions (Wang and Chia 2008). The water level will decrease or increase within the near field, and this change depends on the magnitude between the shear strain caused by seismic shaking and the critical threshold (10^{-4}). However, the water level will increase at regional distances when seismic wave energy exceeds the amount of dissipated energy required to cause undrained consolidation (Yoshimi and Oh-Oka 1975; Hsu and Vucetic 2004; Lai et al. 2004; Wang and Manga 2010).

Earthquake-enhanced permeability mechanism suggests enhancement in rock permeability either due to rock fracturing during earthquakes (Rojstaczer et al. 1995) or other processes like clogging and unclogging associated with aquifer deformation (Shi and Wang 2016) and consolidation of

Seismic Signals in Well Water

Observations, Fig. 2 Records of air pressure, and residual water levels at two wells in the Koyna region, western India, during March-May, 1997. A 23 days precursory drop is clearly seen

surficial deposits (Xue et al. 2016). Sometimes fractures in the earth are filled up with broken rock material during the normal course of groundwater flow and thus become points of local stress concentration increasing local pore pressure. These local stress points are broken when there is a rapid flow of water during an earthquake (Brodsky et al. 2003) redistributing the pore pressure as the permeability increases that can lead to changes in water levels in wells.

Summary

Earthquakes cause dislocations along faults in earth's crust which leads to redistribution of stresses resulting in alteration of subsurface medium properties and flow of groundwater. Anomalous changes were observed in well water levels after local, regional, and teleseismic earthquakes. These induced anomalous changes termed here as "seismic signals" in well water levels are categorized as pre-, co-, post-, and transient anomalies which manifest as preseismic water level drops, a

coseismic step- or a transient spikelike change, and sometimes a gradual post-seismic increase. These signals indicate the spatial distribution of seismic energy density that triggers the different responses. Three mechanisms have been put forward to explain these seismic signals in terms of a fault dislocation model and static poroelastic strain hypothesis where predicted strain is found to be in good agreement with the strain predicted by water level changes around the epicentral area. According to static strain hypothesis, the coseismic steplike anomalies can be explained in terms of coseismic static strain and changes in pore pressure predicted by poroelastic theory. The second is the consolidation hypothesis which states that the increase or decrease in well water levels depends on the magnitude of the shear strain caused by seismic shaking and the critical threshold of strain at local distances. However, the water level will increase at regional distance when seismic wave energy exceeds the amount of dissipated energy required to cause undrained consolidation. Finally, the earthquake-enhanced permeability mechanism suggests enhancement in rock permeability either due to

rock fracturing during earthquakes or other processes like clogging and unclogging associated with aquifer deformation and consolidation of surficial deposits.

Seismic signals in well water levels, while clearly are strain indicators, do not have a well-understood relation to strain. They exhibit “response heterogeneity” in the signals which are highly variable in space and time and thus have no straightforward explanation. The mechanisms put forward to explain these signals may not be mutually exclusive but may occur together and may even be causally related.

The preseismic changes in well water levels are still far from using them as short-term earthquake precursors. Very often, these precursory changes which represent the pre-earthquake phase are very small and therefore not obvious in the raw data which is also affected by atmospheric pressure, significant precipitation, and earth tides. Innovative filtering techniques have to be developed to decipher the earthquake-related anomalies from non-tectonic effects in the data. Definite patterns of earthquake-related water level anomalies have to be established, both site specific and global, so that predictive capabilities can be developed. We realize that earthquake prediction using short-term precursors is not easy, but sound observations which may lead to a physical model must continue. The earthquake-induced water level changes in groundwater have other implications, too. The supply of groundwater, both in terms of quantity and quality, contaminant transport, and underground waste repositories are some of the important issues which need attention. Plans made to manage these issues are based on pre-earthquake scenario which may drastically change, post event. Thus, there is a need to accelerate these studies by casting wider net-expanding observing programs to capture many more events and their precursors.

Seismic Stereotomography

Slope tomography

Definition

Stereotomography is a special form of reflection tomography proposed by Billette and Lambaré in 1998. It aims to reconstruct smooth, spatially varying properties of the subsurface (in particular the wave velocity) from seismic reflection data. Conventional reflection travel-time tomography relies on the

travel-time of continuous reflectors tracked in the prestack dataset over their full extent. On the other hand, stereotomography uses locally coherent reflected events characterized not only by the source and receiver positions and the reflection time, but also by their local slopes (the spatial derivatives of the reflection time with respect to receiver and source positions). Like travel-time tomography methods, stereotomography methods are based on seismic ray theory.

History

The roots of stereotomography go back to 1936 with the publication by F. Rieber of a paper in *Geophysics* describing a new reflection system with controlled directional sensitivity. Soviet scientists recognized the potential of this approach for velocity model building for seismic migration (see ► [“Seismic, Migration”](#)) and developed a method called CDR (controlled-directional-reception) in the 1950s and 1960s, principally by Professor Riabinkin (Billette and Lambaré 1998). A few years later, the approach gained interest from western geophysicists and in particular from Stanford’s Charles Sword, who spread it in his community. By 1998, Billette and Lambaré recast CDR and related approaches in a common theoretical framework under the generic term of slope tomography. These approaches have in common their aim to estimate the velocity model, $c(\mathbf{x})$ ($\mathbf{x}$ denoting the position in the subsurface), from a set of locally coherent reflected events (events that can be visually followed on a few adjacent traces in a given observation domain) characterized by their reflected travel-time, T_{sr} , source and receiver positions, $\mathbf{s}$ and $\mathbf{r}$, and slopes, that is, the spatial derivative of the travel-time, p_s and p_r (Fig. 1). These locally coherent events are interpreted within seismic ray theory (see ► [“Seismic ray theory”](#)) as pairs of ray segments connecting the reflecting point, $\mathbf{X}$, to the shot and receiver positions (Fig. 1). Compared to reflection traveltime tomography, the additional information brought by the slopes allows one to consider the reflection events locally: there is no need to track a reflection event over its full extent in the migrated or unmigrated prestack dataset. The picking (the extraction of the kinematic characteristics of the events, that is, their travel-time and slopes) becomes much easier and can therefore be performed more densely compared with conventional methods.

Within this theoretical frame, Billette and Lambaré also proposed a new approach, based on a generalization of the other slope tomography methods and with the expected benefit of improved robustness with respect to complex media involving multipath ray trajectories. They called it “stereotomography” and detailed its numerical implementation based on an efficient local optimization scheme involving paraxial ray tracing (see ► [“Seismic Ray Theory”](#) and ► [“Inverse Theory, Linear”](#)). Since this pioneering publication,

Seismic Stereotomography, Fig. 1 A locally coherent event in the prestack data cube, characterized by its central source and receiver positions $\mathbf{s}$ and $\mathbf{r}$, slopes p_s and p_r , and travel-time, T_{sr} (Fig. 3 from Lambaré (2008))

stereotomography and, more generally, slope tomography methods have gained in effectiveness and established themselves as powerful approaches for industrial velocity model building. One of their big advantages over the standard tomographic velocity model building methods is the non-linear update of velocity model (see Lambaré et al. (2014))

Data and Model in Slope Tomography

All slope tomography methods (and stereotomography in particular) have in common the description of the dataset. It consists of a set of N locally coherent reflected events characterized by their source and receiver positions, source and receiver slopes, and their travel-times,

$$\mathbf{d} = [(\mathbf{s}, \mathbf{r}, p_s, p_r, T_{sr})_i]_{i=1}^N. \quad (1)$$

Such a dataset needs to be explained by a model consisting of an associated set of pairs of ray segments and a velocity field (Fig. 1). Various cost functions and strategies have been proposed to estimate the optimum model, with important consequences for the allowed model space and optimization process. In all formulations, the model space contains ray parameters and a velocity model, which can be estimated through either joint or sequential optimization, that is, the

tracing of rays followed by a velocity update. In stereotomography, they are optimized jointly. The model ($\mathbf{m}$) consists of:

$$\mathbf{m} = [(\mathbf{X}, T_s, T_r, \beta_s, \beta_r)_i]_{i=1}^N, V, \quad (2)$$

where $\mathbf{X}$ denotes the common starting point for the two ray segments, β_s and β_r denote the starting angles of the rays towards the source and receiver, respectively, T_s and T_r represent the two one-way travel-times associated with the two ray segments, and V represents the set of parameters describing the velocity model (velocity and anisotropic parameter grids, etc.) (Fig. 1). The cost function to minimize reads:

$$C(\mathbf{m}) = \frac{1}{2} (d_{calc}(\mathbf{m}) - d_{obs})^T C_D^{-1} (d_{calc}(\mathbf{m}) - d_{obs}) + Regul(\mathbf{m}, \mathbf{d}). \quad (3)$$

where C_D is the a priori covariance matrix for data parameters (Billette and Lambaré 1998) and $Regul(\mathbf{m}, \mathbf{d})$ stands for regularization terms. When ray segments and velocity are optimized sequentially, ray segments can be determined by relaxing partly the data fitting or the reflection conditions (the two ray segments starting from a common point). Once the rays are traced, the velocity is estimated based on fitting the remaining condition (Billette and Lambaré 1998). Among the most popular methods of this kind, the slope tomographic approach initially proposed by Chauris et al. (2002) is widely used in the industry following Guillaume et al. (2008). In this approach, the ray segments are first recovered for a given velocity fitting source and receiver positions, midpoint slopes, and traveltimes (this is called kinematic migration). The velocity is then updated considering the misfit of the residual move-out slope in the offset direction in the common image gathers.

The numerical scheme used for solving the inverse problem aims at minimizing the cost function (3) through iterative local optimization, using typically a quasi-Newton scheme (see ► “Inverse Theory, Linear”). A local optimization offers an efficient solution for ensuring convergence of the optimization process. It requires the computation of the data and Fréchet derivatives (derivatives of the data with respect to the model parameters), which can be estimated by using ray tracing and paraxial ray tracing, respectively (see ► “Seismic Ray Theory”), provided the model exhibits proper smoothness. Cubic cardinal B-Splines are a good choice which can be used in gridded or multilayered velocity models (for references, see Lambaré et al. (2014)) not only because of their smoothness but also because they act as a model preconditioner to ease the inversion.

Velocity model building from surface reflection data being by nature an ill-posed inverse problem it requires

regularization methods, such as Tikhonov regularization. More advanced, dip-dependent regularizations have also been proposed, allowing the production of structurally-conformed velocity models. Another strategy requires the introduction of other types of data. For example, in dip-constrained tomography, the velocity is updated considering the misfit between the structural dips of the kinematically remigrated reflected events and an expected dip model (Lambaré et al. 2014). Another example is the incorporation of direct arrival travel times measured from surface sources with receivers located in a well, or first arrival travel times from surface-seismic measurements (see Allemand et al. (2017)). Including this kind of data is helpful, for example, to estimate anisotropy in order to reconcile the kinematics of reflected and diving waves.

One of the first and most critical steps in velocity model building is the picking of locally coherent events (see Lambaré (2008) for a review). This can be performed either in the un-migrated data domain or in the (time- or depth-) migrated domain using automatic slope or dip picking tools. If done in the migrated domain, a kinematic demigration step is needed to

recover the so-called kinematic invariants, namely, the kinematic characteristics of the picked locally coherent events in the un-migrated domain (Guillaume et al. 2008). This versatility is a great strength in the approach, which has been extended from surface common-offset migration to any type of prestack depth migration, such as common-angle migration (Montel and Lambaré 2019). After picking, careful editing is needed to remove outliers. This is important as the quality of the picked data has a major influence on the inversion result.

Applications of Slope Tomography

Since it was first published in 1998, stereotomography and slope tomography have been implemented and applied in various contexts: marine streamer, ocean bottom seismic and land data, in 2D and 3D, isotropic and anisotropic contexts, using PP or PS waves (see Lambaré (2008) and Lambaré et al. (2014)).

We show in Fig. 2 an example of such an application (Hermant et al. 2014). The dataset is a high-density full-

Seismic Stereotomography, Fig. 2 Application of slope tomography to a land dataset. Top right: dip picks (in red) superimposed on the depth migrated stack for acquisition azimuth 0 (black to white). Blue curve indicates the location of top of salt (TOS), green curve the base of salt (BOS). Top left: residual move out curves (in red) superimposed on a

selection of common image gathers (black to white) for azimuth sector 0, located in the yellow box. Courtesy of CGG, Petroleum Development Oman, and the Ministry of Oil and Gas of the Sultanate of Oman

azimuth seismic land dataset from South of the Sultanate of Oman. The area exhibits complex geological settings with an alternation of fast carbonate layers and slower shale or clastic layers overlying salt bodies. The associated strong lateral velocity variations are particularly challenging for velocity model building. The picking is done in the migrated domain to get the local dip of the events on the migrated stack and the corresponding local slope of the residual move-out curves in offset in the common image gathers (Fig. 2 (Top)). Figure 2 (Bottom left) shows the velocity model obtained by multi-layer tomography. This slope tomographic approach updates a layered velocity model with explicit velocity discontinuities iteratively repositioned during the updating process. Figure 2 (Bottom right) shows the velocity model after a further step of high definition tomography (an extension of slope tomography aimed at enhancing vertical resolution).

Challenges and Perspectives

Stereotomography and slope tomography methods in general are powerful velocity model building tools widely used in the seismic industry (Lambaré et al. 2014). The picking remains critical, with a major influence on the result. It should be accurate but also as dense as possible. The ability to handle a dense set of picks not limited to a few reflectors, combined with efficient nonlinear solvers and geologically constrained regularizations, allows high-resolution models to be obtained, far exceeding resolution of conventional travel-time tomography. On the other hand suboptimal picking will degrade the result, and a thorough editing should be applied prior to the inversion, for example using machine learning techniques.

In terms of tomographic velocity updates, Sambolian et al. (2019) recently investigated replacing ray tracing of individual pairs of ray segments by the use of travel-time maps (computed here by an eikonal solver). They promote the use of a matrix-free approach in order to invert for denser sets of picks.

An obvious limitation of these methods is the high frequency approximation, especially when dealing with complex media where waveforms have complicated behaviors with tuning effects. Hence, efforts should be made to extend the approach towards full-wave techniques. The connection between stereotomography and full-wave velocity model building, such as Differential Semblance Optimization, has been pointed out (“differential semblance is essentially data-weighted stereotomography, implicitly computed without event picking” Symes (2008)). Note, however, that the introduction of a picking step allows the extraction of the most significant kinematic information from the data, and the selection of events represents, to our minds, a serious advantage that would be worth preserving in full-wave approaches.

Conclusions

In the last 20 years, stereotomography and its variations (under the generic term of slope tomography) have earned their stripes in terms of industrial applications. This success is due to their versatility and efficiency at dealing with the critical velocity model building challenge (a non-linear and ill-constrained inverse problem). Even if full-wave methods are gaining popularity in complex areas, slope tomography remains and will remain a key tool for industrial velocity model building.

Seismic Structure at Mid-Ocean Ridges

Donald W. Forsyth

Department of Geological Sciences, Brown University,
Providence, RI, USA

Definition

Lithosphere	The cool, uppermost layer of the solid earth that moves as a unit and has some long-term elastic rigidity. It usually consists of both crust and the uppermost mantle. The mantle portion is typically characterized by high seismic velocities and low attenuation.
Asthenosphere	A more deformable, low-viscosity layer in the mantle underlying the lithosphere. Characterized by low seismic velocities and relatively high attenuation.
Anisotropy	Physical properties at any one point varying depending on direction; for seismic waves, velocity may depend on direction of propagation and direction of polarization of the wave.

Introduction

Mid-ocean ridges are spreading centers where two oceanic, lithospheric plates move apart. The separation of the plates induces upwelling in the underlying asthenospheric mantle. Because melting temperature decreases with decreasing pressure, as the mantle upwells, it undergoes pressure-release partial melting, producing magma that migrates upward to form new oceanic crust. As the plates move away from the spreading center, heat is lost to the surface conductively by diffusion and convectively by hydrothermal circulation. As the crust and mantle lose heat, the magma solidifies, and the plates thicken and cool with increasing age of the seafloor.

Although the general outline of the processes beneath mid-ocean ridges leading to the formation of new seafloor is well known, there are many questions remaining about the details of the mantle flow, melt generation, and melt migration that have not yet been fully answered. For example, along mid-ocean ridges, spreading centers are offset and segmented by transform faults and overlapping spreading centers. Are there distinct centers of mantle upwelling beneath each ridge segment or is the segmentation a shallow manifestation of stresses within the lithosphere with upwelling a more or less continuous phenomenon in the asthenosphere? How broad and deep is the melt production region?

The propagation of seismic waves through the crust and mantle provides one of the most direct ways of probing the structure beneath the ridges associated with plate separation and crust formation. The velocity, attenuation, and anisotropy of the waves are affected by temperature, composition, the presence of melt or cracks, and the crystal fabric. Tomographic images and maps of crustal and uppermost mantle structure are typically created in active source experiments where artificial sound sources, such as air guns, are recorded by ocean bottom seismometers (OBS) and/or long arrays of hydrophones towed behind ships. Deeper mantle structure is probed using signals generated by distant, teleseismic earthquakes recorded on arrays of ocean-bottom and land seismometers over periods of months to years. The logistical difficulty and expense of such experiments means that relatively few mid-ocean ridges have been studied in detail.

Mantle Structure

A cross section of the shear velocity structure beneath the East Pacific Rise spreading center is shown in Fig. 1 in comparison to the velocity variations that would be expected for simple conductive cooling of the plates if shear velocity were sensitive only to temperature and pressure. This tomographic image is based on the propagation of Rayleigh surface waves across two OBS arrays deployed for periods of 6 and 12 months. The expected thickening of the plate with increasing distance from the ridge axis as the plate cools is clearly observed in the form of increasing shear wave velocity near the

Seismic Structure at Mid-Ocean Ridges, Fig. 1 Tomographic cross section of the East Pacific Rise, comparing predicted shear velocity structure (*top*) to observed structure (*bottom*). Contours are labeled in km/s. Velocities are significantly lower than predicted for temperature effects alone, suggesting the presence of partial melt. (After Harmon et al. (2009))

surface. Velocity changes extend substantially deeper than is predicted and the shear velocity is lower than expected for the direct effects of temperature variations. Both of these departures from the predictions are indications that partial melt may be present, which could reduce the shear (S) wave velocity.

The lowest velocities are observed at depths of 60–80 km, where petrological models predict maximum melt production. There also are very low shear velocities at shallow depths immediately beneath the ridge axis, which may represent higher melt concentrations in the mantle that accumulated as melt migrates upward and inward to form the new oceanic crust at the ridge axis.

Another important feature of the shear velocity structure is the asymmetry across the ridge axis. To the east, beneath the Nazca plate, the high-velocity surface layer increases in thickness more rapidly and the very low-velocity region is absent. This asymmetry is also observed in the degree of shear wave splitting, an indicator of anisotropy, in delays of compressional (P) and S waves, in electrical conductivity, and in the rate of subsidence of the seafloor away from the ridge axis (MELT Seismic Team 1998; Evans et al. 1999). S wave tomography indicates that the asymmetry may extend to depths of 200 km or more (Hammond and Toomey 2003). The asymmetry is probably caused by large-scale mantle flow coming from the hotspot region to the west beneath the Pacific plate, coupled with migration of the spreading center to the west. The fast direction for seismic wave propagation, as indicated by shear wave splitting and Rayleigh wave anisotropy, is perpendicular to the East Pacific Rise, consistent with the alignment of olivine crystals in the mantle expected for plate formation and flow from the west.

The East Pacific Rise is one of the fastest spreading ridges, with full spreading rate of about 14 cm/year. Pronounced asymmetry is also observed across the Reykjanes Ridge south of Iceland (Fig. 2), which has a full spreading rate of

Seismic Structure at Mid-Ocean Ridges, Fig. 2 Tomographic cross section of shear wave velocity structure across Reykjanes Ridge south of Iceland. Note strong asymmetry in upper 100 km between North American plate (west) and European plate (east). (After Delorey et al. (2007))

only about 2 cm/year (Delorey et al. 2007). In this case, the tomographic study took advantage of the existence of arrays of stations on Iceland, which straddles the Reykjanes/Mid-Atlantic Ridge. Like the East Pacific Rise, very low shear velocities (~ 4.0 km/s) indicative of the presence of melt are found in a broad region beneath the ridge. For both the East Pacific Rise and the Reykjanes Ridge, there is too little attenuation of surface waves to attribute the very low velocities to the effect of high temperature alone. Velocities at depths shallower than 80 km are lower on the west side, beneath the North American plate, perhaps due to the westward migration of the ridge and upwelling in the mantle in the wake of the thicker North American lithosphere farther west. The anisotropy pattern is different than for typical mid-ocean ridges, perhaps indicating that there is along-axis flow away from the Iceland hotspot in the asthenosphere.

To date, there have been no experiments that provide good control of along-axis variations in mantle structure at depths of tens of kilometers or more where melt production is expected to occur. In the Gulf of California, a surface wave study showed that there are along-axis variations in shear velocity with minima spaced at intervals of about 250 km, perhaps indicative of discrete upwelling centers (Wang et al. 2009), but that spreading system is flanked by continental crust on both sides and dominated by long transform faults, so it may not be typical. At shallower depths just beneath the Moho (the transition from crust to mantle), there are clearly along-axis variations in P-wave velocity on the northern East Pacific Rise, the boundary between the Pacific and Cocos plates (Toomey et al. 2007). Using long offset arrivals refracting from the Moho (P_n) observed in an active experiment, velocity minima were found spaced about 25 km apart (Fig. 3). P-wave velocities in the minima are 7.4 km/s or less, suggesting the presence of 1–3% melt distributed in films or thin sheets (typical P-wave velocities at the Moho are 7.8–8.4 km/s). However, it is not clear whether these apparent centers of melt lie above centers of upwelling mantle or they represent a scale length associated with melt migration.

Most of the centers of melt concentration lie beneath or very close to the spreading center determined from detailed bathymetric surveys, but one at $9^{\circ}30'N$ is displaced several kilometers from the axis. Because the fast direction for P-wave propagation is skewed from the spreading direction and is not perpendicular to the strike of the ridge axis, Toomey et al., inferred that upwelling and mantle flow at depth may also be skewed, controlling the location of the velocity minima just below the Moho.

Crustal Structure

Basaltic melt migrates upward through the mantle and is focused at the ridge axis. The mechanisms for focusing are

Seismic Structure at Mid-Ocean Ridges,

Fig. 3 Bathymetry of the East Pacific Rise (*left*) and tomographic image of the mantle 9 km beneath the seafloor (*right*). Dashed lines show plate boundary. Solid lines show locations of air gun shots fired at 500-m intervals. Squares and circles are locations of ocean bottom receivers. Contour interval on tomographic image of P-wave velocity is 0.1 km/s. Green lines with double arrowheads indicate fast direction for anisotropic wave propagation. Black lines with arrows indicate direction of relative motion between the Pacific and Cocos plates. Note that some of the slowest region is displaced from the plate boundary. (After Toomey et al. (2007))

still not well known: there may be melt-rich channels at the base of the lithosphere that guide the melt upward and toward the ridge axis; there may be pressure gradients within the deforming mantle that help push the melt toward the axis; or there may be anisotropic cracks or dunite channels that form easy paths for melt migration. Once the melt reaches crustal levels, there may be redistribution along axis through dikes or a continuous magma chamber. It is clear from seismic studies, however, that there is very little magmatic addition to the crust outside the immediate vicinity of the ridge axis. The crust is essentially full thickness at the spreading center itself (Detrick et al. 1987).

The classic model of oceanic crust is a layer of extrusive basalts at the surface in the form of porous pillow basalts and sheet flows, underlain by a region of sheeted dikes that feed the extrusive layer from a magma chamber, and the lower crust consisting of gabbros that solidify from the magma chamber or underlying mush zone. The seismic structure

has also commonly been described in terms of layers that have often been equated to the lithological layering: layer 2A is a low-velocity layer at the surface several hundred meters thick (layer 1 is sediments that are deposited on top of the basaltic crust); layer 2B is a transition region in which the P velocity increases rapidly downward; and layer 3 has low vertical velocity gradients and high P-wave velocities of 6.5–7.0 km/s. A number of investigations, however, have demonstrated that the seismologic layering does not correspond exactly to the lithological layering and that seismic structure is primarily controlled by porosity. The middle to lower crust, layer 3, contains both dikes and gabbro bodies.

At the axis of fast-spreading ridges, there usually is a low-velocity region only a few kilometers wide at most that represents a zone of partial melting that extends throughout the crust (Fig. 4). At the top of this low-velocity region is a very low velocity layer, which is imaged as a prominent reflector in seismic reflection profiles at depths of 1.5–2.5 km on the

Seismic Structure at Mid-Ocean Ridges, Fig. 4 Three-dimensional view of the anomalous P-wave velocity structure of the East Pacific Rise at 9°30'N (a one-dimensional reference model has been subtracted). (From Dunn et al. (2000).) Overlying bathymetry is shown at top, with red shallow to blue, deep. The red regions below the ridge axis correspond to areas of partial melting. The axial magma chamber is at the top of these anomalously slow regions

East Pacific Rise (Detrick et al. 1987). The depth to this reflector tends to increase with decreasing spreading rate or proximity to a fracture zone and it is typically absent at slow-spreading ridges (Singh et al. 2006). The width varies from about 250 m to several kilometers. It is interpreted as the top of an axial magma chamber (AMC) or melt sill, with typical thickness less than 100 m. Modeling of P to S conversions in wide-angle reflections indicates that melt content in the AMC varies from nearly 100% to less than 30% along the ridge (Singh et al. 1998; Canales et al. 2006). Estimates of melt content in the deeper crustal mush zone (consisting of a mixture of melt and crystals) are of the order of 2–8% in the lower crust and 3–12% near the Moho (Dunn et al. 2000). The fact that the zone in which melt is present is so narrow even at fast-spreading ridges means that hydrothermal circulation must be very efficient in removing heat, as purely conductive cooling of the crust would result in a much wider zone of partial melting.

Although there are variations in structure along-axis at fast-spreading ridges, the along-axis variations are much more pronounced at segmented, slow-spreading ridges. Typically, the crust thins approaching transform offsets. Within the fracture zone itself, the basaltic crust may be as thin as 1 km or less, but seismically there may be an altered, fractured layer that is a few kilometers thick and characterized by unusually low velocities, so that it looks like crust. The low-velocity region in the fracture zone, however, probably is mostly mantle that is altered by interaction with water

penetrating down cracks that are repeatedly opened by slip along the transform fault. Near the center of ridge segments between two transform offsets, the crust tends to be thicker and lower in velocity than elsewhere (Fig. 5), suggesting that melt is preferentially delivered to the crust from the mantle at that point. The upper crust at slow spreading ridges is anisotropic, with P-waves traveling faster along axis than perpendicular to it, indicating that faults and fissures are preferentially aligned parallel to the spreading center (Barclay and Toomey 2003).

Summary

The seismic velocity structure of mid-ocean ridges is controlled by crustal thickness, cracking or porosity, temperature, melt, and crystal orientation. Low-velocity regions in the mantle that are caused by high temperatures and partial melt indicate that melt is generated in a broad region beneath spreading centers. Asymmetries in the velocity structure show that upwelling and melting beneath ridges are strongly influenced by global mantle circulation and plate motions. Crustal low-velocity regions are concentrated very near the ridge axis, so melt must migrate both vertically and horizontally to the ridge axis from the broad melt production region. The narrowness of the low-velocity zone in the crust requires that hydrothermal circulation must rapidly cool the crust.

Seismic Structure at Mid-Ocean Ridges, Fig. 5 P-wave velocity structure along the Mid-Atlantic Ridge axis from a non-transform offset on the left to the Oceanographer fracture zone on the right. Crustal thickness from wide-angle reflections off the Moho is shown by thick solid line (open where there are gaps in coverage). The crust is thicker

and the lower crust has lower velocity near the center of the segment. (From Hooft et al. (2000)). The red circles are locations of microearthquakes with uncertainties indicated by error bars. Location of ocean-bottom hydrophones indicated by asterisks

Along-axis variations, particularly at slow-spreading ridges, suggest that melt is preferentially delivered to the center of ridge segments.

Seismic Tomography

Guust Nolet

IRD Geoazur and Université Côte d'Azur, Sophia Antipolis, France

Definition

The term tomography derives from the Greek *τόμος*, or slice. “Seismic tomography” is used for a variety of methods that use transmitted seismic waves to estimate the spatial variations in properties (wave velocity, density, and attenuation) inside the Earth, which are often represented as images of two-dimensional cross-sections or “slices.” It is conceptually different from seismic migration, which uses reflected waves to image sharp discontinuities.

History

In 1971, P. Bois at the Institut Français de Pétrole was the first to suggest the tomographic method in order to locate the causes of delays in seismic waves between two boreholes. His paper predates many future developments but was initially written in French and remained largely unnoticed. In the mid-1970s, Keiti Aki from MIT applied a linear inversion to locate velocity heterogeneities beneath large nuclear monitoring arrays in Norway and Montana, and Harvard's Adam Dziewonski began interpreting the time residuals published by the International Seismological Center (ISC) in the UK in terms of global velocity anomalies.

In 1982, Guy Masters and his colleagues at the Scripps Institution of Oceanography discovered a strong degree-2 component in the geographical distribution of the slight shifts in the spectral peaks of the Earth's normal modes. Since then, the Earth's free oscillations have contributed to constrain the heterogeneity in the Earth at the longest wavelengths and as deep as the inner core. By 1984, John Woodhouse and Adam Dziewonski at Harvard published a first global model for shear velocity in the upper mantle based on long-period surface waves.

However, to image smaller scale anomalies, the shorter wavelengths of P and S-waves are indispensable. In particular, Steve Grand at the University of Texas, Rob van der Hilst and Wim Spakman at Utrecht University and Yoshio Fukao and colleagues at the University of Tokyo pioneered high-resolution body-wave tomography using iterative solvers for the huge systems of linearized equations and established in the early 1990s that some, but not all, subducting slabs are able to sink well into the depths of the lower mantle.

Thermal plumes in the lower mantle were for the first time reliably imaged in 2003 by Raffaella Montelli, using a new

technique of finite-frequency tomography developed by Tony Dahlen and Guust Nolet and their collaborators at Princeton University.

For references and a detailed account of the history of seismic tomography, see the reviews by Romanowicz (2003) and Rawlinson et al. (2010). Nolet (2008) provides a general introduction into the methods of seismic tomography, including the theoretical aspects that are here discussed only briefly.

Onset Times

Much of seismic tomography is based on estimating the arrival time of a seismic body wave by picking the onset of a phase on the seismogram, and interpreting the travel time T using the infinite-frequency approximation of ray theory:

$$T = \int_{\text{raypath}} \sigma(\mathbf{r}) \, ds \quad (1)$$

where the raypath is determined by Snel's law and where σ is the inverse velocity v^{-1} of the wave at the location $\mathbf{r}$. The raypaths may be located between two boreholes, e.g., to monitor the exploitation of an oil or gas field, between several explosive sources and an array of seismographs at the surface (see article: Travel Time Tomography Using Controlled-source Seismic Data), between a seismogenic zone and a local array of seismographs, or between an earthquake and the global network of seismic stations.

The raypath is often approximated by the path calculated for a spherically symmetric Earth or a horizontally layered background model. Examples of global raypaths are given in Fig. 1. This approximation is permitted because ray trajectories render the travel time stationary, such that small deviations in the true ray path location only cause second order errors in the travel time calculated with Eq. 1, a property of rays known by the name of *Fermat's Principle*. In practice,

Seismic Tomography, Fig. 1 Examples of raypaths for a P wave in an equatorial cross-section from a hypothetical earthquake at a depth of 248 km located at 0°N, 150°W

one usually keeps the raypath fixed to its initial approximation. This keeps the inverse problem linear. One then inverts for the difference between the true Earth and a starting- or background model: $\delta\sigma(\mathbf{r}) = \sigma(\mathbf{r}) - \sigma_0(\mathbf{r})$, using the difference between observed time T , and its prediction T_0 from the background model as datum: $\delta T = T - T_0$:

$$\delta T = \int_{\text{raypath}} \delta\sigma(\mathbf{r}) d\mathbf{s} \quad (2)$$

For strongly heterogeneous regions such as subduction zones, one may need to use three-dimensional ray tracing and an iterative approach using Eq. 2 in which rays are recalculated after each modification of the model $\sigma(\mathbf{r})$.

Model Parameterization and Inversion

The change in the model $\delta\sigma(\mathbf{r})$ can be described by a finite number of parameters if it is developed in terms of a basis of M interpolating or “basis” functions $h_k(\mathbf{r})$:

$$\delta\sigma(\mathbf{r}) = \sum_{k=1}^M m_k h_k(\mathbf{r}) \quad (3)$$

The basis functions may be represented by homogeneous cells, linear interpolators in a tetrahedral or other mesh, spherical harmonics, or 3D wavelets. Substitution of Eq. 3 in Eq. 2 gives a formal system of linearized equations for N estimated travel times δT_i , $i = 1, \dots, N$, arranged in a vector $\delta \mathbf{T}$:

$$\delta \mathbf{T} = \mathbf{A} \mathbf{m} \quad (4)$$

where $A_{ik} = \int_{\text{raypath}} h_k(\mathbf{r}) d\mathbf{s}$. Since many raypaths may overlap, this system is usually overdetermined and needs to be solved by a least squares solver that minimizes χ^2 , the length of the misfit vector weighted by the data standard error e_i :

$$\chi^2(\mathbf{m}) = \sum_{i=1}^N \left(\frac{\sum_{k=1}^M A_{ik} m_k - \delta T_i}{e_i} \right)^2 \quad (5)$$

Mathematically, this is accomplished by first dividing the system of Eq. 4 by the standard error of the data (i.e., multiplying by the inverse square root of the covariance matrix $\mathbf{C}$ which is generally assumed to be diagonal), and back-projecting the system using the transpose $\mathbf{A}^T$ of $\mathbf{A}$:

$$\mathbf{A}^T \mathbf{C}^{-\frac{1}{2}} \mathbf{A} \mathbf{m} = \mathbf{A}^T \mathbf{C}^{-\frac{1}{2}} \delta \mathbf{T} \quad (6)$$

One often scales the equations a priori such that the data have unit error $e_i = 1$ and $\mathbf{C} = \mathbf{I}$, which has the same effect. In

the following we therefore ignore $\mathbf{C}$. The overdetermined part of the data allows one to obtain objective estimates for the standard errors in the data (Voronin et al. 2014).

Usually, Eq. 6 is at the same time overdetermined for some parameters and underdetermined for others (the determinant of $\mathbf{A}^T \mathbf{A}$ being zero): there are in that case infinitely many models that satisfy the data within the measurement uncertainty and one needs to regularize the solution. This can be done by choosing the solution that minimizes a weighted penalty of χ^2 , model norm and model roughness, by strongly truncating a development in spherical harmonics or by choosing the sparsest decomposition in wavelets that still satisfies the data. This generally involves a subjective choice between the degree of detail one allows in a model and the goodness of fit to the data. Generally, one aims for a χ^2 approximately equal to the number of data N – in other words, one attempts to fit the data at the level of about one standard deviation. Invariably, a trade-off exists between the detail allowed in the model and the statistical precision with which the model parameters can be determined: the sharper the detail, the more uncertain the m_k .

Regularization can also be done in a fundamentally different way by inverting for local averages in $\delta\sigma(\mathbf{r})$ with a prior specified variance that can be estimated linearly from the data (Backus-Gilbert theory). This can only be done at the expense of a significant increase in computing time. In this case, the tradeoff is between the size of the averaging volume and the model variance: averages over larger volumes are determined with smaller statistical uncertainty. Though computationally expensive, this is statistically superior to any of the other methods. A stable discretized version of Backus-Gilbert theory was developed by Nolet (1985) and for the first time applied to a large tomographic system by Zoroli (2016).

Whatever method is used, the system of Eq. 4 may be very large (e.g., more than 10^6 data for more than 10^5 unknown model parameters). Local parameterizations (cells, as opposed to spherical harmonics) render $\mathbf{A}$ sparse, and the system can be solved efficiently using iterative solvers that adapt to sparse matrices, such as LSQR (Paige and Saunders 1982).

Normal Modes and Surface Waves

The eigenfrequencies ${}_n\omega_\ell^m$ of the Earth are characterized by three quantum numbers ℓ , m , and n , related to the number of nodal surfaces in the displacement field of the Earth with latitude, longitude, and depth, respectively. For a non-rotating, isotropic, spherically symmetric Earth, the spectrum is degenerate in the sense that the frequency is independent of the azimuthal order m . For the real Earth, a weak dependence on m splits each eigenfrequency into $2\ell + 1$ separate frequencies that are too closely spaced to be resolvable except for the

very lowest angular order ℓ . Instead, a composite spectral line or “multiplet” is observed with a peak that depends on the location of the seismic station – a direct consequence of the fact that the $2\ell + 1$ single peaks have amplitudes that depend on geographical location by virtue of their spherical harmonic dependence on latitude and longitude.

Two major strategies exist to exploit the small fluctuations in the spectrum. Decomposing the free oscillation into surface waves traveling in opposite directions, ray theory may be used to establish a linear relationship between the heterogeneity along the great circle between source and receiver and the observed peak shift in the spectral line. At higher frequency, we separate single passages of the surface wave and exploit the linear relationship between fluctuations in the observed phase velocity and the Earth’s heterogeneity. In both cases, the relationship between the Earth’s heterogeneity and the observed datum is a two-dimensional integral along the great circle of the form:

$$\delta\omega = \int_0^a \int_{\text{gc}} K(\mathbf{r}) \delta\sigma(\mathbf{r}) d\mathbf{s} d\mathbf{r}, \quad (7)$$

where the kernel $K(\mathbf{r})$ is computed using first order perturbation theory of the differential equations governing the Earth’s free oscillations.

Alternatively, we may exploit the known distribution of amplitudes of single peaks over the surface of the Earth to invert for the location of these peaks (“mode splitting”). The small frequency shifts $\delta\omega^m$ are themselves the eigenvalues of a splitting matrix $\mathbf{H}$ of which the elements are linearly related to the variation of density and elastic parameters in the Earth. We can estimate $\mathbf{H}$ from the seismic data using autoregressive filtering techniques. This way we avoid any ray-theoretical approximations and obtain a three-dimensional integral constraint that can be used to solve for the large-scale variations in the Earth’s density and elastic properties.

Finite-Frequency Tomography

Modern, broadband digital instrumentation allows for a robust estimation of the delay of an observed seismic wave $s_1(t)$ with respect to a theoretically predicted (“synthetic”) waveform $s_2(t)$ or with respect to the same phase observed elsewhere, by locating the maximum in the cross-correlation $C(t)$ between the two signals:

$$\delta T = \arg \max_{t \in [\tau_1, \tau_2]} C(t), C(t) = \int_{\tau_1}^{\tau_2} s_1(\tau) s_2(\tau - t) d\tau, \quad (8)$$

where the integration interval (τ_1, τ_2) usually (but not necessarily) extends over the window containing a distinct arrivals such as P or S. The cross-correlation delay is influenced by the

distribution of energy within this window and thus fundamentally different from the delay measured by picking the onset of $s_1(t)$. Instead of a “shortest time” satisfying Snell’s law, it represents an integral measure over a time window that is at least as long as the dominant period of $s_1(t)$. While Eq. 1 is correct for onset times, it needs to be modified for delays measured by cross-correlation. Heterogeneities inside the Earth may influence the integral by scattering waves in the direction of the recording station that arrive within the time window. The most serious consequence is that energy may diffract around a small heterogeneity, thus masking or dominating the slower or faster arrival that has crossed the heterogeneity. This phenomenon of “wavefront healing” biases observed delay times to zero, especially if the anomaly is located at some distance from the source and receiver. Nolet and Dahlen (2000) give a theoretical analysis of wavefront healing.

Taking wave diffraction into account leads to a three-dimensional integral constraint of the form:

$$\delta T = \int_V K(\mathbf{r}) \delta\sigma(\mathbf{r}) d^3\mathbf{r}, \quad (9)$$

where the kernel $K(\mathbf{r})$ can be efficiently calculated using ray theory for scattered waves. The effective volume of integration V is roughly equivalent to that of the Fresnel zone of the ray, where the sensitivity is largest. Since a positive change in rock velocity gives a negative change in the travel time, the kernel values within the Fresnel zone are negative. There are, however, sidelobes with a positive sign, where a positive velocity anomaly would give a positive change in the observed travel time. This may seem counter-intuitive, but it is possible because cross-correlations involve a finite time window, and it is the energy distribution in this window, rather than the onset of the wave, that defines the delay measured in this way.

An example of a finite-frequency kernel is shown in Fig. 2. Remarkably, the cross-correlation travel time is insensitive to perturbations in the Earth’s properties at the center of the kernel, which is at location of the ray path. Because of this hole in the sensitivity and their general shape, finite-frequency kernels are often referred to as “banana-doughnut” kernels. Numerical tests have shown that the finite-frequency kernels accurately model the loss of signal caused by wavefront healing, the gradual reduction of a delay caused by waves diffracting around a small heterogeneity. By estimating delays in different frequency bands, one gains information about the size of the heterogeneity in the Earth.

Though finite-frequency kernels were initially proposed to provide a better theoretical modeling of long-period signals affected by wavefront healing, they offer the advantage of being able to model the healing as a function of frequency, and thus obtain independent information on the size of the

Seismic Tomography, Fig. 2 The sensitivity of the cross-correlation time to the earth structure, for a long-period P wave from a surface source at 0° N, 120° W, recorded at a distance of 60°. The kernel is plotted in an equatorial cross-section of the mantle, the color scale runs from large negative values (red) to positive (blue). The sensitivity is zero (yellow) at the location of the geometrical ray-path, forming a “doughnut hole” in the banana-shaped kernel. The white line denoted the kernel values at 90°

heterogeneity. Such multiple-frequency tomography may significantly increase resolution (Sigloch et al. 2008). Finite-frequency sensitivity can also be formulated for the amplitude perturbations caused by attenuation and by focusing/defocusing (focusing cannot be handled with ray-theory because ray theory does not model amplitudes correctly at low frequency and is very nonlinear at high frequency).

Instead of inverting for a cross-correlation delay or an amplitude perturbation, one can formulate a 3D sensitivity directly for the observed time series, though this has the disadvantage that the observed and predicted waveforms have to be close enough in phase that the phase difference can be adequately modeled by adding a small perturbation to the waveform itself (in fact approximating $e^{i\phi} \approx 1 + i\phi$). This limits the inversion to waveforms with small time mismatches, in contrast to the delays estimated through Eq. 8, which remain linear for large anomalies.

All types of data – delays, amplitudes, and waveform mismatches – can be iteratively inverted using an adjoint approach, in which best fitting model is sought along the gradient $\nabla_m \chi^2$ (Tromp et al. 2005), e.g., for delay times scaled to unit variance:

$$\nabla_m \chi^2 = \mathbf{A}^T (\mathbf{A} \mathbf{m} - \delta \mathbf{T}) \quad (10)$$

For waveforms, the matrix $\mathbf{A}$ is in this case the matrix representation of a finite-difference or spectral-element algorithm that produces the predicted seismograms and $\mathbf{A}^T$ is the adjoint operator that projects the seismograms back in time. Since this allows one to backproject all residual seismograms for one earthquake with only one calculation, and since only the product of the adjoint matrix and the residual data vector is needed, this allows us to avoid computing the partial

derivatives separately for each datum δT_i with respect to each model parameter m_k . The adjoint approach has some advantages over a direct matrix inversion for large-scale problems, in particular those with few sources and many stations, because it does not require the storage of a large matrix, which is especially important for waveform inversions. Since the gradient is recalculated for every iteration, the method lends itself naturally to tomographic inversions that are strongly nonlinear, such as one expects for imaging of the crust or the D'' region just above the Earth's core. However, Mercier and Nolet (2013) showed that the inversion of delay times measured by cross-correlation are highly linear in most depth regions of the Earth. For a technical description of the adjoint method (also referred to as “residual back-propagation”) see the article: Seismic, Waveform Modeling and Tomography.

Summary

The equations of seismic tomography are integral equations; the observations are weighted averages of the properties of the Earth (Eq. 9). Though often treated as line integrals, assuming ray theory is valid, a delay of a 1 Hz P wave measured by cross-correlation senses a volume or Fresnel zone inside the Earth that is several hundred km wide. The inversion of integral equations demands care to avoid that noise (errors in the data) are interpreted as small differences in observed delays, which may require large variations in the Earth's properties. This imposes a fundamental limitation to the resolving power of seismic waves that even finite-frequency theory or waveform modeling cannot completely avoid. The theoretically best available horizontal resolution, using the highest observable seismic frequencies, is of the order of hundred km in the lower mantle. In practice, this lower limit is not yet reached because of the limited coverage of the Earth's surface with seismic stations. On land, the coverage can be improved markedly using temporary deployments of seismic arrays, but this is much more difficult and expensive to do in the oceanic domain. Major improvements on a global scale are therefore to be expected only if we solve the problem of oceanic seismometry. It is expected that floating seismographs (see article “Mermaids”), and possibly also strain signals extracted from fiber optic cables on the ocean floor, will soon make this possible.

Seismic Velocity and Temperature Relationships

Kalachand Sain

Wadia Institute of Himalayan Geology, Dehradun, India

Definition

Seismic velocity is defined as the speed with which a seismic wave travels through a medium and is measured in km/s, whereas temperature is a physical property that quantitatively expresses hot and cold. It is the manifestation of thermal energy, present in all matter, and is expressed in °C. Seismic velocities of subsurface rocks decrease with temperature but experience opposite effects due to increase in pressure (depth).

Velocity-temperature equation: On an average, the pressure increases at a rate of 30 MPa/km and the temperature raises at a rate of 25 °C/km from surface to deeper parts of the Earth. Since seismic velocity (V) decreases with temperature (T) and increases with pressure (P), we need to know the combined effects of P and T for interpreting seismic velocities at different depths. The generalized relation for the variation of velocity with depth Z can be expressed as

$$\frac{dV}{dZ} = \left(\frac{dV}{dP}\right)_T \frac{dP}{dZ} + \left(\frac{dV}{dT}\right)_P \frac{dT}{dZ} \quad (1)$$

where $\left(\frac{dV}{dP}\right)_T$ denotes the change in velocity with pressure at constant temperature (isotherm), and $\left(\frac{dV}{dT}\right)_P$ is the change in velocity with temperature at constant pressure (isobar). $\frac{dP}{dZ}$ and $\frac{dT}{dZ}$ are the vertical pressure and temperature gradients respectively.

To make petrological inferences, the crustal and lithospheric seismic velocities are to be corrected to the experimental reference values (i.e., constant pressure of 100 MPa and room temperature of 20 °C). Rybach and Buntebarth (1984) have defined the correction factor (f) to the P-wave velocity (V_P) at a given P and T as

$$\begin{aligned} V_P(20^\circ\text{C}, 100\text{MPa}) &= V_P(P, T)f \\ &= V_P \left[1 + \Delta T \frac{\partial V_P}{\partial T} - \Delta P \frac{\partial V_P}{\partial P} \right] \end{aligned} \quad (2)$$

The correction factors for granites, gneisses, amphibolites, gabbros, and ultrabasic rocks of both Precambrian and Phanerozoic period are given in Table 2 of Rybach and Buntebarth (1984). As per eq. (2), the corrections to the field velocities at depths from 1 to 50 km are of the order of ± 0.1 km/s. As a

matter of fact, the increase in velocity with pressure is nearly compensated by the decrease in velocity due to temperature increasing with depth.

Velocity variation with temperature for some reservoir rocks: The change in seismic velocities with temperature also depends on the saturation of rock. The results of Wang and Nur (1990) in heavy oil sands and hydrocarbon-saturated rocks show that both V_P and V_S decrease with increasing temperature. Since V_S is not affected by fluids, the decrease in V_S is due to changes in rock frame and in rock fluid interactions. The V_P in heavy oil sands (Tosaya et al. 1987) shows a dramatic decrease. As temperature increases from 25 °C to 125 °C, V_P can drop by 35% to almost 90%. Heavy oils are highly viscous and a strong interfacial force exists between oil and rock grains. The viscosity of oil and interfacial force decrease due to rise in temperature, which decreases the rigidity and bulk modulus leading to reduction in seismic velocities. For temperature up to about 150 °C, changes in pore fluid properties play dominant role in changing the velocity. Though there is a negative correlation between seismic velocity and temperature, Ryan and Shalev (2014), from drilling results in Montserrat (West Indies), showed that above ~220 °C there is a positive correlation into a geothermal reservoir. They hypothesized that anomalous variation is controlled by the first-order hydrothermal mineral assemblage.

Perry et al. (2006) compared temperature and velocity of Moho refracted phase, Pn, for various mineralogical models of the upper mantle from seismic refraction and heat flow studies and demonstrated that the theoretical velocity-temperature conversion used for interpretation of seismic tomographic models is in good agreement with the observations. Schutt et al. (2018) used the velocity-temperature relationship in modeling the deep geotherm within few km of the uppermost mantle in western USA using the Pn velocity.

The temperature is a fundamental factor in determining the lithospheric strength, thickness, buoyancy, and mass flux for geoscientific investigation of the subsurface. For example, if temperature of the lower crust is found sufficiently warm, the lower crust may be weak that can decouple the upper crustal and mantle strain fields, affecting the style of deformation. Based on deep seismic studies and gravity modeling in a huge territory of north Eurasia, Yegorova and Pavlenkova (2015) showed that seismic velocities in the upper mantle mainly reflect the temperature regime with no direct velocity-density relationship, as characterized by high-velocity, low-density and low heat flow.

Acknowledgments The author is grateful to the Director of Wadia Institute of Himalayan Geology, Dehradun, for his consent to publish this work. This has a Wadia contribution WIHG/0037.

Seismic intrinsic attenuation

Definition

Linear viscoelastic attenuation. The fractional loss of seismic energy in a material in which elastic deformation (strain) induced by one cycle of a seismic wave or mode lags in time the applied stress associated with the wave or mode.

Apparent seismic attenuation. The loss of energy in a propagating seismic wave or standing mode due to viscoelasticity combined with the loss of scattered energy redistributed in time and space by heterogeneity.

Introduction

The amplitude of seismic waves decreases with increasing distance from earthquake, explosion, and impact sources. How this amplitude decrease occurs and how it depends on frequency of the seismic waves are fundamentally important to the efforts to describe Earth structure and seismic sources.

The decay of amplitude of seismic waves with increasing distance of propagation through Earth is known as seismic wave attenuation. The attenuation occurring under high-temperature rheological conditions in the Earth's interior can be called seismic viscoelastic attenuation.

Seismic attenuation and its variation with location within Earth are useful for determining the anelastic properties of Earth as a function of depth. Seismic attenuation also shows large lateral variations that can be related to lateral variations in geological and geophysical properties not as easily detected by measurement of seismic velocities. In addition to providing information on a physical property, research in seismic attenuation has also been strongly motivated by more practical problems. One problem has been the prediction of ground motion due to probable earthquakes in different regions. The frequency content and decay with distance of this strong ground motion is an important input to the design of earthquake-resistant structures and to disaster forecasting (see ► [“Earthquakes, Strong-Ground Motion”](#)). Another problem has been to estimate the size and detectability of underground nuclear tests (see ► [“Seismic Monitoring of Nuclear Explosions”](#)).

How Do Seismic Waves Attenuate?

The attenuation of seismic waves is due to three effects: geometric spreading, intrinsic attenuation, and scattering.

Geometric Spreading

Geometric spreading leads to an energy density decrease that occurs as an elastic wave front expands with increasing distance from its source. In a homogeneous Earth of constant velocity and density, the geometric spreading of a seismic body wave is proportional to the reciprocal of the distance between source and receiver. In the real Earth, velocity and density vary strongly with depth and less so laterally. Given a model of this variation, however, the geometric spreading of a body wave can be easily calculated (see ► [“Seismic Ray Theory”](#)).

Intrinsic Viscoelastic Attenuation

Intrinsic (viscoelastic) attenuation occurs at high temperatures due to internal friction during the passage of an elastic wave. It is controlled by the thermal and defect properties of the medium in which the wave is propagating. It can result in a phase lag between strain and stress giving rise to strain energy dissipation and associated frequency dependence (dispersion) of the relevant modulus or speed of the propagating elastic wave. The microscopic mechanisms of intrinsic attenuation have been described in several different ways, including the resistive and viscous properties of oscillator models of the atoms in crystalline lattices, the movement of interstitial fluids

between grain boundaries and cracks (O'Connell and Budiansky 1977), and the frictional sliding of cracks. Jackson (1993, 2007) reviews laboratory experiments that investigate microscopic mechanisms of intrinsic attenuation. This entry concentrates on the measurement of intrinsic attenuation from recordings of seismic waves at great distance.

Scattering Attenuation

Scattering attenuation occurs when elastic energy is scattered and redistributed into directions away from the receiver or into waves arriving in later time windows at the receiver (see ► [“Seismic Waves, Scattering”](#)). Scattering takes place by reflection, refraction, and mode conversion of elastic energy by wavelength-scale irregularities in the medium. These irregularities are discontinuous or rapid variations in the velocity and/or density of the medium. In the crust and uppermost mantle, variations in velocity and density can be particularly strong in the lateral as well as the vertical direction.

Linear Viscoelasticity

Rheology

A stress is a vector force per unit area applied to a solid. A strain is nondimensional measure of the deformation of the solid due to the applied stress, such as the change in a length element divided by the original length. The equation that relates stress and strain is sometimes termed the *rheology* or the *constitutive* relation (see ► [“Mantle Viscosity”](#)). A linear viscoelastic rheology can be described by a linear differential equation:

$$L_1 \sigma(t) = L_2 \varepsilon(t) \quad (1)$$

where L_1 and L_2 are any linear combinations of operators of the time, $\frac{d^n}{dt^n}$ or $\int dt^n$. This type of equation can describe both the elastic strain of a material over a short time interval of applied stress as well as its viscous behavior and flow over a longer time interval (Gross 1953; Nowick and Berry 1972; Jackson et al. 2005; Kohlstedt 2007).

Anelastic Hysteresis

Seismic oscillations at distances beyond several fault lengths from an earthquake excite small strains less than 10^{-6} . These strains are recoverable during a cycle of seismic oscillation and lag the applied stress of the oscillation in time. Because of the time lag, a cycle of increasing and decreasing stress does not produce a perfectly proportional increase and decrease in strain. Instead a hysteresis loop occurs (Fig. 1). The area enclosed by the hysteresis loop is a measure of the energy lost due to heat and internal friction. During the stress cycle associated with the passage of a seismic wave, the

Seismic Viscoelastic Attenuation, Fig. 1 Stress-strain hysteresis curve showing the behavior of strain during a cycle of applied stress induced by a propagating seismic wave

energy lost to this internal friction is not available to deform the adjacent regions of the solid ahead of the wave front, and therefore the amplitude of the wave decreases.

From the hysteresis curve, one can see that the stress-strain relation cannot be described by a simple constant of proportionality in the time domain. A more complicated relation involving an integral over time is required to describe strain at any instant of time as a function of the prior time history of the applied stress. By Fourier transforming the rheologic equation, however, and keeping only terms describing the short-term anelastic behavior, the stress-strain relation can be simply expressed either by means of a complex elastic modulus $\hat{G}(\omega)$ or by its reciprocal, $\hat{J}(\omega)$ the complex elastic compliance:

$$\hat{\sigma}(\omega) = \hat{G}(\omega) \hat{\varepsilon}(\omega) \quad (2a)$$

$$\hat{\varepsilon}(\omega) = \hat{J}(\omega) \hat{\sigma}(\omega) \quad (2b)$$

The elastic modulus $\hat{G}$ and compliance $\hat{J}$ must be complex numbers to describe the phase lag of strain. They must also be frequency dependent because the phase lag of strain depends on the time history of stress, the shape of the hysteresis curve changing with different load histories. All the usual measures of anelasticity, including the frequency-dependent quality factor $Q(\omega)$ and the dispersion of the complex phase velocity $\hat{v}(\omega)$, can be expressed in terms of the complex modulus or complex compliance (Jackson and Anderson 1970). The trend of the frequency dependencies can be inferred from the time lag of strain from applied stress.

A feature of the complex modulus is that its real part will be smaller at zero or very low frequency and larger at infinite or very high frequency. That is, there will be an instantaneous response of strain to the applied stress, which is smaller than the eventual equilibrium response after longer time. The difference between the modulus at infinite frequency $G(\infty)$, representing the instantaneous or *unrelaxed* response, and the

low-frequency limit of the modulus $G(0)$, for the equilibrium or *relaxed* response, is called the *modulus defect* ΔG , with

$$\Delta G = G(\infty) - G(0) \quad (3)$$

The relaxed and unrelaxed moduli are pure real numbers that can be determined by observing a sequence of hysteresis curves for increasing frequencies of monochromatic loads. The frequency dependence of the real part of the modulus G at frequencies between 0 and ∞ implies that the propagation of a stress pulse will be dispersive, with higher frequencies traveling faster than lower frequencies.

Q and Complex Velocity

Since simple mechanical systems, composed of springs and dashpots and simple electric circuits, also obey linear equations of the form of Eqs. 2a and 2b, there are analogies between the quantities describing these systems and quantities in the stress-strain relation. For example, strain behaves like voltage, stress like current, and the complex compliance $\hat{J}(\omega)$ like the complex impedance of an electric circuit. Similar to the resonance phenomenon in circuits and mechanical systems, a Q can be defined by the average energy W per cycle divided by the energy lost or work done per cycle, ΔW :

$$Q = \frac{W}{\Delta W} \quad (4)$$

Large Q 's imply small energy loss; small Q 's imply large loss. Q is a measure of the area contained in the hysteresis loop of a stress-strain cycle. The inverse of Eq. 4, Q^{-1} , is sometimes simply termed the *attenuation or internal friction* (Knopoff 1964).

Plane waves of frequency ω and propagating in the + or - x direction can be defined by the phasor $\exp[i(\omega t \mp kx)]$ where $\hat{k}$ is a complex wave number $\frac{\omega}{\hat{c}}$ and $\hat{c}$ is a complex velocity defined from the local density ρ and complex modulus $\hat{G}$, with

$$\hat{c} = \sqrt{\frac{\hat{G}}{\rho}} \quad (5)$$

From the average energy density and loss per cycle of a complex plane wave, it can be shown that $Q = \frac{\text{Re}(\hat{G})}{\text{Im}(\hat{G})}$.

It is often less confusing to report the reciprocal parameter Q^{-1} , which represents the usually small perturbations to perfect elasticity.

The $Q^{-1}(\omega)$ Relaxation Spectrum

Since $\hat{G}$ depends on frequency, Q also depends on frequency. Zener (1960) described the frequency-dependent effects on an elastic modulus of a solid having a single characteristic time τ

for the relaxation of stress. A distribution of relaxation times can be constructed to give a Q^{-1} having a general dependence on frequency. The function $Q^{-1}(\omega)$ is called the *relaxation spectrum*. In the Earth and in many solid materials, the relaxation spectrum is observed to be slowly varying and nearly constant over a broadband of frequencies (Lekić et al. 2009). A theoretical requirement is that the attenuation Q^{-1} cannot increase faster than ω^1 or decrease faster than ω^{-1} . Figure 2 shows how a continuous distribution of relaxations can produce a Q^{-1} that is nearly constant with a frequency over a broadband. Once the limits of an absorption band are specified, however, it is not possible to have an arbitrarily high Q^{-1} (low viscoelastic Q) over an arbitrarily broad frequency band without making an unrealistically large modulus defect ΔG . Measured modulus defects in shear are typically less than 25%.

Velocity Dispersion

Although the dispersion in elastic moduli had long been known and predicted from the theories of viscoelasticity, it only began to be widely recognized in seismology when velocity models determined in the low-frequency band from the normal modes of the Earth (0.0001–0.01 Hz) were compared with velocity models determined in a high-frequency band (0.1–10 Hz) of body waves (Dziewonski and Anderson 1981). The models were found to differ, and the difference was found to agree with the amount of dispersion predicted from average Q models of the Earth. For example, since the Preliminary Reference Earth Model (PREM) was derived from observations of both the travel times of body waves and the eigenfrequencies of free oscillations, it reports velocities referenced at both 0.001 Hz and 1 Hz.

Another more subtle effect of this velocity dispersion can be seen in the propagation of pulses as body waves. A stress

disturbance that propagates from its point of initiation as a symmetric narrow Gaussian or triangle-shaped function in time gradually evolves into an asymmetric pulse (Fig. 3). High frequencies traveling faster than low frequencies are preferentially loaded into the front of the pulse (Futterman 1962; Carpenter 1967). Common theories for the physical mechanism of earthquakes as either frictional slip on a plane or a propagating crack triggered by tectonic stress often predict a far-field displacement pulse that has either a different or opposite form of asymmetry than that predicted for the effect of viscoelastic attenuation. These differences can assist in separating the effects of the source-time history from the effects of viscoelastic attenuation.

Effects of Scattering

Equivalent Medium

At frequencies that are so low that wavelengths are much larger than the characteristic scales of heterogeneity, the attenuative effects of scattering can usually be neglected. At sufficiently low frequency, little energy is lost to scattering, and the medium behaves like an equivalent medium, having properties that are an average of small-scale heterogeneities.

Stochastic Dispersion

The most complicated domain to calculate the effects of scattering is where the wavelength is of the order of the scale length of the heterogeneity (Fig. 4). In this domain, the presence of heterogeneities can profoundly alter the propagation of the wavefield, affecting both the initial cycle of a body wave pulse and the motion immediately following the initial cycle or *coda*. At distances less than 2000 km and frequencies

Seismic Viscoelastic Attenuation, Fig. 2 Viscoelastic dispersion of seismic velocity (*top*) and attenuation (*bottom*) showing a relaxation spectrum constant with frequency between two corner frequencies

Seismic Viscoelastic Attenuation, Fig. 3 Pulse distortion showing the effects of viscoelastic dispersion for variable low-frequency corner and peak attenuation

higher than 1 Hz, scattered coda waves dominate the signature of S waves propagating in Earth's heterogeneous crust. Sato et al. (2012) review the theory and measurement of the apparent attenuation Q_C^{-1} of these coda waves. They describe strategies to separate the contribution of intrinsic from scattering attenuation to Q_C^{-1} based on the shape and frequency content of the energy envelopes of coda waves.

For longer range, some of the important effects of scattering can be illustrated by propagating body waves in a one-dimensional medium consisting of thin planar layers in which the velocity in each layer is assigned randomly (O'Doherty and Anstey 1971; Richards and Menke 1983). In fully three-dimensional structure, many of the effects of multiple scattering can be efficiently calculated by a radiative transport modeling of the energy of coda wave envelopes (Margerin 2013). These calculations predict body waves to exhibit a stochastic dispersion in which high-frequency energy is transferred into the coda. Neglect of stochastic dispersion can bias some estimates of intrinsic attenuation. Estimates of the spectral amplitude over a narrow time window can differ depending on the length of window analyzed, with less attenuation of higher frequencies estimated from longer time windows.

Pulse measurements such as width and rise time may also be biased because higher-frequency energy has been transferred out of the pulse into the later coda. This behavior is opposite to the effects of intrinsic attenuation on a propagating pulse, in which higher frequencies arrive at the beginning of the pulse. A symmetrically shaped displacement source pulse loses less of its symmetry as it propagates through the heterogeneous medium (Fig. 5). Anisotropy of the scale lengths of heterogeneity can also be important factor (Hong and Wu 2005), attenuation being strongest for paths for which the wavelength is of the order of the characteristic scale length in the medium in that direction.

Seismic Viscoelastic Attenuation, Fig. 4 Example heterogeneity in the Earth and the directional dependence of attenuation of a body wave pulse for wavelengths that are approximately equal to either the dominant scale length (isotropic heterogeneity) or the dominant scale length in the direction of propagation (anisotropic heterogeneity)

Effects of Anisotropy

The existence of general anisotropy in the real part of the elastic modulus has the potential to bias some estimates of anelastic attenuation from either shear wave pulses or surface waves. In a medium having general anisotropy, the decompositions of shear wave motion into SH and SV motion will each contain the interference of two orthogonal shear wave polarizations that are neither SH nor SV (see ► [“Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting”](#)). The broadening of the SH component due to the interference of two quasi-S waves arriving close in time can be mistaken for the broadening due to anelastic attenuation. The regions of the deep Earth characterized by the strongest elastic anisotropy are the upper 400 km of the mantle (Silver 1996) and the lowermost 400 km of the mantle near the core-mantle boundary (Panning and Romanowicz, Panning and Romanowicz 2006). The effects of elastic anisotropy must be removed by combined analysis of SV and SH components of motion, resolving the polarizations of two quasi-S waves, before viscoelastic attenuation can be properly measured.

Measurement and Modeling Attenuation

Measurements of amplitude of seismic waves may be taken directly from seismograms or from their frequency spectra. To measure the attenuation, we must predict its effects from a model and vary the parameters of the model to fit the observed amplitude, amplitude ratio, or waveform. The effects of intrinsic attenuation in any modeling algorithm operating in

Seismic Viscoelastic Attenuation, Fig. 5 Pulse distortion showing the effects of scattering attenuation for variable scale lengths and velocity perturbation calculated by Cormier and Li (2002) using the Dynamic Composite Elastic Modulus (DYCEM) theory of Kaelin and Johnson (1998)

the frequency domain can be simply obtained by allowing elastic moduli and propagation velocities to become complex. Elastic boundary conditions, reflection and transmission at boundaries, travel times, and amplitudes are calculated exactly as in a non-attenuating solid but with elastic moduli and associated velocities analytically continued to complex values. This step of analytic continuation of real moduli to complex moduli is the same whether one wishes to predict the waveform of a body wave or surface wave or spectrum of free oscillations. The size of the imaginary part of the elastic moduli, parameterized by the value of Q^{-1} as a function of depth and frequency, is chosen to match an observed waveform, spectrum, amplitude ratio, or spectral ratio.

The Attenuation Operator for Body Waves

As an example of these procedures, consider an experiment with body waves. The effects on a body wave of source radiation, geometric spreading, reflection-transmission, and intrinsic attenuation are most conveniently expressed in the frequency domain by a product of complex functions. The complex $\hat{\Omega}(\vec{x}, \omega)$ spectrum of a body wave propagation from a point $\vec{x}_o$ to a receiver at $\vec{x}$ is

$$\hat{\Omega}(\vec{x}, \omega) = \bar{B}(\vec{x}_o, \vec{x}, \omega) \hat{S}(\omega) \hat{A}(\omega) \quad (6)$$

The function $\hat{S}(\omega)$ is the Fourier transform of the source-time function. $\bar{B}(\vec{x}_o, \vec{x}, \omega)$ incorporates a product of reflection-transmission coefficients, reverberations at source and receiver, geometric spreading, and source radiation pattern. In the frequency domain, an attenuation operator $\hat{A}(\omega)$ is defined by

$$\hat{A}(\omega) = \exp \left[i\omega \hat{T}(\omega) \right] \quad (7)$$

where $\hat{T}(\omega)$ is the complex travel time obtained by integrating the reciprocal of complex velocity along a ray or normal to the wave front of the body wave:

$$\hat{T}(\omega) = \int_{\text{ray}} \frac{ds}{\hat{c}(\omega)} \quad (8)$$

The effects of attenuation on reflection-transmission coefficients and geometric spreading through the complex velocity are much smaller and can be neglected unless the attenuation is very large (Q is very small). For $Q \gg 1$, $\hat{A}(\omega)$ can be rewritten as

$$\hat{A}(\omega) = \exp \left[\frac{-\omega t^*(\omega)}{2} \right] \exp \left\{ i\omega \left[\text{Re} \hat{T}(\infty) - \frac{H[t^*(\omega)]}{2} \right] \right\} \quad (9)$$

where

$$t^*(\omega) = \int_{\text{ray}} \frac{Q^{-1}}{\hat{c}(\omega)} ds \quad (10)$$

In Eq. 9, the attenuation effect is contained in the factor $\exp \left[\frac{-\omega t^*(\omega)}{2} \right]$, and the dispersive effect is in the factor $\exp \left\{ i\omega \left[\text{Re} \hat{T}(\infty) - \frac{H[t^*(\omega)]}{2} \right] \right\}$. The operator H is a Hilbert transform. In a band of frequencies in which Q and t^* are nearly constant

$$H[t^*(\omega)]/2 = \frac{\ln(\omega/\omega_0)}{\pi} t^* \quad (11)$$

where ω_0 is a reference frequency contained in the band (Liu et al. 1976). The value of $T(\infty)$ need not be known and can be replaced by some reference time or predicted from an Earth model for the phase being analyzed. The Hilbert transform relation in Eq. 11 for the dispersive phase of $\hat{A}(\omega)$ says that $\hat{A}(\omega)$ must be a minimum phase filter in the frequency domain. In general, the Fourier transform of the source-time function, $\hat{S}(\omega)$, is not a minimum phase filter, which can help in the separation and discrimination of the source spectrum from the effects of $\hat{A}(\omega)$ in the total expression for the far-field spectrum $\hat{\Omega}(\vec{x}, \omega)$.

The phase given by Eq. 11 will be accurate only between and far from the low- and high-frequency corners of the relaxation spectrum. Accurate representations of $\hat{A}(\omega)$ across a broad frequency band can be obtained for general relaxation spectra by substituting expressions for complex velocity $\hat{c}(\omega)$ in Eq. 8 obtained by superposing multiple Zener relaxations centered on single relaxation times whose strength is varied to achieve a desired shape for the relaxation spectrum. A useful expression for $\hat{c}(\omega)$ that is accurate for all frequencies across a relaxation spectrum, which is flat between two corner frequencies, can be derived from formulae for complex modulus given by Minster (1978) and is

$$\hat{c}(\omega) = c_{\text{ref}}(\omega_0) \frac{\sqrt{1 + 2\pi Q^{-1} \ln[\psi(\omega)]}}{\text{Re} \sqrt{1 + 2\pi Q^{-1} \ln[\psi(\omega_0)]}} \quad (12a)$$

where

$$\psi(\omega) = \frac{i\omega + 1/\tau_1}{i\omega + 1/\tau_2} \quad (12b)$$

with τ_1 and τ_2 the relaxation times corresponding to the low- and high-frequency corners, respectively. $c_{\text{ref}}(\omega_0)$ is a real velocity at the reference frequency ω_0 .

Most measurements of attenuation attempt to measure only the amplitude effect of attenuation through the term $\exp[-\omega t^*(\omega)/2]$ from the spectral shape of body waves. There are basically two types of experiments commonly reported: (1) matching of spectral decay rates and (2) spectral ratios. In experiment (1), a shape for the displacement source spectrum $\hat{S}(\omega)$ is assumed usually to be a flat level followed by a decay of ω^{-2} above a corner frequency. The additional decay observed at high frequencies in data spectra is taken as a measure of t^* in $\exp[-\omega t^*(\omega)/2]$. In experiment (2), a ratio of two different seismic phases from the same source is observed in which the source spectrum is assumed to approximately cancel and the factor related to ratios of geometric spreading and near source and receiver crustal reverberations can be assumed to contribute a simple constant scalar factor. If the phases analyzed are recorded at the same receiver and are incident at nearly the same angles, then crustal reverberations at the source and receiver will approximately cancel. Both types of experiments usually apply some type of smoothing to the spectra to remove biasing effects of spectral holes caused by interfering crustal multiples, source complexities, scattering, and multipathing that are not included in the simple propagation model. Figure 6 illustrates an attenuation experiment of this type.

Since t^* measures only the path-integrated effect of attenuation, many such experiments for different ray paths, bottoming at a range of different depths, are needed to construct a model of Q as a function of depth. Serious

breakdowns in this approach, however, exist for cases in which the factorization of the observed spectrum into a product of a geometric spreading, source spectrum, and crustal effects is no longer accurate. One such case is when the body waves in question experience frequency-dependent effects of diffraction near caustics or grazing incidence to discontinuities. The spectral ratios of PKnKP waves, for example, are dominated by the effects of frequency-dependent reflection and transmission coefficients at grazing incidence to the core-mantle boundary. Instead of decreasing linearly with increasing frequency, an observed spectral ratio increases with frequency and exhibits a curvature in a log-log plot, which is consistent with a Q near infinity ($Q^{-1} = 0$) in the other core (Cormier and Richards 1976).

It is becoming more common to model and invert for viscoelastic attenuation parameters in the time domain, including not only the magnitude of the viscoelastic attenuation parameter Q^{-1} but also its frequency dependence. Examples of such a study are the inversions for Q^{-1} in the inner core assuming either a viscoelastic (Li and Cormier 2002) or a scattering origin of attenuation (Cormier and Li 2002). In these studies, the combined effects of mantle attenuation and source-time function were first modeled by fitting P waves observed in the great circle range 30–90°. Attenuation in the liquid outer core was assumed to be zero. Parameters defining a viscoelastic relaxation spectrum in the inner core were then varied to match the observed PKIKP waveforms. Care must be taken to examine a broad range of attenuation parameters because waveform inversions of this type are very nonlinear. Equally good fits between observed and predicted waveforms can sometimes be achieved with quite different domains of parameters.

Seismic Viscoelastic Attenuation, Fig. 6 The steps (top) to measure the path-integrated attenuation t^* of P waves in the mantle from a log-log plot (bottom) of stacked PP and P spectra (A_{PP} and A_P). The distances of observed P and PP spectra are chosen such that each turning ray path of PP is identical in shape and length to that of the single turning ray path of P in the mantle. (Adapted from figures in Warren and Shearer 2000)

Free Oscillations and Surface Waves

Measurements of attenuation in the low-frequency band of the free oscillations of the Earth are conducted in the frequency domain by observing the width of the individual resonance peaks associated with each mode. These measurements face special problems associated with the broadening produced by lateral heterogeneity of elastic Earth structure. This heterogeneity splits the degenerate modes of a radially symmetric Earth, making a set of modes that would have the same frequency have slightly different frequencies. The slightly different frequencies of the split modes may not be easily resolved in the data spectra and can be confused with the broadening of a single resonance peak of a mode caused by attenuation.

Lateral heterogeneity also complicates the measurement of viscoelastic attenuation of surface waves. Heterogeneity introduces focusing, defocusing, and multipathing, all of which must be accurately modeled to understand the separate attenuative effects of viscoelasticity.

The frequency band of free oscillation and surface waves (0.001–0.1 Hz), however, offers the best hope of obtaining radially symmetric whole-Earth models of viscoelastic attenuation in this frequency band. This is because lateral variations in attenuation structure are averaged by the gravest modes of oscillation and surface waves that make multiple circuits around the Earth. Computational advances have made the division between free oscillation and surface wave studies fuzzier, with common approaches now amounting to time-domain modeling of complete low-frequency (<0.1 Hz) seismograms for combined three-dimensional models of viscoelasticity and heterogeneity.

Numerical Modeling

Fully numerical modeling of the seismic wavefield allows the combined effects of heterogeneity and viscoelasticity in three dimensions to be predicted. If the numerical technique is formulated in the frequency domain, substituting a complex velocity for an assumed relaxation spectrum can incorporate viscoelastic attenuation.

If the technique is formulated in the time domain by a finite difference approach, it is neither simple nor efficient to incorporate attenuation by convolution of the wavefield calculated in a non-attenuating medium with an attenuation operator $A(t)$, where $A(t)$ is the inverse Fourier transform of $\hat{A}(\omega)$ defined in Eq. 9. Instead, time-domain *memory functions* can be defined to describe a viscoelastic relaxation (Robertsson et al. 1994; Blanch et al. 1995) that can be integrated over time simultaneously with the equations describing particle velocity or displacement and stress. In practice, only three-memory functions, distributed evenly over the logarithm of their characteristic times, are required to simulate a broad frequency band in which Q^{-1} varies slowly.

Interpretation of Attenuation Measurements in the Earth

Shear Versus Bulk Attenuation

In the most general theory of viscoelasticity, it is possible to have energy loss occur during both a cycle of volumetric strain and shear strain. Since the velocity of a P wave depends on both the bulk and shear moduli, the attenuation Q_P^{-1} of a P wave can be written as a linear combination of the attenuations Q_P^{-1} and Q_S^{-1} defined from complex shear and bulk moduli:

$$Q_P^{-1} = L Q_S^{-1} + (1 - L) Q_K^{-1} \quad (13)$$

where $L = (4/3) (V_S/V_P)^2$ and V_P and V_S are the compressional and shear velocities, respectively (Anderson 1989). Although

plausible mechanisms for defects in bulk moduli have been found in both laboratory measurements and analytic models of specific attenuation mechanisms, measurements on real data find that bulk dissipation in the Earth is small and, in most cases, can be neglected. One exception may occur when the pressure and temperature state in a narrow depth regions of the Earth are close to those near a phase transition, either solid-liquid (Stevenson 1983) or solid-solid (Ricard and Chambat 2009). Except for these regions, intrinsic attenuation occurs almost entirely in shear, associated with lateral movement of lattice defects, grain boundaries, and/or fluids rather than with changes in material volume. Hence, assuming $Q_K^{-1} = 0$ and a Poisson solid, for which $V_P = \sqrt{3} V_S$,

$$Q_P^{-1} = \frac{4}{9} Q_S^{-1} \quad (14)$$

and the parameter for path-integrated attenuation of S waves t_S^* approximately equals $4t_P^*$. Most experiments confirm these values. Jackson (2007) reviews several situations in which measureable bulk attenuation exists. In the majority of these cases, Q_K^{-1} is no more than several percent of Q_S^{-1} . Morozov (2015), however, has demonstrated that assuming zero bulk attenuation leads to an auxetic medium, in which Poisson's ratio becomes negative. He proposes a starting assumption for bulk attenuation in which $Q_K^{-1} = 0.4 Q_S^{-1}$. This instead predicts $Q_P^{-1} = \frac{2}{3} Q_S^{-1}$ and $t_S^* = 2.6 t_P^*$. In support are observations at frequencies higher than 1 Hz that typically find $t_S^* < 4 t_P^*$. These observations may alternatively be an effect of scattering rather than bulk attenuation. With scattering, the apparent Q_P^{-1} can approach the apparent Q_S^{-1} , especially when it is estimated from pulse widths or spectra taken in a frequency band in which wavelengths are on the order of richest heterogeneity scale lengths of the medium. In this case, the assumption of viscoelastic attenuation occurring mainly in shear can aid in separating the effects of scattering from intrinsic attenuation.

Frequency Dependence

When the results of attenuation measurements determined from free oscillations and body waves in the 0.0001–0.1 Hz band began to be compared with observations of body wave spectra in the 1–10 Hz band, it became apparent that even under the assumption of a white source spectrum, an increase in Q with frequency was necessary to explain the amplitude of spectra in the 1–10 Hz band.

Thermal Activation

Frequency dependence of viscoelastic attenuation has been interpreted in terms of physical mechanisms of attenuation that are thermally activated. In these mechanisms, the low-frequency corner of an absorption band f_L is tied to a

relaxation time τ_L , where $f_L = 1/(2\pi\tau_L)$. The time τ_L depends on temperature T and pressure P as follows:

$$\tau_L = \tau_0 \exp\left(\frac{E^* + PV^*}{RT}\right) \quad (15)$$

where E^* and V^* are the activation energy and volume, respectively. Both the low- and high-frequency corners (f_L , f_H) of an absorption band are assumed to be similarly affected, temperature and pressure acting to slide the absorption band through a band of frequencies. A typical width to expect for the relaxation spectrum of the mantle is about five orders of magnitude in frequency, $\tau_L/\tau_H = 10^5$ (Minster and Anderson 1981; Anderson and Given 1982). A simplified model of an absorption band with depth in the Earth's mantle is shown in Fig. 7. The movement of the absorption band toward lower frequencies (longer periods) in the mantle below 400 km depth is consistent with the type of behavior shown in Fig. 8 for the t^*_S measured from shear waves of an earthquake. The difference in the location of the absorption band with respect to the band of seismic frequencies is consistent with models of the temperature and pressure profiles of the Earth's mantle for specific values of E^* and V^* . Relaxation times are also affected by the grain size of minerals, which may increase from millimeter to centimeter in the upper 400 km of the mantle (Faul and Jackson 2005). A rapid increase in temperature with depth can rapidly change the location of the absorption band with respect to the seismic band. Given a specific temperature profile, estimated values of the activation energy and volume, and grain size, a combined shear velocity and Q_S profile can be predicted and modified to fit an observed shear velocity profile.

Seismic Viscoelastic

Attenuation, Fig. 7

A frequency- and depth-dependent model of shear attenuation in the Earth's mantle derived from modeling broadband shear waves. This model has been used by the National Earthquake Information Center (NEIC) to correct for viscoelastic attenuation in the reported radiated elastic energy from earthquakes (Boatwright and Choy 1986; Choy and Boatwright 1995)

Regional Variations

Romanowicz and Mitchell (2015) review and interpret both global and many regional variations in intrinsic attenuation, including correlations with velocity perturbations. Tomographic images of perturbations to seismic velocities and attenuations in the mantle can qualitatively be interpreted as images of lateral temperature variations, leaving open the possibility of additional contributions to the observed heterogeneity from chemical variations. In the upper mantle, tectonically active regions overlain by radiogenically younger crust are more attenuating than the mantle underlying inactive regions such as continental shields (Fig. 9). The shape of the frequency dependence across the seismic band seems to remain similar in different regions, although the Q at a given frequency is lower for a tectonically young region than for an older shield region. Although motion of interstitial water and partial melt can produce high attenuation, grain boundary and defect mechanisms in a dry mantle have been shown to be equally effective in explaining regions of high attenuation in the upper mantle, except possibly behind island arcs and directly beneath active spreading ridges (Karato and Jung 1998; Faul and Jackson 2005).

Generally, perturbations in attenuation Q^{-1} inversely correlate with those in shear wave velocity (Roth et al. 2000). The correlations between shear velocity and shear attenuation appear to be consistent with thermal activation, in which the dispersive effect of attenuation acts jointly with variations in the high-frequency corner of the mantle relaxation spectrum to produce the observed variations in travel time and frequency content. Deep chemical differences between the upper mantle beneath shields and that beneath young continents and oceans and in the deep mantle, however, have

been suggested by comparing anomalies in shear velocity versus bulk velocity V_K , where $V_K = \sqrt{V_P^2 - (4/3)V_S^2}$. Milder lateral temperature differences in the mid- and lower mantle tend to make the relaxation spectrum more laterally stable in height, width, and location within a frequency band, reducing the observed lateral heterogeneity in velocity and attenuation in these regions.

Global models of attenuation of the type shown in Fig. 9 often do not have the resolving power to detect spatially

concentrated regions of high-attenuation and sharp spatial gradients found in regional studies beneath and near island arcs, mid-ocean spreading ridges, and hot mantle plumes. Long-established lateral variations, such as high-attenuation west of the Rocky Mountains in North America and low-attenuation east (Der et al. 1982), are not very apparent. Denser path coverage from either body or surface waves, however, is becoming increasingly available from sensor networks such as the USArray, making it possible to resolve smaller spatial scales (Fig. 10).

Seismic Viscoelastic Attenuation, Fig. 8 Path-integrated attenuation t^* of S waves in the mantle as a function of frequency determined from modeling broadband shear waves predicted from the frequency- and depth-dependent attenuation model shown in Fig. 7 (Choy and Cormier 1986)

Strain Dependence

Laboratory measurements of Q in rocks find dependence in strain beginning at strains of about 10^{-6} . The strain dependence decreases with increasing confining pressure. The Q is also strongly dependent on moisture and interstitial fluids between cracks in rocks and grain boundaries and soils. These observations are consistent with a physical mechanism of frictional sliding across cracks. Unlike viscoelastic relaxations, which are representative of all linear mechanisms, frictional sliding is an inherently nonlinear mechanism, depending on strain amplitude.

Estimates of the onset of nonlinearity may be made by calculating the strain associated with the seismic wave being analyzed. A rough estimate can be obtained by assuming that the wave front is a plane wave and dividing the particle velocity by the propagation velocity. For example, the particle

Seismic Viscoelastic Attenuation, Fig. 9 Inverted upper mantle shear velocity perturbations and shear attenuation. (From Dalton et al. 2009)

Seismic Viscoelastic Attenuation, Fig. 10 Regionally averaged Rayleigh wave attenuation at four periods. (From Bao et al. 2016). Longer periods sample deeper into the upper mantle

velocities of body waves observed in strong ground motion recordings from 0 km to 10 km from the hypocenter of a magnitude 6 earthquake are typically 0.01 m/s. If the body wave propagates at 3 km/s, the strain observed at the strong ground motion site is roughly 0.01 m/s divided by 3×10^3 m/s or $\text{strain} = 3.3 \times 10^{-5}$. This value is likely to be in the nonlinear regime of surficial rocks having open cracks or pores. In this strain regime, it becomes important to solve the elastic equation of motion with nonlinear terms in its rheology. Bataille and Calisto (2008) describe a perturbative approach to nonlinear rheology, demonstrating that strain dependence behaves in much the same way as elastic scattering does in linear elasticity, transferring energy to the later coda of a body wave. Delépine et al. (2009) describe a finite element approach to solve the problem of a more general 3-D, nonlinear, viscoelastic medium.

Summary

The intrinsic attenuation of seismic waves in the Earth has been found to be consistent with loss mechanisms that are thermally activated. The observed regional and frequency dependences of seismic Q agree with the expected lateral variations in a geotherm having a rapid temperature increase in the upper 400 km of the mantle, followed by a slower vertical and lateral variation in the mid- and lower mantle. High velocities correlate with regions of low attenuation; low seismic velocities correlate with regions of high attenuation. Measurements are consistent with losses primarily in shear rather than bulk deformations.

The existence of lateral heterogeneity in the elastic properties of the Earth complicates the measurement of viscoelastic properties. The longer scale lengths of heterogeneity can split modes of free oscillation and focus and defocus body waves and surface waves. Shorter scale lengths scatter seismic energy, broaden the waveforms of body waves, and redistribute energy into different time and angular windows. Observations that are useful for discriminating between the effects of scattering attenuation versus viscoelastic attenuation include the ratio of apparent P wave attenuation to apparent S wave attenuation, the rate of velocity dispersion within a frequency band, and the apparent viscoelastic modulus defect. The intensity of heterogeneity in percent fluctuation of velocities and densities is higher at shorter scale lengths at shallower depths in the Earth's crust and upper mantle. There is still a need for experiments that determine finer details of how the distribution of heterogeneity changes with depth and lateral location in the Earth and its anisotropy of scale lengths. Many, if not most, experiments have not completely removed the effects of heterogeneity on the apparent attenuation, making their results an upper bound on the viscoelastic Q^{-1} .

Laboratory experiments find a transition from linear to nonlinear rheology at strains of the order of 10^{-6} . The observed strain dependence of Q and its dependence on pressure in the shallow crust agree with a mechanism of frictional sliding of cracks. It is still unknown how and at what strain levels linear superposition begins to break down close to a seismic source.

Although a consensus has been reached on the major features and thermal activation of intrinsic attenuation in most of the Earth's upper mantle, this is less true of other deep regions of the Earth. Definitive experiments are still needed for the determination of Q^{-1} in the lowermost 400 km of the mantle, where increased lateral heterogeneity exists across a broad spatial spectrum, complicating the separation of its effects from those of viscoelasticity. In the inner core, there is still a need to understand the linkage between observed lateral variations in velocity, elastic anisotropy, and scattering (Calvet and Margerin 2008) as well as an apparent anisotropy of attenuation (Makinen et al. 2014).

Elastic waves in homogeneous and inhomogeneous media

Definition

The Earth is a complex medium containing heterogeneities over many scales. Its mechanical properties have great variability as well. The influence of heterogeneities on seismic wave propagation is therefore studied intensively by numerical modeling to explain observations. Modeling of seismic wave propagation is an essential ingredient in many aspects of exploration seismology, ranging from survey design methods to imaging and inversion algorithms. The increase in available computational power enabled the development of powerful numerical techniques for the accurate calculation of synthetic seismograms in three-dimensional (3D) models of the Earth. This chapter presents a glimpse of a variety of these numerical methods.

Introduction

In 1969, Keiiti Aki first focused attention on the appearance of continuous wave trains (called coda), in the tail portion of individual seismograms of local earthquakes as a direct evidence of the random heterogeneity of the lithosphere. Models for seismic wave propagation through inhomogeneous elastic media have been developed using deterministic approaches such as model theory for layered media. In 1954, Norman A. Haskell made a great contribution to theoretical geophysics with his famous paper in which he showed how seismic surface waves could be computed for an Earth modeled by an arbitrary number of plane parallel layers, each one with arbitrarily prescribed physical properties. His work was based on Thomson's work, and it is now known as the Thomson-Haskell method. In his pioneering work, Claerbout (1968) recognized the solution to the inverse problem of determining the medium from the seismogram. Numerical modeling of

seismic wave propagation in an inhomogeneous media is becoming more important in seismic exploration. A wide variety of recent numerical strategies implies treating Earth models with successively increasing complexity. The realistic computational models can include anisotropic media, non-planar interfaces between layers and blocks, velocity/density/quality factor gradients inside layers, and often with free surface topography. In particular, the rheology of the medium should allow for realistic attenuation. We can divide the different approaches to numerically solve the wave equation in complex media into three main classes: *direct methods*, *integral equation methods*, and *ray tracing methods* (see Table 1 and Carcione et al. (2002)). In order to solve the wave equation using *direct methods*, the geological model needs to be approximated by a numerical mesh. There are no restrictions about material variability and different rheologies can be implemented. These methods give solution to the wave equation in the time domain. They can be very accurate provided a sufficiently fine grid, but they are computationally more expensive than analytical or ray tracing methods. *Integral equation methods* are inspired in Huygens' principle. These methods formulate the solution of a problem in terms of values at the domain's boundary. Integral equation methods have an interesting conceptual advantage over direct methods, which is the reduction of one space dimension. Moreover, integral equation methods (in the frequency domain) do not need absorbing boundaries. They match easily the boundary conditions and do not suffer from grid dispersion. However, these methods require the knowledge of Green's function which is limited to a few cases (see Kausel 2006). *Ray tracing* or *asymptotic methods* are approximate because they do not take into account the complete wavefield. The wavefield is considered as an ensemble of certain events of relatively high frequency, each arriving at certain traveltimes and having certain amplitude.

Direct Methods

A convenient way to classify numerical methods to solve wave equation is to use a variational description. If the equation of motion and the boundary conditions are prescribed in their differential form and the solution approach deals directly with them, it corresponds to the *strong formulation*. Such are the cases of finite differences (FE) and pseudospectral (PS) methods. On the other hand, the methods that seek to reduce the errors use an integral form of the equation of motion weighting the error by means of trial functions, corresponding to the *weak formulation*. They are also known as variational methods. Such is the case of finite element (FE) method. The free or natural boundary conditions are automatically satisfied in the weak formulation.

Seismic Wave Propagation in Real Media: Numerical Modeling Approaches, Table 1 Classification of numerical methods to model seismic wave propagation in real media

Direct methods	Finite differences (FD), pseudospectral (PS), finite element (FE), spectral element method (SEM), finite volume (FV), discontinuous Galerkin (DG), discrete element method (DEM)
Integral equation methods	Boundary element method (BEM), indirect boundary element method (IBEM), fast multipole method (FMM), domain integral methods (DIM)
Asymptotic or ray tracing methods	Gaussian beams

Finite Difference Method

The basic idea of finite difference methods is to compute the partial derivatives by an approximation based on Taylor series expansions of functions near the point of interest. Forward and backward time derivatives lead to implicit or explicit schemes. In general, an implicit method is computationally more expensive than an explicit method, due to the requirement of solving large matrix equations. When applying finite differences in the implicit scheme only for 1D problems, the matrix to be inverted is tridiagonal, which is very convenient in terms of computational cost. However this is not the case for 2D problems. Nevertheless, using the method of dimensional splitting, one can replace the multidimensional problem by a succession of much simpler one-dimensional problems, and as a result it is possible to build tridiagonal matrices and combine their results to compute the desired time derivative. This ingenious approach is described in Bayliss (1986), Mufti (1985), and Emerman et al. (1982). The Taylor series expansion method is usually used to calculate finite difference coefficients, and the calculation error increases with the frequency of data. To further suppress numerical dispersion, numerous methods have been proposed based on the modification of finite difference coefficients. For example, Liu and Sen (2009) have obtained implicit finite difference formulae derived from fractional expansion of derivatives which form a system of linear equations. Obviously, the explicit schemes are computationally simpler. Later, Liu (2013, 2014) optimized the finite difference coefficients by least squares method in a wide frequency range, which completed the finite difference forward modeling results. Chu and Stoffa (2012) proposed a finite difference method, implicit both in space and in time, for the scalar wave equation. The authors used a three-level implicit splitting time integration method for the temporal derivative and implicit finite difference operators of arbitrary order for the spatial derivatives. Both the implicit splitting time integration method and the implicit spatial finite difference operators require solving systems of linear equations.

Therefore a vast majority of earthquake ground motion modeling and exploration seismology studies use explicit FD schemes. Virieux in a couple of papers (1984) and (1986) for SH and P-SV cases respectively was the first to introduced explicit time domain staggered FD in seismology. This method is easy to implement, to introduce different kinds of sources, and to consider viscoelasticity. In addition, the local nature of finite difference operators makes the method suitable for parallelization. In seismic applications, the following velocity-stress formulation is widely used:

$$\begin{aligned}\frac{\partial \sigma_{ij}}{\partial x_j} + f_i &= \rho \frac{\partial v_i}{\partial t} \\ \frac{\partial \sigma_{ij}}{\partial t} &= c_{ijkl} \frac{\partial e_{kl}}{\partial t}\end{aligned}\quad (1)$$

where the first time derivative of the displacement u is the velocity v , σ_{ij} is the stress, $\partial e_{kl} = (v_{k,l} + v_{l,k})/2$, being e_{kl} the strain and c_{ijkl} is the fourth-order stiffness tensor with elastic coefficients for linear elastic solids, f_i is the i th component of the body force vector $\mathbf{f}$ that can be written in terms of the moment tensor as follows:

$$\mathbf{f} = -\mathbf{M} \cdot \nabla \delta(\mathbf{x} - \mathbf{x}_s) S(t) \quad (2)$$

where $\mathbf{x}_s$ denotes the source position, δ is the Dirac delta, and $S(t)$ denotes the source time function. Evaluating the second time derivative of Eq. (1), i.e., $\ddot{u} = \partial_t v$ (double dot denotes twice time derivative), at times $(n+1)\Delta t$ and $(n-1)\Delta t$ by a Taylor expansion yields

$$\frac{\partial^2 u^n}{\partial t^2} = \frac{1}{(\Delta t)^2} \left[u^{n+1} - 2u^n + u^{n-1} - 2 \sum_{l=2}^L \frac{(\Delta t)^{2l}}{(2l)!} \frac{\partial^{2l} u^n}{\partial t^{2l}} \right] \quad (3)$$

When applied (3) to numerically approximate spatial and time derivatives in the 1D scalar wave equation

$$\frac{1}{\beta^2} \frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial x^2}, \quad (4)$$

we obtain the Lax-Wendroff scheme:

$$\frac{1}{\beta^2} \frac{u_i^{n+1} - 2u_i^n + u_i^{n-1}}{(\Delta t)^2} = \frac{u_{i+1}^n - 2u_i^n + u_{i-1}^n}{(\Delta x)^2}. \quad (5)$$

This equation represents the discretization of (4) in the x - t space. Now, consider that we have a Cartesian system of coordinates (x, y, z) with a fourth-order computational domain taking into account the time, i.e., (x, y, z, t) . A convenient spatial-time grid is given by a set of discrete points (x_i, y_j, z_k, t_n) expressed as $x_i = x_0 + i\Delta x$, $y_j = y_0 + j\Delta y$,

$z_k = z_0 + k\Delta z$, and $t_n = t_0 + n\Delta t$; $i, j, k, n = 1, 2, \dots$. The spatial increments Δx , Δy , and Δz are usually referred to as grid spacings, and (x_0, y_0, z_0, t_0) are initial values for these variables, while Δt is the time step. The value of a function u at a grid position (x_i, y_j, z_k, t_n) is given by $u_{i,j,k}^n = u(x_i, y_j, z_k, t_n)$. It is possible to have nonuniform grids, and the other important consideration is whether all functions are approximated at the same grid positions. The conventional, partly staggered, and staggered grids are illustrated in Fig. 1. An important observation is pointed out for finite difference solutions of hyperbolic equations. Accuracy increases with increasing Δt , for central differences, up to a limit defined by the Courant-Friederickson-Lewy stability condition (assuming $\Delta x = \Delta z$, in 2D):

$$\frac{V_{\max} \Delta t}{\Delta x} \leq \frac{1}{\sqrt{2}} \quad (6)$$

where $V_{\max}$ is the maximum velocity considered in the model.

The choice among the different schemes is made to improve accuracy, reduce memory requirements, and deal with anisotropy media. Recently, the use of the partly staggered grid was upgraded by Saenger et al. (2000) and Saenger and Bohlen (2004). The authors called the grid rotated staggered grid since they obtained the spatial FD operator by the rotation of the standard staggered grid operator. They used this scheme to successfully simulate media with heterogeneities (cracks, pores, free surface, and anisotropy). Rotated

staggered grids have been also used to model planar and non-planar dynamic rupture models (see Cruz-Atienza et al. (2007)). The main limitations of FD are the extensive consumption of computational resources in terms of both core memory and CPU time. However, Furumura and Chen (2005) performed large-scale parallel FD simulations of seismic wave propagation to model strong ground motions during damaging earthquakes. Parallel FD simulation allowed Saito and Furumura (2009) to successfully simulate tsunami generation. A complete review of FD methods can be found in Moczo et al. (2007). Maeda et al. (2017) developed an open-source software package, called Open-source Seismic Wave Propagation Code (OpenSWPC), for parallel numerical simulations of seismic wave propagation in 3D and 2D (P-SV and SH) viscoelastic media based on the finite difference method in local-to-regional scales. The authors include a frequency-independent attenuation model based on the generalized Zener body and an efficient perfectly matched layer for absorbing boundary condition.

Irregular interfaces are difficult to deal with finite differences; however some successful efforts have been made to address this issue. One example is given in Rao and Wang (2018) where the authors propose a summation-by-parts finite difference method that can be used for models with non-rectangular meshes across fluctuating interfaces, and it can achieve desirable simulation accuracy. Almuhaideb and Tokzö (2015) developed a 2D finite difference solver for the elastic wave equation that combines a fourth-order

Seismic Wave Propagation in Real Media: Numerical Modeling Approaches,

Fig. 1 Spatial grid cells in the conventional, partly staggered, and staggered grids (see Moczo et al. 2007)

ADER scheme (Arbitrary high-order accuracy using DERivatives). Liu et al. (2018) modeled seismic wave propagation in fractured media using an integral method with tetrahedral grid cells. This approach is derived from finite element and finite difference methods in heterogeneous media. It is flexible in modeling irregular interfaces and surface topography. Sun et al. (2017) simulated seismic wave propagation across a 2D topographic fluid and solid interface at the sea bottom by the finite difference method. In this method, seismic waves in seawater are governed by acoustic wave equations, whereas seismic waves in solid earth are governed by elastic wave equations. Li et al. (2019) proposed a seismic forward modeling method for fluid-solid coupled media with a transition layer. The second-order acoustic wave pressure equation and the second-order elastic wave displacement equation in heterogeneous media are used in the fluid and solid media, respectively.

Anisotropy

Anisotropy is caused by structural alignment of elements that are smaller than the wavelength employed for seismic data acquisition. Examples of structures that cause anisotropic effects are fine layering, tectonic grain, orientation and intensity of cracking. One way to include these effects in the model is to consider that elastic properties at a given point might vary with direction. Therefore by including anisotropy in the model, alignments of small-scale heterogeneities are captured. The alignment effects might lead to important

petrophysical information. To consider anisotropy in a FD simulation, one needs to define c_{ijkl} the fourth-order stiffness tensor in Eq. (1). For example, to model the effect of layering (see Fig. 2) one can consider the following stiffness tensor

$$C = \begin{bmatrix} c_{11} = 66.6 & c_{12} = 19.7 & c_{13} = 39.4 & 0 & 0 & 0 \\ c_{12} & c_{11} & c_{13} & 0 & 0 & 0 \\ c_{13} & c_{13} & c_{33} = 39.9 & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} = 10.9 & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{66} \end{bmatrix} \quad (7)$$

where $c_{66} = (c_{11} - c_{12})/2$, the density given by $\rho = 2590 \text{ Kg/m}^3$, and the units for the elastic constant are in GPa. The example represents the Mesaverde clay shale (see Thomsen 1986 and Carcione et al. 1992). This kind of stiffness tensor with these five elastic constants characterizes a medium of class IV according to the classification given by Payton (1983), and it is called transversely isotropic medium (since it has the vertical z -axis as a symmetrical axis). Notice that due to the anisotropy, in Fig. 2, the different plane cuts xy -plane, xz -plane, and yz -plane the wave fronts do not propagate at the same speed. In Gao and Huang (2017), an improved rotated staggered grid method with fourth-order temporal accuracy is applied to simulate elastic wave propagation in anisotropic media. Inspired by the idea of rotated staggered grid finite difference method, Zou and Cheng (2017) proposed a modified pseudospectral method for wave propagation in arbitrary 3D anisotropic media.

Seismic Wave Propagation in Real Media: Numerical Modeling Approaches, Fig. 2

(Left) Illustration of a transversely isotropic medium. The example represents the Mesaverde clay shale. The six elastic constants (for the stiffness tensor in Eq. (1) that generate this medium are given by $c_{11} = 66.6 \text{ GPa}$, $c_{12} = 19.7 \text{ GPa}$, $c_{13} = 39.4 \text{ GPa}$, $c_{33} = 39.9 \text{ GPa}$, $c_{44} = 10.9 \text{ GPa}$, and $c_{66} = (c_{11} - c_{12})/2$ and the density $\rho = 2590 \text{ Kg/m}^3$. (Right) A layered medium that represents the anisotropic effect

Pseudospectral Method

The pseudospectral method (PS) is based mainly on Fourier and Chebyshev differential operators. The spatial derivative is computed in the frequency-wavenumber domain as follows:

$$\frac{\partial u(x, t)}{\partial x} = \frac{1}{2\pi} \int_{-\infty}^{\infty} \left(\int_{-\infty}^{\infty} u(\xi, t) e^{-ik\xi} d\xi \right) ike^{ikx} dk, \quad (8)$$

(see Kreiss and Oliger (1972), Kosloff and Baysal (1982), Furumura et al. (1998)). In Eq. (8) the interior integral corresponds to the spatial Fourier transform of $u(x, t)$. The product by ik within the integrand of the exterior integral makes the x -derivative when performing the pass to space domain. The PS with Fourier has the disadvantage of periodic properties, called wraparound. Both Fourier and Chebyshev are accurate up to the maximum wavenumber of the mesh that corresponds to a spatial wavelength of two grid points (at maximum grid spacing for the Chebyshev operator). Like FD methods, they are also unable to model surface waves with the same accuracy as body waves because of the one-way treatment that needs to be performed in order to implement the free surface condition (e.g., Carcione 1994).

Finite Element and Spectral Element Methods

The finite element (FE) method is more efficient than FD or PS when dealing with complex geometries (irregular interfaces) and heterogeneous media and handling boundary conditions. This method is also applicable with inelastic constitutive models. Bielak et al. (2005) have developed an efficient FE-based computational platform for large-scale ground motions. Low approximation orders may lead to a large numerical dispersion (see Marfurt (1984)). As a result, mesh refinement is required to reduce numerical dispersion but may lead to a large numerical cost even if parallelization is possible. High-order FE methods became more efficient when the spectral element method (SEM) appeared using Chebyshev polynomials as interpolating functions (see Seriani et al. (1992), Priolo et al. (1994), Komatitsch and Villotte (1998), Komatitsch and Tromp (1999)). This method introduced the use of the Lagrange polynomials as interpolating functions which produces a diagonal mass matrix when using the Gauss-Lobatto-Legendre quadrature.

Discontinuous Galerkin Method

The Discontinuous Galerkin method (DG) is a technique that uses discontinuous basis functions to formulate a Galerkin approximation. Given a mesh of the analysis domain, the DG method approximates the solution within each element by a

function from a low-dimensional vector space of functions, e.g., as a linear combination of basic functions like polynomials. For a pair of adjacent mesh elements, the approximate solution computed in the interior of the elements does not have to agree on their common boundary. Some of the advantages of this method are:

- It can sharply capture solution discontinuities relative to a computational mesh.
- It simplifies adaptation since inter-element continuity is neither required for mesh refinement and coarsening.
- It conserves the appropriate physical quantities (e.g., mass, momentum, and energy) on an element-by-element basis.
- It can handle problems in complex geometries to high order.
- Regardless of order, it has a simple communication pattern to elements sharing a common face that simplifies parallel computation. With a discontinuous basis, the DG method produces more unknowns for a given order of accuracy than traditional finite element or finite volume methods, which may lead to some inefficiency. The DG method is harder when applied to unstructured meshes; in particular, it is harder to formulate limiting strategies to reduce spurious oscillations when high-order methods are used. Nevertheless, Käser and Dumbster (2006) have successfully implemented the method for elastic wave propagation on unstructured meshes.

For an introduction to the key ideas, basic analysis, and efficient implementation of discontinuous Galerkin methods and a review of the state of the art, we refer the reader to the book by Hesthaven and Warburton (2008). Fernandez et al. (2018) shows a hybridizable and embedded discontinuous Galerkin method for wave propagation problems in fluids, solids, and electromagnetism. In Shukla et al. (2019) a nodal discontinuous Galerkin method with a Lax-Friedrichs flux is used to model the wave propagation in transversely isotropic and poroelastic media. Furthermore, Shukla et al. (2019b) applied a high-order weight-adjusted discontinuous Galerkin scheme for the numerical solution of three-dimensional (3D) wave propagation problems in anisotropic porous media including for the first time a sub-cell level to deal with cases where heterogeneities are present.

Integral Equation Methods

Boundary Element and Indirect Boundary Element Methods (BEM and IBEM).

Among Integral equation methods it is the boundary element method. The formulation of direct boundary integral equation method (BIE) in elastodynamics is back to the pioneering work of Somigliana (1885). Considering a volume

of elastic material V bounded by a surface S , the displacement field u_i at a point $\mathbf{x}$ and time t can be expressed as a function of the values of the displacement and traction t_j along the boundary through Somigliana's representation theorem:

$$cu_i(\xi, t) = \int_0^t d\tau \int_S \left[t_j(\xi, \tau) G_{ij}(\xi, t, \mathbf{x}, \tau) - u_j(\xi, \tau) \sum_{jik}(\xi, t, \mathbf{x}, \tau) n_k(\xi) \right] dS(\xi) \quad (9)$$

where $G_{ji}(\xi, t, \mathbf{x}, \tau)$ and $\sum_{jik}(\xi, t, \mathbf{x}, \tau)$ are the responses in terms of displacement and stress, time t , and point ξ of an infinite homogeneous medium to a unit force impulse, applied at time τ at point $\mathbf{x}$ in the direction i and $n_k(\xi)$ is the normal boundary pointing outside V . The volumetric body sources are assumed to be null, but if present, their contribution can be easily added as follows:

$$cu_i(\xi, t) = \int_0^t d\tau \int_S \left[t_j(\xi, \tau) G_{ij}(\xi, t, \mathbf{x}, \tau) - u_j(\xi, \tau) \sum_{jik}(\xi, t, \mathbf{x}, \tau) n_k(\xi) \right] dS(\xi) + \int_0^t d\tau \int_V G_{ij}(\xi, t, \mathbf{x}, \tau) f_i(\mathbf{x}, \tau) dV \quad (10)$$

where

$$c = \begin{cases} 1, & \xi \in V \\ 1/2, & \xi \in S \\ 0, & \mathbf{x} \notin V \end{cases} \quad (11)$$

assuming that S has smooth boundaries. The values of c come from the volume integration of the product $\delta(\mathbf{x} - \xi, t - \tau) \mathbf{u}_j(\xi, \tau)$, and the value accounts for the integration of the Dirac's delta and its position. Green's function for the homogeneous, isotropic, elastic media can be found in Aki and Richards (1980).

The indirect formulation of the elastodynamic problem expresses the wavefield as an integral over the boundary of elementary source radiations as follows:

$$u_i(\mathbf{x}, t) = \int_0^t d\tau \int_S \phi_j(\xi, \tau) G_{ij}(\mathbf{x}, t, \xi, \tau) dS(\xi) \quad (12)$$

where $\phi_j(\xi, \tau)$ denotes τ the force density distribution applied at time at point ξ of the surface S . In this equation we have assumed that the volumic forces are null. If present, their contribution needs to be added. Equation (10) can be seen as the mathematical transcription of Huygens' principle, which states that each point of diffracting boundary acts as a secondary source of wave radiation. This principle applies to

any wave front as well. Equation (12) is also the mathematical expression of the exploding reflector concept widely used in seismic exploration (see Claerbout 1985). The fictitious distribution ϕ_j is an intermediate variable which needs to be solved in the boundary integral equations before the wavefield can be computed. This is the reason why this formulation is called indirect.

The discretization of the boundaries leads to the discretization of the BIE, and the application of boundary conditions transforms BIE into a system of linear equations which in general is not symmetric. The resolution of this system is usually done implicitly and in the frequency domain. Comprehensive introduction of integral equation methods can be found in the books by Bonnet (1999), Dominguez (1993), and Manolis and Beskos (1988). In seismology, the BEM is used to study the effect of irregular topography on earthquake ground motion, both in 2D and 3D problems. This method has been also used to simulate elastic wave propagation in media with cracks; for example, in Fig. 3 we have an irregular crack strike by a cylindrical SH incident wave (first column) and the same crack strike by a plane SH incident wave with 0° and 30° , measured with respect to the z -axis (second and third columns, respectively) (see Iturrarán-Viveros et al. 2005; Pointer et al. 1998). A complete review on the use of BEM for seismic problems can be found in Bouchon and Sánchez-Sesma (2007). In Liu et al. (2016) the IBEM has also been applied to model elastic wave propagation in a 3D fluid-saturated poroelastic half-space. Perton et al. (2016) shows a new implementation of the IBEM that allows to simulate elastic wave propagation in complex configurations made of embedded regions that are homogeneous with irregular boundaries or with flat layers.

Fast Multipole Method in Elastodynamics

Two types of fast multipole method (FMM) are available for elastodynamics in the frequency domain. The first one is the low-frequency FMM. As for static cases, the complexity of this algorithm is $O(N)$. This complexity is due to the fact that the wavelength is much larger than the domain size. On the other hand, if the wavelength is shorter than the geometrical feature, the complexity of low-frequency FMM increases to $O(N^2)$, and the method is not efficient any longer. For this reason, computational efficiency of fast BEMs in the mid-frequency regime is enhanced by using the so-called diagonal form for the Helmholtz Green's function, proposed by Rokhlin (1990), with a complexity of $O(N \log N)$. The upper limit stems from the fact that the size N becomes intractable at high frequencies, but the diagonal form also breaks down at very low frequencies and must be replaced with other types of expansions. The method for low frequencies was developed by Fujiwara (1998). The first 3D implementation was proposed by Fujiwara (2000) using a multilevel and diagonal form. The author presents some low-frequency seismic-oriented examples. Chaillat et al.

Seismic Wave Propagation in Real Media: Numerical Modeling Approaches, Fig. 3 Snapshots of displacements for (left) a cylindrical SH wave striking an irregular crack, (middle) a plane SH wave with

incident angle 0° striking an irregular crack, and (right) a plane SH wave with incident angle 30° striking an irregular crack. The set of snapshots are taken at (a) $t = 1.25$ s (b) $t = 1.71$ s, and (c) $t = 2.03$ s

(2009) also addressed problems in 3D. Yoshida (2001) proposed a low-frequency FMM for crack problems in 3D.

Analytic Solutions for Nonhomogeneous Media

Since analytic solutions help to assess numerical methods, some attempts to develop analytic solutions for particular cases of mildly anisotropy media are briefly described. In

Sánchez-Sesma et al. (2001), authors developed approximate analytical formulae for elastic 2D Green's functions for a constant-gradient propagation velocity medium. These solutions correspond to unit line forces per unit length: the anti-plane SH line source and the in-plane P-SV line sources, respectively. They are based on the asymptotic ray theory and account for both near-source effects and low frequencies. The orthogonal bipolar coordinates are depicted in Fig. 4.

The approximate solution for the 2D scalar case is given by

Seismic Wave Propagation in Real Media: Numerical Modeling Approaches, Fig. 4

(Left) Schematic illustration of the bipolar coordinate system. Both rays and wave fronts are circular. Rays depend upon takeoff angle j_0 . $t = \xi t_0$, where $t_0 = h/\beta(0)$ and ξ is one of the bipolar coordinates (the other is j_0). The distances R_1 and R_2 from the poles to point P are displayed. The plane for which $z = -h$ corresponds to null propagation velocities. (Top right) This solution is used to compute Green's function for the scalar case in the time domain with a source located at (1,1), $\beta(0) = 500$ m/s and $\beta(z_{\max}) = 3000$ m/s. Wave fronts depend on traveltime

$$G_{22}(\omega, \tau) \approx \Lambda \frac{1}{4\mu_0} H_0^{(1)}(\omega\tau) \quad (13)$$

where Λ is defined as follows

$$\Lambda = \left(\frac{1 + \gamma z_0}{1 + \gamma z} \right)^{\frac{1+\eta}{2}} \left[2 \ln \left(\frac{R_2 + R_1}{R_2 - R_1} \right) \frac{(z_0 + h)(z + h)}{R_1 R_2} \right]^{1/2} \quad (14)$$

where z_0 = depth of the source, β_0 = shear wave velocity at the source level, $\beta(0)$ = shear wave velocity at $z = 0$, ρ_0 = mass density at source level, $\gamma = 1/h$, h = distance from depth $z = 0$ to the level where the propagation velocity is null ($z = -h$), $j_0 = \sin^{-1}[2x(z_0 + h)/R_1 R_2]$ = take off angle, $R_1 = (x^2 + (z - z_0)^2)^{1/2}$, and $R_2 = (x^2 + (z + z_0 + 2h)^2)^{1/2}$. The travel time t is given by

$$\tau = t_0 \ln \left(\frac{R_2 + R_1}{R_2 - R_1} \right) = 2t_0 \tanh^{-1} \left(\frac{R_1}{R_2} \right) = t_0 \xi \quad (15)$$

In Watanabe and Payton (2006) and (2002), Green's functions are obtained exactly for radially symmetric waves and for transient and time-harmonic SH waves in inhomogeneous anisotropic elastic solids, respectively. Since time-harmonic conditions have been assumed, viscoelastic material behavior can be captured through the introduction of complex-valued wave speeds.

Equivalent Media Theories

When one wishes to model highly heterogeneous media, one possibility is to make the continuum hypothesis (see Christensen 1979; Hudson 1991). A real material with its atomic and molecular structure is replaced by an equivalent continuum model, which remains a continuum no matter how much it is subdivided. The macroscopic mechanical properties of the material remain unchanged. This hypothesis works as long as the scale of observation is much larger than the scale length of the molecular structure (Rayleigh scattering regime). Microfractures, pores, and other heterogeneities with uniform statistical distributions can be replaced by an equivalent or effective medium provided that the scale of the observation is much larger than the scale of the heterogeneities. This is an attractive approach in exploration seismology since the scale of the observation, or seismic wavelengths, is much larger than the scale length of the heterogeneities present in the subsurface. The concept of equivalent media clearly implies that if the stress, strain, or displacements are measured on a large enough scale, the values obtained and the relationship between them will be that of homogeneous continuum. This implies some kind of spatial averaging process. Nevertheless, scales much smaller than the minimum wavelength (used in the numerical model) are present in the earth model. Therefore effective media theories which allow to average small scales of the original medium without losing

the accuracy of the wavefield computation are needed. In Capdeville and Marigo (2007), authors applied two-scale homogenization technique to the wave equation in layered media. The order 0 homogenization provides the same result as the one given by Backus (1962). The order 0 is not enough to obtain an accurate solution especially for surface waves. Higher-order homogenization terms (up to 2) allowed them to obtain accurate surface waves. Lately Capdeville and Marigo (2010) proposed an original nonperiodic homogenization technique in 1D. The extensions to 2D and 3D are foreseen.

Asymptotic Ray Tracing Methods

An accurate estimation of travel time is needed to map heterogeneities in the Earth's subsurface. Traveltime computation schemes fall within one of these two categories: first-arrival traveltime and ray theory-based traveltime. The first-arrival traveltime corresponds to the first arrival of the complete wavefield at a specified receiver position, and it is not a function of the type of wave (e.g., head wave, direct wave, etc.). Most of the schemes, which estimate first-arrival traveltimes, are based on the solution of eikonal equation. Vidale (1988, 1990) proposed different versions of finite difference solution of the eikonal equation along expanding square (in 2D) and along an expanding cube (in 3D) to compute first-arrival traveltimes in isotropic media. Schneider et al. (1992) proposed a method based on Fermat's principle for traveltime computation in isotropic media that uses a local ray-trace solution of the eikonal equation. Ray tracing can be classified into two categories: (1) initial-value ray tracing and (2) boundary value ray tracing. In initial-value ray tracing, a fan of rays is shot from the source in the model, and some kind of extrapolation scheme is used to estimate the traveltime at a particular point in the model. Paraxial extrapolation (Červený, 1985) is one of the most popular methods of traveltime extrapolation. An excellent review on ray theory can be found in Červený (2001).

Poroelastic and Thermoelastic Media

In addition to complex geometries, different rheologies, and anisotropy, current numerical techniques are concentrating efforts to include porosity and fluid saturation in their models. Reservoir rocks can be modeled as a porous solid matrix where the pore space is fully saturated with a pore fluid. The analysis of wave propagation in fluid-saturated porous media is different in nature than that of elastic wave propagation. Biot's model is generally used to describe this effect (Biot 1956, 1962). Two approaches exist to derive the poroelastic equations of motion and the constitutive laws. One method is to use homogenization methods. The laws to describe the

medium are first derived on the microscopic scale of porosity. Then they are passed to macroscopic scale by homogenization. Pride et al. (1992) used an averaging procedure to derive the poroelastic equations similar to Biot (1956) and Biot (1962). O'Brine (2010) used rotated staggered grid to model wave propagation in 3D poroelastic media. Figure 5 shows snapshots of the vertical component of the solid velocity and the relative fluid velocity (with respect to the solid velocity) at times $t = 0.225$ ms and $t = 0.255$ ms, respectively. At the low-frequency range (Figs. 5a and b), the slow P wave is highly diffusive and vanishes that we can only see it in its static mode at the source location. However, at the high-frequency range, the slow P wave propagates through the medium (Figs. 5c and d) according to Biot's theory. This numerical simulations were produced using an optimal implicit finite difference method (Itzá et al. 2016) and are in agreement with the results given in the paper by Sheen et al. (2006). For a comprehensive account on this subject, the reader may be referred to the book by Carcione (2014). Moreover, a numerical algorithm for simulation of wave propagation in linear thermoelastic media, based on a generalized Fourier law of heat transport, computed by using a grid method based on the Fourier differential operator is presented in Carcione et al. (2019).

Boundaries

When modeling the propagation of elastic waves in any medium, the waves reaching the neighborhood of the boundaries will create reflected waves. This is a nonphysical phenomenon that we want to avoid. On top of the model, we would like to impose a free surface. Therefore for the top boundary, we need a reflected boundary, and for the other three boundaries (in 2D), we need nonreflecting absorbing boundaries. In most of the numerical schemes described here, there are boundary conditions to be imposed, or it is necessary to implement absorbing boundary conditions to eliminate spurious reflections due to the finite computational domain. The free surface boundary condition is implemented by adding a fictitious line of grid nodes next to the top boundary and using the one-side differences to approximate normal derivatives and centered difference to approximate tangential derivatives (see Kelly et al. (1976) and Graves (1996)). The simplest and more effective absorbing boundary conditions consist of a sponge along the artificially truncated edges of the domain. Clayton and Enquist (1977) proposed a kind of absorbing boundary condition based on replacing the wave equation in the boundary region by one-way wave equation that does not allow energy to propagate from the boundaries to the numerical domain. An alternative scheme suggested by Cerjan et al. (1985) is based on gradual reduction of the amplitudes in a strip of nodes along the boundaries for the mesh. Béranger (1994, 1996) first introduced perfectly

Seismic Wave Propagation in Real Media: Numerical Modeling Approaches, Fig. 5 Snapshots of vertical component from a gas-water contact model. (a, c) Snapshots of solid velocity. (b, d) Snapshots of relative fluid velocity (to solid velocity)

matched layers (PMLs) for electromagnetism. The main idea is to define a selective attenuation of the fields propagating in one prescribed direction. PMLs for elastic wave propagation were developed by Basu and Chopra (2003, 2004) and Komatitsch and Martin (2007). The velocity-stress formulation of PMLs for elastic wave equations has been introduced by Collino and Tsogka (2001). It was applied to viscoelastic (Martin and Komatitsch 2009) or poroelastic (Zeng et al. 2001; Martin et al. 2008) media. Meza-Fajardo and Papageorgiou (2008) demonstrated that for any anisotropic media, the classic PML exhibits instabilities. In addition, they presented a generalization of the classical perfectly matched layer PML (called multi-axial perfectly matched layer (M-PML)) to a medium in which damping profiles are specified in more than one direction.

Hybrid absorbing boundary conditions can significantly suppress artificial boundary reflections by inserting a transition area between the boundary and the inner area. The wavefield in the transition area is computed by linearly weighting the wavefield from one-way wave equation and that from two-way wave equation. This leads to a smooth variation from the computational area to the boundary via the transition area and thus greatly reduces boundary reflections.

In Liu and Sen (2018), the authors proposed two techniques to further enhance the absorbing effect. Firstly, they widen the boundary from one point to several points. Secondly, they adopt nonlinear weighting coefficients instead of linear ones.

Summary

Modeling the Earth is a challenging task. With the increase of computational power, direct modeling techniques start to open the door to inversion problems. All numerical methods share at the same time their own disadvantages and weaknesses (high computational costs and storage requirements, poor accuracy, nonstructured grids, hard implementations, system matrix full) with the agreeable flavor of equivalent advantages (reduction of one dimension of the problem, system matrix diagonal or sparse, no need for absorbing boundaries, easy implementation, easy to model topographies or complex geometries). The nature of the problem gives us the appropriate guide to choose one method over others. In this entry, we briefly cover some numerical techniques to model elastic waves in heterogeneous media. However, the literature on all available methods is very extensive, and we include only some references.

Seismic Waves, Scattering

Ludovic Margerin
Institut de Recherche en Astrophysique et Planétologie,
Observatoire Midi-Pyrénées/C.N.R.S., Toulouse, France

Definition

Scattering of seismic waves is best defined by reference to a laterally homogeneous or slowly varying medium where the wave fronts can be perfectly tracked and the propagation of waves can be successfully described by geometrical methods such as ray theory. In the presence of obstacles, or lateral

variations of elastic parameters, wave fronts are distorted and seismic energy can be deflected in all possible directions: a phenomenon known as wave scattering. Specific to seismic waves are the possible mode conversions between various polarizations: compressional, shear, and Rayleigh waves.

Introduction

The scattering of seismic waves is intimately related to the heterogeneous nature of Earth materials on a variety of spatial scales. Well-logs data or geological maps offer direct but limited access to the nature of heterogeneities in the Earth. As elastic waves can propagate all the way through the Earth, they constitute the primary tool to sound deep heterogeneities. While the pioneering studies of seismic scattering were largely focused on the lithosphere, the presence of scatterers in the mantle and solid core has been confirmed in a number of recent studies (see Shearer and Earle 2008, for a review). Hence, the field of seismic scattering has become of interest in global seismology too. For a thorough review of pre-1990s works in seismic scattering, we refer the reader to Wu (1989). A comprehensive reference on the topic is the book by Sato and Fehler (1998). Reviews of recent methodological and observational developments are given in Sato et al. (2008).

Statistical Description of the Earth

To introduce the various scale lengths that enter in the modeling of seismic scattering, it is convenient to consider a thought-experiment such as the one shown in Fig. 1. We imagine an incident plane wave propagating through a heterogeneous medium. As evidenced by the analysis of well-logs (see for instance Wu et al. 1994), the density and the elastic constants fluctuate in the Earth in a very complicated way. In such a situation, it is convenient to think of the Earth as a particular realization of an ensemble of random media sharing similar statistical properties. The goal of the stochastic imaging methods is to infer some information on the nature of the randomness from the statistical fluctuations of the wavefield. This is a difficult task because the statistical properties of the Earth are nonhomogeneous: they are expected to depend on the geological setting and on the depth. In addition, in the case of the Earth, the random fluctuations are superimposed on a deterministic background, usually represented by a 1-D reference model such as PREM (Dziewonski and Anderson 1981). It is customary to assume that the spatial variations of the background velocities are slow compared to the typical scale length of the random medium. In this limit of separation of spatial scales, it is possible to consider the scattering medium as locally homogeneous. We may therefore hope to characterize large-scale variations of small-scale heterogeneities.

Seismic Waves, Scattering, Fig. 1 Basic concepts of seismic scattering. We consider a thought-experiment where an incoming plane wave propagates through a chunk of random medium with typical dimension

L . As the plane wave progresses through the heterogeneous medium, scattering operates and deflects energy in all space directions. The transmitted wavefield is distorted and attenuated

If we think of the medium as random and continuous, the fluctuations of a parameter such as the density ρ are characterized to lowest order by a correlation function (Rytov et al. 1989b):

$$\psi(\mathbf{x}) = \langle \rho(\mathbf{r} - \mathbf{x}/2) \rho(\mathbf{r} + \mathbf{x}/2) \rangle, \quad (1)$$

where the brackets denote an average over the ensemble of random media. In Eq. 1, we have used an assumption of statistical homogeneity. In the case of a locally homogeneous medium, the correlation function may be allowed to vary slowly with the variable $\mathbf{r}$. $\psi(\mathbf{x})$ is maximum for $x = 0$, where it is equal to the total variance of the fluctuations denoted by ϵ^2 and goes to zero over a typical spatial scale a which is known as the correlation length. Common choices for ψ are Gaussian and exponential functions but a wide range of other possibilities exist (Klimeš 2002). An equivalent description of the medium fluctuations is provided by the power spectrum of heterogeneities $F(k)$ defined as:

$$\psi(\mathbf{x}) = \frac{1}{(2\pi)^3} \iint \int_{-\infty}^{+\infty} \Phi(\mathbf{k}) e^{i\mathbf{k} \cdot \mathbf{x}} d^3k \quad (2)$$

$\Phi(\mathbf{k})$ quantifies the distribution of the total variance of the fluctuations over all possible length scales. A very useful tool to represent the heterogeneity of fluid or solid geophysical media is the Von-Karman correlation function, whose power spectrum can be written as (Sato and Fehler 1998):

$$\Phi(\mathbf{k}) = \frac{8\pi^{3/2} \epsilon^2 a^3 \Gamma(k + \frac{3}{2})}{\Gamma(k) (1 + k^2 a^2)^{k+3/2}}. \quad (3)$$

In Eq. 3, ϵ denotes the RMS fluctuations, a is the correlation length and $\kappa > 0$ is the Hurst exponent which acts as a cutoff of the small-scale features in the medium. The power spectrum (Eq. 3) shows a plateau at small wave numbers up to a corner value $k_c \sim 1/a$. For k much larger than k_c , the power spectrum decreases algebraically as $k^{2\kappa+3}$. Note, however, that this description does not apply to Gaussian random media. This is not a severe restriction, since Gaussian media are often regarded as too smooth to represent faithfully the heterogeneities in the Earth. This point of view is confirmed by the analysis of well-logs (Shiomi et al. 1997), which further shows that only the parameter κ can usually be recovered from observations.

The Coherent and Incoherent Fields

Following the statistical approach, it is natural to characterize the propagation in the random medium by calculating the moments of the wavefield u . This yields a simple classification of the various components of the random field. The first moment $\langle u \rangle$ defines the coherent wave (Rytov et al. 1989a; Sheng 1995) and corresponds to the part of the field which survives after an average over the statistical ensemble has been performed. In a typical seismological experiment, the measured field is the sum of two terms: the ensemble average

$\langle u \rangle$ and a fluctuating part u_f . The coherent field mostly contributes in a time window around the seismic primaries, which may also be termed the ballistic waves. Although the coherent field is an important component of the ballistic field, it has to be carefully distinguished from it (Derode et al. 2001). Statistical wave theory shows that the mean field decays like $e^{-L/2l}$, where L is the propagation distance and l is known as the mean free path (Sheng 1995). The mean free path gives the typical spatial scale over which a significant amount of energy has been transferred from the coherent to the incoherent or fluctuating part of the wavefield. The incoherent part of the wavefield contributes to all portions of the seismogram and forms the coda of the earthquake records. It is important to realize that the term “incoherent” just indicates the generation of waves that propagate in a direction which differs from that of the incident wave. It does not imply that the phase information has been lost. In section “[Interferometry with Scattered Waves](#)”, we will demonstrate that the so-called incoherent field is in fact highly “coherent” in the sense that it gives rise to very useful interference effects.

The Propagation Regimes

The distinction between the fluctuating and ensemble average part of the wavefield is useful to characterize the propagation regime. For propagation distances typically less than the mean free path, the measured field is dominated by the coherent wave: this is the weak fluctuation regime (Rytov et al. 1989a). As shown in Fig. 1, after propagating through several inhomogeneities, the most important observation is the distortion of the incident plane wave front. This gives rise to fluctuations of both phase and amplitude, from which information on the statistical properties of the medium can be extracted. For propagation distances much larger than the mean free path, the coherent wave completely vanishes and one is left with the fluctuating part only: this is the strong fluctuation regime (Rytov et al. 1989a). Since by definition the ensemble average of the fluctuating part u_f is zero, it is only through the consideration of the second moment of the field that one can model the propagation of scattering when fluctuations are strong. Specific approaches will be developed in sections “[Envelope Modeling: Markov Approximation](#)” and “[Envelope Modeling: Radiative Transfer](#)”.

At this stage, it is natural to raise the following question: How can we measure the mean free path in the Earth? First, it is important to note that one has to consider at least two different mean free paths since both longitudinal and transverse waves propagate through an elastic medium. In the laboratory, there are well-calibrated techniques to measure the mean free path based on ensemble averaging. Unfortunately, these methods cannot be transposed to field experiments. Instead, the common seismological practice consists in correcting the seismograms for the travel-time fluctuations

caused by long wavelength variations of the velocity before stacking or averaging the records. The field obtained after such a processing is called the traveltime-corrected mean field. Sato (1982, 1984) and Wu (1982) have demonstrated that this field decays exponentially on a scale which is much larger than the mean free path, because the traveltime correction in fact removes the long wavelength components of the medium fluctuations. A theoretical discussion of various averaging procedures and their application to seismic data is given by Shapiro and Kneib (1993).

Analysis of Transmission Fluctuations

As announced in introduction, we now review the various approaches that have been developed to infer the statistical properties of the Earth from an analysis of seismic wave scattering. We will first introduce a method which is well adapted to the analysis of fluctuations of amplitude and phase of teleseismic P waves recorded on a dense array. Such an approach has been pioneered in the 1970s by Aki (1973) and has been subsequently developed by Wu and coworkers (Wu and Flatté 1990; Zheng et al. 2007; Zheng and Wu 2008). In this approach, one considers a small time window around the direct P -wave at teleseismic distance. It is usually assumed that at sufficiently large distance from the source, the wave front incident from the mantle can be approximated locally by a plane. By using sufficiently deep earthquakes, it is possible to avoid the effects of strong heterogeneities in the vicinity of the source. As the plane wave progresses through the lithosphere, the wave front is distorted and the amplitude and phase of the ballistic waves measured on the array fluctuate. Zheng and Wu (2005) have very carefully discussed the correct measurement practice. The main pulse recorded on the vertical component of the seismometer is first isolated from the rest of the signal. After Fourier transformation, the amplitude A and the phase ϕ of the pulse is obtained at a given frequency. This operation is repeated at all stations of the array, and the phase field is subsequently unwrapped spatially, i.e., possible phase discontinuities are removed. It is not correct to measure the phase of the field by picking the first arrival since, as a consequence of scattering, the medium is dispersive and the first arrivals propagate with the group velocity.

Basic observables are the fluctuations of the phase and of the logarithm of the amplitude. The reason why one considers the logarithm of the amplitude is that this quantity enters in the Rytov representation of the wavefield (Rytov et al. 1989a):

$$u = u_0 e^{\psi}, \quad (4)$$

where u_0 is the reference plane wavefield in the background medium and ψ is a complex phase:

$$\operatorname{Re} \psi = \ln \frac{A}{A_0} \quad \operatorname{Im} \psi = \phi - \phi_0 \quad (5)$$

Scattering theory based on the Rytov representation is more accurate than the standard Born approximation in the transmission geometry. In Eq. 5, A (resp. A_0) and ϕ (resp. ϕ_0) denote the amplitude and unwrapped phase of the field (resp. reference field). From the array measurement, one can estimate the transverse coherence function of the phase field which is defined as:

$$C_\phi(\mathbf{r}) = \langle \phi(\mathbf{x}) \phi(\mathbf{r} + \mathbf{x}) \rangle, \quad (6)$$

where the points $\mathbf{x}$ and $\mathbf{x} + \mathbf{r}$ lie on the surface of the Earth. More generally, one can consider the transverse angular coherence function of the two phase fields corresponding to two incoming plane waves with different incident wavevectors $\mathbf{k}$ and $\mathbf{k}'$ (Wu and Flatté 1990; Chen and Aki 1991).

The interpretation of the phase coherence function is based on two major theoretical approaches, with different domains of validity. These approaches rely on the basic physical assumption that the medium fluctuations have a spatial scale, a , which is much larger than the probing wavelength, λ . In this regime, the scattering occurs preferentially in a small angular cone around the forward direction. As a consequence, one can usually neglect the backscattered waves and consider one-way propagation only. The crucial nondimensional parameter that governs the properties of the phase is known as the wave parameter, D , which is defined as (Rytov et al. 1989a):

$$D = \frac{\lambda L}{a^2} \quad (7)$$

In the numerator of Eq. 7, the length $\sqrt{\lambda L}$ provides the typical size of the first Fresnel zone which can be interpreted as the typical volume sampled by the waves around a ray of length L . The region $D \ll 1$ can be conveniently treated with the methods of geometrical optics. In this regime, there are some well-established results for the phase coherence function of a single plane wave with vertical incidence: (1) The variance of the phase is proportional to the total variance of the medium fluctuations and increases linearly with the propagation distance L . (2) The typical correlation length of the phase is proportional to the correlation length of the random medium. This result makes sense physically, since parts of the incident wave front which are located a distance a apart – a , the correlation length – will visit different inhomogeneities. This provides a very useful method to map the typical scale of heterogeneities. The geometrical optics approach is rather flexible and allows the treatment of more complex

situations. Kravtsov et al. (2003) have adapted the method to the reflexion geometry usually encountered in exploration geophysics.

The method of geometrical optics usually breaks down for $D > 1$ as caustics may develop for sufficiently large propagation distances. In order to account properly for diffraction effects, it is important to use a wave-based approach. As in the problem of transmission fluctuations in which the propagation is essentially one-way, it is convenient to consider the depth variable z as an evolution variable and to neglect the backscattered waves. In this case, the usual Helmholtz equation can be replaced by the following parabolic approximation for the wavefield:

$$2ik_0 \frac{\partial u}{\partial z} + \Delta_\perp u - 2k_0^2 \frac{\delta c}{c_0} u = 0, \quad (8)$$

where $\Delta_\perp = \partial_x^2 + \partial_y^2$ represents the Laplace operator in the plane perpendicular to the main propagation direction. The parabolic approximation is accurate for low-angle scattering only, which is consistent with the scaling $\lambda/a \ll 1$. In this regime, a very powerful approach couples scattering theory and the Rytov representation of the wavefield to obtain expressions for the coherence function that extend the results of geometrical optics to the region $D > 1$. We refer to Wu and Flatté (1990) for further details on the derivation.

The first application to data was made by Aki who estimated the correlation length and total variance of the velocity fluctuations from the cross-coherence of amplitude and phase under the LASA array (Aki 1973). In this pioneering work, he further approximated the correlation function of the medium with a Gaussian function. It was later realized that this choice was not always the most appropriate since many studies revealed that the more general Von-Karman correlation function could be used to describe a broad class of random media. Flatté and Wu (1988) developed a two-layer model of heterogeneity of the upper mantle based on observed transverse and angular correlation functions at NORSAR. By superimposing a layer with Hurst exponent 1/2 extending from 15 to 250 km depth upon a layer with flat power spectrum extending from 0 to 200 km depth, they were able to explain satisfactorily the joint measurements of phase and amplitude fluctuations. The most recent developments by Zheng et al. (2007) and Zheng and Wu (2008) allow the treatment of velocity gradient in the reference medium. Their general formalism offers the possibility to perform a nonparametric inversion, i.e., the full power spectrum of the fluctuations at depth can in principle be mapped from the surface measurements of angular correlation functions. For a complete description of the method as well as numerous references to the literature, we refer to the review by Zheng and Wu (2008).

Envelope Modeling: Markov Approximation

We now consider a regime of propagation where the fluctuating part of the field is larger than the coherent part. In this regime, an interesting phenomenon termed “envelope broadening” can be used to retrieve information on the statistical fluctuations of velocities in the medium. Enveloped broadening is illustrated in Fig. 2, where small earthquakes have been recorded at epicentral distances of the order of 150 km in eastern Japan. On these data, we can observe a delay between the onset of the direct shear wave and the maximum of the amplitude. Such a delay is characteristic of the strong forward-scattering regime where the waves follow “snake-like” paths around the ballistic trajectory between source and station. As clearly shown in Fig. 2, envelope broadening depends on propagation distance and frequency band. It is also noticeable that very heterogeneous regions such as volcano areas give rise to much stronger envelope broadening than the usual crust. The clear path dependence suggests the possibility to use regional variations of the onset to peak delay time to map heterogeneities in the crust, in order to develop a stochastic tomography in the strong fluctuation regime.

Such an approach has been pioneered by Sato in the late 1980s. A recent review of the topic in seismology is given by Sato and Korn (2009). Based on the parabolic approximation, Sato (1989) derived an equation for the two-point, two-frequency coherence functions of the wavefield for incident plane waves. This technique which was originally introduced in astrophysics has been termed “Markov approximation.” In the case of regional propagation, it is preferable however to consider the radiation from a point source. Following Saito et al. (2002), we write the coherence function of the field as follows:

$$\Gamma(\mathbf{r}_{\perp 1}, \mathbf{r}_{\perp 2}, r, \omega_d, \omega_c) = \langle U(\mathbf{r}_{\perp 1}, r, \omega_1) \langle U(\mathbf{r}_{\perp 2}, r, \omega_2)^* \rangle, \quad (9)$$

where ω_c and ω_d denote the central $(\omega_1 + \omega_2)/2$ and modulation $\omega_1 - \omega_2$ frequency, respectively. The introduction of two frequencies is demanded by the nonstationarity of the envelope records. The source station distance is denoted by r and the points $\mathbf{r}_{\perp 1}$ and $\mathbf{r}_{\perp 2}$ lie in a plane perpendicular to the wave front. The time dependence of the observed coda envelopes around the frequency ω_c is obtained by setting $\mathbf{r}_{\perp 1} = \mathbf{r}_{\perp 2}$ and taking a Fourier transform over ω_d .

The basic idea of the so-called Markov approximation is to consider one-way propagation and to neglect backscattering. The different slices of the medium perpendicular to the main propagation direction independently perturb the local ray direction in a random fashion. As a consequence, the distribution of ray directions at a distance r_0 from the source depends solely on the heterogeneities that have been met for

$r < r_0$ (Sato 1989; Sato and Korn 2009). Such an approximation is valid for strong forward-scattering, i.e., when the relation $\lambda > a$ applies. This does not mean that the Markov approximation cannot be used if the medium contains heterogeneities with scale lengths shorter than the wavelength. Indeed, the large-scale fluctuations contribute predominantly to the field measured in the transmission geometry. Scattering at large angles caused by small-scale fluctuations mainly plays the role of an apparent energy loss which adds to the intrinsic losses (Sato 1989). In order to quantify the typical validity region of the Markov approximation, it is useful to introduce a quantity known as the transport mean free path (Sheng 1995) and defined as:

$$l^* = \frac{l}{1 - \langle \cos \theta \rangle}, \quad (10)$$

where $\langle \cos \theta \rangle$ is the mean cosine of the scattering angle. The transport mean free path can be interpreted as the typical length beyond which the waves have lost memory of their initial propagation direction. In the case of large-scale fluctuations, the transport mean free path l^* is typically one or two orders of magnitude larger than the scattering mean free path l . For propagation distances of the order of the transport mean free path, backscattering can no longer be ignored and one must appeal to other methods to be described in section “Envelope Modeling: Radiative Transfer”.

As carefully explained in the paper of Sato (1989), there are two basic phenomena that contribute to the observed envelope shape. The first one is termed “the wandering effect” and is purely statistical in nature. It corresponds to the small arrival time fluctuations in the line-of-sight propagation direction. It leads to a Gaussian spread of an initially delta-like pulse. This reshaping can only be observed upon ensemble averaging and is therefore not of primary importance in seismology. The second phenomenon is the increase of the typical duration of the seismogram with propagation distance which has been termed “pulse” – or may be more appropriately – “envelope broadening.” It reflects the angular spreading of the wave propagation directions as they interact with the medium heterogeneities. For a general Von-Karman correlation function, a time scale t_m characterizes the typical duration of the seismogram (Saito et al. 2002):

$$t_m = C \left(\varepsilon^{1/(p-1)} a^{-1} \right)^{2-2/p} \omega^{-2+4/p} r_0^{1+2/p}, \quad (11)$$

where ε denotes the root mean square fluctuations, ω is the central frequency of the signal, r_0 is the hypocentral distance and C is a numerical pre-factor which depends on the wavespeed, and on the Hurst exponent κ . The parameter p is an increasing function of κ and varies from 1.2 to 2 for

Seismic Waves, Scattering, Fig. 2 Example of earthquake records showing the phenomenon of envelope broadening. Paths a, b, c propagate through a very heterogeneous volcanic region. A large delay between the onset of S waves and the maximum amplitude is clearly

$0 < \kappa \leq 1$. Formula (11) reveals interesting characteristics of the envelope broadening phenomenon. For a smooth medium, i.e., a medium poor in small-scale features, the parameter p is close to 2 and, as a consequence, the typical envelop duration is frequency-independent. Such a result also holds for the Gaussian correlation function and is in sharp contradiction with observations. As a consequence, the frequency dependence of envelope duration offers access to the degree of roughness of Earth's heterogeneities. Accurate measurements of the exponent κ requires that absorption

observed. This phenomenon further depends on the frequency band considered. Paths d, e, f do not cross the heterogeneous region and show more impulsive envelopes with small onset to peak delay time. (Reproduced from Takahashi et al. 2007)

and – to some extent – scattering losses caused by small-scale heterogeneities be incorporated in envelope modeling (Saito et al. 2002).

In practical applications to data, a characteristic time, t_q , is measured as a function of frequency and hypocentral distance: $t_q = t_p + t_{1/2}$, where t_p is the duration from onset to peak and $t_{1/2}$ is the decay time of the envelope from the peak to RMS half-peak value. Note that the observations are usually focused on the S wave train for which pulse broadening is usually much clearer than for P waves. The observations are

then compared to those numerically obtained by the Markov approximation for a wide range of correlation lengths, RMS perturbations and intrinsic quality factor. In general it is not possible to estimate independently ϵ and a since various combinations of these two parameters may yield the same characteristic time t_m . However, by analyzing separately the distance and frequency dependence of t_q , the intrinsic quality factor Q_s , the parameter p , and in turn, the Hurst exponent κ can be estimated. For applications to seismic observations, we refer to, e.g., Scherbaum and Sato (1991), Obara and Sato (1995), and Saito et al. (2005).

As illustrated in Fig. 2, for comparable hypocentral distances and frequency bands, the envelope shapes may strongly depend on the direct ray path. Such an observation calls for the introduction of large-scale variations of small-scale heterogeneities. Such an approach has been taken by Takahashi et al. (2007) who mapped strongly heterogeneous regions beneath quaternary volcanoes in northeastern Japan from the observed path dependence of the characteristic broadening time t_q . A complete tomographic approach to estimate the power spectrum of small-scale heterogeneities from envelope broadening data was further developed and applied to northeastern Japan by Takahashi et al. (2009).

Gusev and Abubakirov (1999a, b) developed a tomographic method to map the transport mean free path in the Earth based on body wave envelope broadening. Their approach is simpler since they consider the inversion of a single parameter. From the knowledge of the frequency dependence of the transport mean free path, it is possible to put constraints on the parameters ϵ , a , and κ . The Markov method has recently been extended to the case of vector waves by Sato (2006, 2007, 2008). The theoretical approach relies on the introduction of scalar and vector potentials for P and S waves, respectively. The employed Helmholtz decomposition neglects the conversions between P and S waves, which is justified in the high-frequency regime $\lambda \gg a$, up to a characteristic coupling time τ^{PS} between P and S waves. Extensions of the Markov method to the vectorial case allow the modeling of the observed energy envelopes of the transverse components of the wavefield after the onset of the direct P -wave. The observation of such transverse energy is another manifestation of the randomization of the ray directions in a scattering medium. Alternative explanations for this phenomenon are mode conversions or anisotropy. In the case of a statistically homogeneous Gaussian medium with thickness h , Sato (2006) showed that the ratio between the peak total intensity and the peak intensity on the transverse component of the P pulse scales like $\epsilon^2 h/a$. Interestingly, this relation is free from absorption, since it cancels out in the intensity ratio. Based on this approach Kubanza et al. (2007) made a global study of energy envelopes of transverse components in the P wave train observed at teleseismic distances and found good correlation between the strength of heterogeneity and the tectonic setting.

Envelope Modeling: Radiative Transfer

When the propagation time and distances become very large compared to the ballistic time, or when the acquisition geometry is in the reflection mode, it becomes crucial to take into account scattering at large angle. A powerful approach to model seismogram envelopes in scattering media in such cases is provided by radiative transfer theory. In seismology, radiative transfer was introduced in the mid-1980s by Wu (1985) with a first application to data by Wu and Aki (1988). Physically, the equation of transfer is a local statement of energy conservation in a random medium and incorporates an arbitrarily high number of scattering events. The radiative transfer equation also takes into account the anisotropy of the scattering process, in particular large-angle scattering. Therefore, it enables the complete modeling of seismogram envelopes including coda waves, i.e., the late arrivals of the seismogram. A review of the radiative transfer approach in seismology is given by Margerin (2005).

The study of coda waves has been pioneered by Aki (1969) and Aki and Chouet (1975). In this last reference, the authors developed two famous models of scattering: the single-scattering approximation and the diffusion approximation. The single-scattering model applies for propagation distances of the order of, or less than the mean free path. This model has been very popular until studies by Gusev and Abubakirov (1987) and Hoshihara (1991) pointed out the importance of multiple scattering. Recently, the diffusion model has known a revived interest in connection with seismic experiments on volcanoes (Wegler and Lühr 2001; Wegler 2004). The single-scattering and diffusion models are respectively short-time and large-time asymptotics of the radiative transfer equation. Mathematically, radiative transfer takes the form of an integro-differential equation for an angularly resolved energy flux known as the specific intensity $I(\mathbf{r}, \hat{\mathbf{k}}, t, \omega)$. The specific intensity quantifies the amount of energy flowing around the direction $\hat{\mathbf{k}}$ in a small frequency band $[\omega, \omega + \delta\omega]$ during a time interval $[t, t + dt]$ through a small surface element located at $\mathbf{r}$. Although the concept of specific intensity was first introduced on a phenomenological basis, it is now well understood that it is in fact connected to the Wigner-Ville distribution of the wavefield (Ryzhik et al. 1996):

$$I(\mathbf{r}, \hat{\mathbf{k}}, t, \omega) = C \iint \langle u(t - \tau/2, \mathbf{r} + \mathbf{x}/2) u(t + \tau/2, \mathbf{r} - \mathbf{x}/2)^* \rangle e^{-i\mathbf{k} \cdot \mathbf{x} + i\omega\tau} d^3x d\tau, \quad (12)$$

where the brackets denote an ensemble average. The key to understand this definition is the notion of separation of scales. In Eq. 12, one must think of the intensity as a slowly varying function of the time t , as compared to the fast oscillations of

the wavefield described by the frequency ω . Similarly, the average intensity varies slowly in space as compared to the wavelength. Such a separation of scales is well satisfied by high-frequency seismograms and guarantees that the Wigner distribution can be interpreted as a local power spectrum of the wavefield. It is important to note that interference effects are neglected in the transfer approach. This can be justified on the basis of the small phase shifts that occur upon scattering and which will be different for waves visiting different heterogeneities.

An important step in the development of radiative transfer was the introduction of the Monte Carlo method, which is a flexible numerical technique to solve the transfer equation. It has been introduced in seismology by Gusev and Abubakirov (1987). The Monte Carlo method simulates the random walk of particles, which change direction of propagation at the end of each step. The step length has an exponential distribution with parameter the scattering mean free path, and the change of direction upon scattering is provided by a probabilistic interpretation of the differential scattering cross-section. The latter quantity can be obtained from the Born approximation at frequencies below the geometrical optics limit. The validity of this approximation has been discussed by Wegler et al. (2006a) and Przybilla and Korn (2008). The Monte Carlo method can be shown to yield an exact solution of the transfer equation (Papanicolaou et al. 2000). The variance of the result typically decreases like the square root of the number of simulated random walks.

An important application of the radiative transfer approach was developed by Fehler et al. (1992) and Hoshiya (1993) who proposed a method to infer the mean free path and intrinsic quality factor in the crust from the space time dependence of the energy radiated by small earthquakes. The method is based on the estimation of the energy in three successive time windows starting with the direct S wave arrivals. Such multiple lapse-time window analysis has been applied in various regions of the world to give estimates of the level of heterogeneity in the crust. Typically, the mean free path of the crust around 1 Hz ranges from a few tens to a few hundred kilometers. The method has some limitations since it assumes isotropic scattering and a uniform distribution of scatterers in a half-space.

It was pointed out by Gusev and Abubakirov (1987), Abubakirov and Gusev (1990) and Hoshiya (1995) that the observed shape of envelopes of body waves is incompatible with isotropic scattering, since no broadening occurs in this case. Based on the comparison between modeled and observed S wave seismogram envelopes, Gusev and Abubakirov (1996) were able to infer a Hurst exponent ranging between $1/4$ and $1/2$ in the crust. In the case of crustal propagation at regional distances, the field is dominated by guided waves. To take into account the role of stratification and scattering in the Earth, Hoshiya (1997), Margerin et al.

(1998), and Yoshimoto (2000) have shown how to incorporate depth-dependent velocity and mean free path in the Monte Carlo method. Margerin et al. (1999) numerically solved the radiative transfer equation in the crustal geometry and confirmed the importance of the leakage of energy at the Moho to explain the decay of the coda, as first proposed by Korn (1990).

Other applications of radiative transfer pertain to the study of the seismic source. Nakahara et al. (1998) proposed a method based on radiative transfer theory to infer the distribution of high-frequency radiation on the fault plane of large earthquakes. They considered the different part of the fault to be independent and modeled the propagation using a multiple isotropic scattering model. Sens-Schönfelder and Wegler (2006a) devised a method to infer the seismic moment of small crustal earthquakes recorded at regional distance. Another important application concerns the modeling of wave propagation in very heterogeneous structures such as volcanoes, where the mean free path can become as small as a few hundred meters. A review of recent development in the field is provided by Del Pezzo (2008). It is to be noted that in cases where the typical propagation distance is much larger than the mean free path, the radiative transfer equation can be simplified to a simple scalar diffusion equation for the total energy density of P and S waves. The diffusion approach to the modeling of seismic energy propagation in volcanoes has been advocated by Wegler (2004).

Radiative transfer theory is still in an active stage of development. A radiative transfer equation for elastic waves has been introduced in seismology by Zeng (1993), Sato (1994), and Ryzhik et al. (1996). This equation takes into account in a rigorous way the coupling between P and S waves. A Monte Carlo method to solve this elastic transfer equation was developed by Margerin et al. (2000). A comparison of finite-difference and Monte Carlo simulations by Przybilla and Korn (2008) demonstrated the accuracy of the radiative transfer approach to simulate the coupling and multiple scattering of P and S waves. An extension of the radiative transfer equation to incorporate the coupling between surface and body waves is a major challenge. An important step in this direction was made by Maeda et al. (2007) who incorporated the coupling between Rayleigh and body waves in the single-scattering approximation. The impact of anisotropic scale lengths has been studied by Margerin (2006) who derived a radiative transfer equation with an angular-dependent scattering mean free path.

Global-Scale Scattering

The subject of seismic scattering at the global scale was first developed in the early 1970s in connection with short-period precursors to phases such as PP (King et al. 1975) and PKP

(Cleary and Haddon 1972). Accompanying the improvement of the global seismic network and the availability of high-quality data, evidences for the importance of scattering in the deep Earth have accumulated in recent years. The study of precursors to deep phases such as *PKP* (Hedlin et al. 1997) and *PKKP* (Earle and Shearer 1997) has been used to put constraints on the heterogeneities in the deep mantle and core. Observation and modeling of anomalous propagation of seismic waves in the subducting lithosphere have put forward the role of scattering by elongated heterogeneities in slabs (Furumura and Kennett 2005). The presence of strong scatterers in Earth's inner core has been revealed by a number of studies (Vidale and Earle 2000; Koper et al. 2004; Poupinet and Kennett 2004). Vidale and Earle (2000) used data from nuclear explosions recorded on the LASA array to demonstrate that the long-lasting signal following the ballistic *PKiKP* phase was not caused by the response of the crust but were genuine scattered waves radiated from the inner core. They showed examples of slowly-emergent and long-lasting *PKiKP* signals recorded at an epicentral distance of about 60° . This last point is particularly important, since it corresponds to incidence angles of *P* waves at the inner core boundary such that the reflection coefficient vanishes. The coda of *PKiKP* thus provides a direct proof of the presence of scatterers in the inner core.

Since the deep Earth interior is usually thought to be much less heterogeneous than the lithosphere, much of the modeling work has been focused on the single scattering approximation (Hedlin et al. 1997; Vidale and Earle 2000; Leyton and Koper 2007). The radiative transfer approach was introduced in global seismology by Margerin and Nolet (2003a, b) to improve the modeling of the precursors to the *PKP* wave. In particular, they demonstrated the ability of radiative transfer to incorporate complicated ray geometry such as the one imposed by the severe drop of velocity at the core–mantle boundary. The Monte Carlo method was further developed by Shearer and Earle (2004) who proposed a scheme to simulate the multiple scattering of elastic waves at the global scale, including the coupling between *P* and *S* waves. Their method was applied to the study of the coda envelopes of teleseismic *P* waves. To explain the observations, they proposed a 1-D model of Earth small-scale heterogeneity composed of a heterogeneous 200 km top-layer (4% RMS perturbations) overlying a less heterogeneous 400-km layer (3% RMS perturbations). At the base of the mantle, a 600 km thick layer with 0.5% RMS perturbations is required to achieve a good fit to the data. Shearer and Earle (2004) concluded that attenuation is dominated by scattering in the upper-mantle and by absorption in the lower mantle.

In addition to global studies of scattering of short-period waves, an interest in the scattering of long-period surface waves has recently arisen. Maeda et al. (2006) performed an (f, k) analysis of the vertical components of three large

earthquakes recorded on the Japanese Hi-Net in the 90–180 s period band. They find that the signals recorded between the first multi-orbiting Rayleigh wave arrivals are composed of waves coming from all directions with phase velocities of the order of the Rayleigh wave fundamental mode. This suggests that in the period band of interest, scattered Rayleigh waves are present in the data at short lapse time. After typically 30,000 s, the multi-orbiting Rayleigh waves have strongly decayed. The (f, k) analysis demonstrates that the signal is dominated by waves with very large phase velocities, thereby implying the dominance of higher-mode Rayleigh waves. Such a phenomenon is to be expected on the ground that higher modes sample the deeper parts of the Earth with high intrinsic quality factor. To model the coda of multi-orbiting Rayleigh waves, Sato and Nishino (2002) developed a radiative transfer equation on the sphere assuming the multiple isotropic scattering of the fundamental mode Rayleigh wave. In their approach, the coupling with higher modes is neglected. They observe a systematic discrepancy between observed and modeled seismogram envelopes which also suggests that higher modes dominate the data at lapse times larger than 30,000 s.

Interferometry with Scattered Waves

Green Function Retrieval

As explained in section “Introduction”, the incoherent field refers to the waves that average out when a mean over an ensemble of random media is performed. These waves are incoherent in the sense that, at a given point of the medium, they propagate in space directions that differ from that of the mean field. But “incoherence” does not imply that the phase information has been lost (Campillo 2006). Campillo and Paul (2003) were the first to demonstrate the existence of correlations between the coda waves recorded at two distant points in the heterogeneous crust. Such correlations emerge after sufficient temporal and source averaging. Following Lobkis and Weaver (2001), Campillo and Paul (2003) proposed that the correlation tensor of the coda wavefields recorded at two points *A* and *B* is in fact proportional to the Green's tensor G_{ij} between these two points. In the frequency domain, such a relation can be mathematically formulated as follows:

$$\langle u_i(B, \omega) u_j(A, \omega)^* \rangle \propto \text{Im} G_{ij}(B, A, \omega). \quad (13)$$

The proportionality factor depends on the details of the source spectrum. The occurrence of the imaginary part of the Green's function on the right-hand side of Eq. 13 physically means that the correlation of two wavefields is proportional to a combination of the retarded and advanced Green's functions. The appearance of the advanced Green's function is

most easily understood by noting the equivalence between correlations and time-reversal experiments. We will not discuss this analogy, but the interested reader can refer to Derode et al. (2003).

In seismology, the brackets in Eq. 13 usually denote an average over time windows in the coda and over earthquake sources. An example of emergence of the retarded and advanced Green's function in the correlation of coda waves recorded on a temporary network deployed in Alaska is illustrated in Fig. 3. The maximum of the correlation is always shown for positive times, but it is nevertheless possible to

distinguish some coherent arrivals at negative times. The reconstruction of the Green's function from coda waves is intimately related to the concept of equipartition, which is a fundamental consequence of multiple scattering. Loosely stated, equipartition stipulates that plane P , S , Rayleigh, and Love waves coming from all possible directions compose the wavefield. That the Green's function of the medium is recovered if the equipartition state is reached has been shown for an infinite elastic medium by Sánchez-Sesma and Campillo (2006). Based on the single-scattering approximation for scalar waves, Sato (2009) demonstrated that the correlation

Seismic Waves, Scattering, Fig. 3 Example of Green's function reconstruction from coda waves recorded in Alaska. A location map of the experiment is shown on the left. The inset shows all the station pairs analyzed in this study. On the right, all possible terms of the correlation tensor are represented as a function of the correlation time on the

horizontal axis and the epicentral distance between the two stations on the vertical axis. For each station pair, the three components of the seismometers have been rotated onto the radial (R), transverse (T), and vertical (Z) reference frame. (Reproduced from Paul et al. 2005)

of coda waves recorded at two stations enables the reconstruction of the ballistic Green's function between the two stations. Snieder (2004b) derived the reconstruction of the Green's function from coda waves based on the stationary phase approximation. An experimental verification of the equipartition principle has been performed by Hennino et al. (2001). In Fig. 3, we can observe a clear time asymmetry in the reconstructed Green's function. This seems to contradict the equipartition principle. Such a time asymmetry has been studied by Paul et al. (2005). These authors demonstrate that a flux of energy directed from the earthquake source to the station can persist even at very large lapse time in the coda. Such an energy flux breaks the temporal symmetry of the correlations unless the distribution of earthquakes around the station covers all azimuths.

Monitoring Temporal Variations

An interesting application of wave multiple scattering pertains to the detection of weak changes in dynamic media, i.e., media evolving with time. The methods which make use of scattered waves to probe changes in complex media have been termed “diffusing acoustic wave spectroscopy” in acoustics and “coda wave interferometry” (CWI) in seismology. In this article, we focus on applications to seismic waves. A theoretical approach of the method is provided by Snieder (2006). For a very accessible review of this broad topic in physics, we refer to Snieder and Page (2007). A comprehensive review of monitoring applications in seismology is given by Poupinet et al. (2008).

The key idea of CWI is to take advantage of the long propagation paths of scattered waves, which accumulate small phase differences on their way from source to station. An example of monitoring the medium changes at the Merapi volcano is shown in Fig. 4. In this experiment, a repeatable source is used to generate seismic waves that propagate

through the volcano. The fact that the source is highly reproducible is important, as any small difference between seismograms recorded at different time instants can be interpreted as a change of the propagating medium. Natural repeating sources such as earthquake doublets can also be exploited to probe medium changes. The doublets correspond to small earthquakes breaking the same fault patch at different times of occurrence (Poupinet et al. 1984). As shown in Fig. 4, the changes are virtually undetectable on the first arrivals. In the coda, the medium changes are manifested by a small time delay between two very similar waveforms. In the case of the Merapi data shown in Fig. 4, an analysis of the delay times as a function of the time lag in the coda reveals that the two seismograms are nearly stretched versions of one another. This means that the two waveforms can be related by a similarity transformation $t \rightarrow t/(1 + \epsilon)$ of the time variable. Such an observation can be interpreted as a very small change of the wave velocity δv in the propagating medium. The relation between the stretching parameter ϵ and the velocity variation reads (Sens-Schönfelder and Wegler 2006b):

$$\epsilon = -\frac{\delta v}{v} \quad (14)$$

In practice, the velocity change can be estimated by measuring the delay time which maximizes the correlation between the two signals. Such a procedure can be applied to moving time windows in the coda, of typical duration, a few central periods. The relation (14) is valid for acoustic waves only. A formula valid for elastic coda waves in the equipartition regime has been derived by Snieder (2002). Ratdomopurbo and Poupinet (1995), and Wegler et al. (2006b) found that the shear velocity increases prior to eruptions at the Merapi volcano, an observation interpreted as a

Seismic Waves, Scattering, Fig. 4 Illustration of the principle of coda wave interferometry. A controlled and repeatable source is used to probe the Merapi volcano with seismic waves. The signals recorded at a time interval of 1 year are shown by blue and black lines. The insets show the

comparisons of waveforms in the early part of the signal (E) and in the late part of the signal (L). In the later portion, a clear time shift between the two traces can be observed. (Reproduced from Snieder 2004a)

pressurization effect due to the magma ascent. Typically, relative velocity changes of the order of 10^{-5} – 10^{-4} can be detected (Poupinet et al. 2008). This makes coda wave interferometry the ideal tool to study the rheology of materials (Snieder et al. 2002).

As a final example of the use of scattered waves, we consider a method which has been termed “passive image interferometry” (Sens-Schönfelder and Wegler 2006b) which combines coda wave interferometry with the principle of Green’s function reconstruction from coda waves. Passive interferometry uses ambient noise – instead of coda waves – to reconstruct the Green’s function. The coda part of the reconstructed Green’s function is subsequently used to monitor temporal variations in the medium. A great advantage of this method as compared to the usual coda wave interferometry lies in the fact that noise records allow a continuous reconstruction of the Green’s function over very long time periods. Brenguier et al. (2008) demonstrated the possibility to detect very small medium changes at Le Piton de la Fournaise volcano in la Réunion Island. Applications to the study of the recovery phenomena in sediments affected by strong ground motion are developed in Sawazaki et al. (2009).

Summary

This article presents a nontechnical introduction to the various phenomena and methods pertaining to the scattering of seismic waves. The basic concepts of seismic scattering are introduced with the aid of a thought-experiment. The topics covered include the interpretation of transmission fluctuations, the broadening of envelope at regional distances, the interpretation of coda waves at local and global scales, and the use of scattered waves in seismic interferometry. The methods developed in seismic scattering offer powerful tools for the stochastic imaging of Earth’s structure at spatial scales that cannot be resolved by traditional tomographic methods. In addition, scattered seismic waves are extremely sensitive to slight temporal changes of the medium. Using the interferometric approach, multiply-scattered coda waves can be used to monitor the evolution of the dynamic Earth.

Seismic Zonation

Yanxiang Yu, Mengtan Gao and Guangyin Xu
Institute of Geophysics, China Earthquake Administration,
Beijing, China

Definition

Seismic zonation. The process of subdividing the territory into regions with respect to the level of seismic hazard. The result of seismic zonation is usually presented as a map, which is based on seismic hazard map.

Introduction

Seismic zonation is useful for hazard reduction such as earthquake-resistant design of structures, risk analysis, land-use planning, etc. Many earthquake-prone countries developed seismic zonation maps. Seismic zonation map is usually revised or updated periodically with the progress in methodology and accumulation of new data. Seismic intensity (see ► [“Earthquakes, Intensity”](#)) or ground motion parameters such as peak ground acceleration (PGA), peak ground velocity (PGV), and spectral acceleration at specific natural period are mostly adopted in seismic zonation map. In the early stage, most seismic zonation maps were in terms of intensity, but since the 1980s, ground motion parameters have become popular. More commonly, such maps take the exceeding probability of 10% within 50 years (return period 475 years) as standard.

Methodology

The basic method to develop seismic zonation map is the seismic hazard analysis (see ► [“Seismic Hazard”](#)) approach. Both deterministic and probabilistic approaches are adopted. Although some new deterministic approaches based on the computation of synthetic seismograms are used in recent years in developing seismic zonation maps (Parvez et al. 2003), nevertheless probabilistic approaches are more popular. The seismic zonation maps, based on seismic hazard maps (see ► [“Seismology, Global Earthquake Model”](#)), of many countries are developed by the use of probabilistic approach. The well-known USGS National Seismic Hazard Maps (Algermissen and Perkins 1976; Algermissen et al. 1990; Frankel et al. 1996, 2002; Petersen et al. 2008) and the Global Seismic Hazard Assessment Programme (GSHAP) are the typical (see ► [“Seismic Hazard”](#)) ones. In this article, only probabilistic method is briefly introduced.

The probabilistic method (usually referred to as PSHA – probabilistic seismic hazard analysis) was first introduced by Cornell (1968) and since then widely adopted and modified (McGuire 1978; Bender and Perkins 1982). There are four basic steps for assessment of PSHA (Fig. 1):

- Step 1: Definition of seismic sources. Sources may range from small faults to large seismotectonic provinces with uniform seismicity. The type of seismic source can be both line or area sources.
- Step 2: Definition of seismicity recurrence characteristic for the sources, where each source is described by an earthquake probability distribution, or recurrence relationship. A recurrence relationship indicates the chance of an earthquake of a given magnitude to occur anywhere inside the

source during a specified period of time. An upper bound earthquake is chosen for each source, which represents the maximum event to be considered.

- Step 3: Development of ground motion attenuation relationships. This is usually done empirically from strong motion records (see ► [“Earthquakes, Strong-Ground Motion”](#)).

- Step 4: Determination of the hazard at each site. In this case, the effects of all the earthquakes of different sizes occurring at different locations in different earthquake sources at different probabilities of occurrence are integrated into one curve that shows the probability of exceeding different levels of ground motion level (such as PGA) at the site during a specified period of time.

There are two basic assumptions in the seismic hazard analysis method at present: (a) Seismicity in the region around the site in the past indicates that in future, the recurrence rate of given site is the same as that of historic period. (b) Seismicity of the region can be expressed by tectonic earthquakes in the region, i.e., the seismic activities distribute homogeneously in a certain tectonic area or an active fault.

The two assumptions accord with the two principles of historic earthquake repeatness and tectonic extrapolation. The difference is that the PSHA adds a new concept of magnitude interval recurrent rate and the hazard is evaluated with probabilistic analysis method. The method can provide the exceedence probability of different ground motion extent (intensity, acceleration, etc.) at the site in specific time intervals, so that the earthquake resistant parameters can be selected with different exposure period, risk level, and various engineering structures.

Example: Seismic Zonation Map of China (2001)

The first seismic zonation map of China was compiled by Wong (1921) after the Haiyuan earthquake, which occurred in 1920. After that, three versions of seismic zonation map were developed in 1957, 1977, and 1990 (Shi et al. 1992). The 1957 version demonstrated the maximum affected intensity of China. The 1977 version was provided by using the methodology of long-term and middle-term earthquake prediction. This version of seismic zonation map demonstrated the maximum encountered intensity in the forthcoming 100 years. This map was adopted by the building code. The 1990 version used probabilistic method. The seismic intensity with exceeding probability of 10% within 50 years was given in the map. It was used in the building code and other regulations related with seismic design. In 2001, a new seismic zonation map of China was issued. This map also used probabilistic method.

Seismic Zonation,**Fig. 1** Approaches of probabilistic seismic hazard analysis

The PGA and characteristic period of response spectrum T_g with exceeding probability of 10% within 50 years were given in the map. The probabilistic method used in developing seismic zonation of China (2001) was a little bit different from PSHA.

Most earthquakes in China are intraplate earthquakes (see ► [“Seismicity, Intraplate”](#)). Their non-homogeneity in space, non-stationarity in time were shown in the historical earthquake catalogs. The PSHA method applied in China can reveal non-homogeneity in space, non-stationarity in time. The approaches applied differ from PSHA in two aspects:

1. Evaluating seismicity and determining magnitude distribution, total annual occurrence rate of the province are on the basis of the seismic tendency estimation and the seismic characteristics analysis.
2. Annual rates of sources in all magnitude intervals are determined by spatial distribution functions, which describe relative risk among sources in the province.

The technical approach for developing the national seismic zonation map of China (2001) is shown in Fig. 2 (Gao 2003).

Seismic Zonation, Fig. 2 Technical approach of developing national seismic zonation map of China (2001)

The key scientific problems in compiling this map are: (a) how to treat the uncertainties in the evaluation of seismicity parameters and the delineation of potential sources as well as the attenuation relationship; (b) how to select the suitable parameters in the zonation map to fit the need of seismic design; and (c) how to use the domestic data and the data from the world to get the attenuation of the ground motion parameters.

The logic tree method is adopted to treat the uncertainties in seismic hazard analysis. The multi-set of potential source delineations was used. Four groups of scientists participated in the work of potential sources delineations based on the independent background and database. There are four sets of potential sources adopted in the logic tree analysis. Figure 3 is one of the potential source set.

Site-related seismic response spectrum is the base of seismic design for ordinary industry and civil construction. The site-related response spectrum is not only closely related to the earthquake environment, but also related to the soil condition. It is very difficult to decide site-related response spectrum by a single parameter such as intensity or peak

acceleration. According to the results from seismic hazard assessment and the building code, the basic parameters used in the seismic zoning map to provide site-related response spectrum are PGA and the characteristic period of the response spectrum.

The attenuation relationships for the acceleration response spectrum platform value S_a and the velocity response spectrum platform value S_v were developed by modifying corresponding attenuation relations in the western United States according to the differences of intensity attenuation relations. Then the PGA and the characteristic period of response spectrum of acceleration T_g were defined as:

$$\begin{aligned} PGA &= \frac{S_a}{2.5} \\ T_g &= 2\pi \frac{S_v}{S_a} \end{aligned} \quad (1)$$

The country was divided into 40,000 grids. The probabilistic seismic hazard analysis for every grid was performed. The ground motion parameters with exceeding probability

Seismic Zonation, Fig. 3 One of the seismic potential source set used in developing national seismic zonation of China (2001)

10% within 50 years (return period 475 years) were determined.

The new zoning map includes two specific maps. One is PGA in gravity unit g (Fig. 4) and the other is T_g in second (Fig. 5). The scale of the maps are 1:4,000,000. The soil condition is medium hard soil. From these two parameters, the design response spectrum can be determined easily by (Eq. 2):

$$Sa(T) = 2.5a \begin{cases} 6T + 0.4 & 0 \leq T < 0.1 \\ 1 & 0.1 \leq T < T_g \\ T_g/T & T \geq T_g \end{cases} \quad (2)$$

where a is PGA in g , T is the natural period in second.

In the acceleration map (Fig. 4), the territory is divided into seven zones. The acceleration for the seven zones are 0.05, 0.05, 0.10, 0.15, 0.20, 0.30, and ≥ 0.40 g , respectively.

In the characteristic period zoning map (Fig. 5), the territory of China is divided into three zones. Zone 1 is the region with $T_g = 0.35$ s, zone 2 with $T_g = 0.40$ s, and zone 3 with $T_g = 0.45$ s.

For different soil conditions, the T_g value should be adjusted as Table 1, but the PGA value does not change with soil conditions.

The new national seismic zonation map of China serves as the obligatory state standard, which took effect in August 1, 2001. For the ordinary newly constructed buildings, the standard must be followed.

Seismic Zonation, Fig. 4 Illustration of acceleration zonation map of China

Summary

Seismic zonation is a process of estimation of the seismic hazard in terms of parameters of ground motion for a certain area. Assessment results in seismic zonation map compilation, which reflects territorial distribution of the seismic hazard (see ► [“Seismic Hazard”](#)). Seismic zonation map is useful for hazard reduction such as earthquake-resistant design of structures, risk analysis, land-use planning, etc. Many countries apply seismic hazard maps in anti-seismic codes. Recently, the probabilistic seismic hazard analysis method is more commonly used in compiling seismic zonation map. The seismic zonation maps take the exceeding probability of 10% within 50 years (return period 475 years)

as standard. Seismic zonation will develop with the development of seismic hazard assessment methodology and anti-seismic policy.

Definition

Seismic noise: permanent motion of the Earth surface that is not related to earthquakes or specific controlled sources.

Introduction

Traditional observational methods in seismology are based on earthquake records. It results in two main shortcomings. First, most techniques are based on waves emitted by earthquakes that occurred only in geologically active areas, mainly plate boundaries. This results in a limited resolution in all other areas where earthquakes are not present. Second, the repetition of earthquakes is rare, preventing the study of continuous changes within active structures such as volcanoes or faults.

Also at smaller scales in the context of geophysics prospecting, the resolution is limited by the number and power of sources, making it difficult to image large areas and/or deep structures. Similarly, reproducible sources are necessary for time-lapse monitoring leading to long-duration surveys that are difficult to achieve.

Nowadays, the seismic networks are producing continuous recordings of the ground motion. These huge amounts of data consist mostly of so called seismic noise, a permanent vibration of the Earth due to natural or industrial sources. Passive seismic tomography is based on the extraction of the coherent contribution to the seismic field from the cross-correlation of seismic noise between station pairs.

As described in many studies where noise has been used to obtain the Green's function between receivers, coherent waves are extracted from noise signals even if, at first sight, this coherent signal appears deeply buried in the local incoherent seismic noise. Recent studies on passive seismic processing have focused on two applications, the noise-extracted Green's functions associated to surface waves leads to sub-surface imaging on scales ranging from thousands of kilometers to very short distances; on the other hand, even when the Green's function is not satisfactorily reconstructed from seismic ambient noise, it has been shown that seismic monitoring is feasible using the scattered waves of the noise-correlation function.

Theoretical Basis for the Interpretation of Noise Records at Two Stations

Passive seismology is an alternative way of probing the Earth's interior using noise records only. The main idea is to consider seismic noise as a wave field produced by randomly and homogeneously distributed sources when averaged over long time series. In this particular case, cross-correlation between two stations yields the Green's function between these two points. In the case of a uniform spatial distribution of noise sources, the crosscorrelation of noise records converges to the complete Green's function of the medium, including all reflection, scattering, and propagation modes. However, in the case of the Earth, most of ambient seismic noise is generated by atmospheric and oceanic forcing at the surface. Therefore, the surface wave part of the Green's function is most easily extracted from the noise cross-correlations. Note that the surface waves are the largest contribution of the Earth response between two points at the surface.

Historically speaking, helioseismology was the first field where ambient-noise cross-correlation performed from recordings of the Sun's surface random motion was used to retrieve time-distance information on the solar surface. More recently, a seminal paper was published by Weaver and Lobkis (2001) that showed how, at the laboratory scale, diffuse thermal noise recorded and cross-correlated at two transducers fastened to one face of an aluminum sample provided the complete Green's function between these two points. This result was generalized to the case where randomization is not produced by the distribution of sources, but is provided by multiple scattering that takes place in heterogeneous media.

By summing the contributions of all sources to the correlation, it has been shown numerically that the correlation contains the causal and acausal Green's function of the medium. Cases of non-reciprocal (e.g., in the presence of a flow) or inelastic media have also been theoretically investigated. Derode et al. (2003) proposed to interpret the Green's function reconstruction in terms of a time-reversal analogy that makes it clear that the convergence of the noise-correlation function towards the Green's function is bonded to the stationary phase theorem. For the more general problem of elastic waves, one could summarize that the Green's function reconstruction depends on the equipartition condition of the different components of the elastic field. In other words, the emergence of the Green's function is effective after a sufficient self-averaging process that is provided by random spatial distribution of the noise sources when considering long-time series as well as scattering (e.g., Gouédard et al. 2008 and references herein).

Applications in Seismology

For the first time, Shapiro and Campillo (2004) reconstructed the surface wave part of the Earth response

by correlating seismic noise at stations separated by distances of hundreds to thousands of kilometers, and measured their dispersion curves at periods ranging from 5 s to about 150 s. Then, a first application of passive seismic imaging in California (e.g., Shapiro et al. 2005; Sabra et al. 2005) appeared to provide a much greater spatial accuracy than for usual active techniques. More recently, the feasibility of using the noise cross-correlations to monitor continuous changes within volcanoes and active faults was demonstrated (e.g., Brenguier 2008a, b). These results demonstrated a great potential of using seismic noise to study the Earth interior at different scales in space and time. At the same time, the feasibility of both noise-based seismic imaging and monitoring in every particular case depends on spatio-temporal properties of the available noise wavefield. Therefore, a logical initial step for most of noise-based studies is to characterize the distribution of noise sources. Also, in many cases, knowledge of the distribution of the noise sources can bring very important information about the coupling between the Solid Earth with the Ocean and the Atmosphere. So far, we can identify three main types of existing seismological applications related to noise correlations: (1) studies of spatio-temporal distribution of seismic noise sources, (2) noise-based seismic imaging, and (3) noise-based seismic monitoring.

Noise Source Origin and Distribution

Distribution of noise sources strongly depends on the spectral range under consideration. At high frequencies (>1 Hz), the noise is strongly dominated by local sources that may have very different origins and are often anthropogenic. At these scales, the properties of the noise wavefield should be studied separately for every particular case and no reasonable generalization can be done. At longer periods, noise is dominated by natural sources. In particular, it is well established that two main peaks in the seismic noise spectra in so-called microseismic band (1–20 s) are related to forcing from oceanic gravity waves. It has been also argued that at periods longer than 20 s, the oceanic gravity and infragravity waves play a major role in the seismic noise excitation. The interaction between these oceanic waves and the solid Earth is governed by a complex non-linear mechanism (Longuet-Higgins 1950) and, as a result, the noise excitation depends on many factors such as the intensity of the oceanic waves but also the intensity of their interferences as well as the seafloor topography (e.g., Kedar et al. 2008). Overall, the generation of seismic noise is expected to be strongly modulated by strong oceanic storms and, therefore, to have a clear seasonal and non-random pattern.

Seismic noise in the microseismic spectral band is dominated by fundamental mode surface waves. It is currently debated whether the surface wave component of microseisms is generated primarily along coastlines or if it is also generated in deep-sea areas. Inhomogeneous distribution and seasonality of microseismic noise sources is clearly revealed by the amplitude of the Rayleigh wave reconstructed in noise cross-correlations (e.g., Stehly et al. 2006) as shown in Fig. 1. At the same time, body waves were detected in the secondary microseismic band and can be sometimes associated with specific storms. Figure 2 shows that sources of microseismic P waves are located in specific areas in deep ocean and exhibit strong seasonality as determined from the analysis of records by dense seismic networks (Landes et al. 2010).

Noise-based Seismic imaging

Numerous studies has demonstrated that, when considered over sufficiently long times, the noise sources become sufficiently well distributed over the Earth's surface and that dispersion curves of fundamental mode surface waves can be reliably measured from correlations of seismic noise at periods between 5 and 50 s for most of interstation directions. This led to the fast development during recent years of the ambient-noise surface wave tomography. It consists of computing cross-correlations between vertical and horizontal components for all available station pairs followed by measuring group and phase velocity dispersion curves of Rayleigh and Love waves (e.g., Bensen et al. 2007). This dispersion curves are then regionalized (e.g., Lin et al. 2009) and inverted to obtain three-dimensional distribution of shear velocities in the crust and the uppermost mantle. After first results obtained in southern California (Shapiro et al. 2005; Sabra et al. 2005), this method has been applied with many regional seismological networks (e.g., Yao et al. 2006; Lin et al. 2007; Yang et al. 2008a). At smaller scales, it can be used to study shallow parts of volcanic complexes (e.g., Brenguier et al. 2007). The ambient-noise surface wave tomography is especially advantageous in context of dense continent-scale broadband seismic networks such as available in USA (e.g., Moschetti et al. 2007; Yang et al. 2008b) and Europe (e.g., Stehly et al. 2009). At these scales, noise-based imaging can be used to obtain high-resolution information about the crustal and the upper mantle structure including seismic anisotropy (e.g., Moschetti et al. 2010) and can be easily combined with earthquake-based measurements to extend the resolution to larger depths (e.g., Yang et al. 2008b). An example of results obtained from combined noise and earthquakes based surface wave tomography in western USA is shown in Fig. 3.

Seismic, Ambient Noise Correlation, Fig. 1 Comparison between seasonal variations of the location of seismic noise sources and significant wave height. (a) and (c) Geographical distribution of the apparent source of the Rayleigh waves detected in the 10–20 s noise cross correlations during the winter and the summer, respectively. (b) and (d) Global distribution of the square of wave height measured by TOPEX/Poseidon during the winter and the summer, respectively. (From Stehly et al. 2006)

Seismic, Ambient Noise Correlation, Fig. 2 Seasonal variation of the location of P-wave seismic noise sources in the secondary microseismic band (0.1–0.3 Hz) determined from the analysis of records at the three seismic networks indicated with white stars. (From Landes et al. 2010)

Seismic, Ambient Noise Correlation, Fig. 3 Shear-velocity structure of the crust and the upper mantle obtained from the inversion of the USArray data. (a) and (b) Horizontal cross-sections at depths of 5 and 100 km. (c) and (d) Vertical cross-sections along profiles delineated by

the white lines in (b). Black lines outline the Moho. Topography is superimposed above individual cross sections. The black triangles represent active volcanoes in the Cascade Range. (From Yang et al. 2008b)

Noise-based Monitoring

One of the advantages of using continuous noise records to characterize the earth materials is that a measurement can easily be repeated. This led recently to the idea of a continuous monitoring of the crust based on the measurements of wave speed variations. The principle is to apply a differential measurement to correlation functions, considered as virtual seismograms. The technique developed for repeated earthquakes (doublets), proposed by Poupinet et al. 1984, can be used with correlation functions. In a seismogram, or a correlation function, the delay accumulates linearly with the lapse time when the medium undergoes a homogeneous wave speed change, and a slight change can be detected more easily when considering late arrivals. It was therefore reasonable, and often necessary, to use coda waves for the measurements of temporal changes. Noise-based monitoring relies on the auto-correlation or cross-correlation of seismic noise records (Sens-Schönfelder and Wegler 2006; Brenguier et al. 2008a, b). When data from a network are available, using cross-correlation take advantage of the number of pairs with respect to the number of stations. It is worth noting that the use of the coda of the correlation functions is also justified by the fact that its sensitivity to changes in the origin of the seismic noise is much smaller than the sensitivity of the direct waves. Several authors noted that an anisotropic distribution of sources leads to small errors in the arrival time of the direct waves, which can be evaluated quantitatively (e.g., Weaver et al. 2009). While in most of the cases, they are acceptable for imaging, they can be larger than the level of precision required

when investigating temporal changes. The issue of the nature of the tail (coda) of the cross-correlation function is therefore fundamental and was analyzed by Stehly et al. (2008). These authors showed that it contains at least partially the coda of the Green function, i.e., physical arrivals which kinematics is controlled by the wave speeds of the medium. It can therefore be used for monitoring temporal changes. As an illustration of the capability of this approach, we present in Fig. 4 a measure of the average wave speed change during a period of 6 years in the region of Parkfield, California. Two main events occurred in this region during the period of study: the 2003 San Simeon and 2004 Parkfield earthquakes. In both cases, noise-based monitoring indicates a co-seismic speed drop. The measured relative variations of velocity before de San Simeon earthquake are as small as 10^{-4} . The changes of velocity associated with earthquakes are associated with at least two different physical mechanisms: (1) the damage induced by the strong ground motions in shallow layers and fault zone, as illustrated by the co-seismic effect of the distant San Simeon event, and (2) co-seismic bulk stress change followed by the post-seismic relaxation, as shown with the long-term evolution after the local Parkfield event, similar in shape to the deformation measured with GPS.

Summary

Continuous recordings of the Earth surface motion by modern seismological networks contain a wealth of information on the structure of the planet and on its temporal evolution.

Seismic, Ambient Noise Correlation, Fig. 4 Relative seismic velocity change during 6 years measured from continuous noise correlations in Parkfield. The dashed lines indicated two major earthquakes: the San

Simeon event that occurred 80 km from Parkfield and the local Parkfield event. (Modified from Brenguier et al. 2008b)

Recent developments shown here make it possible to image the lithosphere with noise only and to detect temporal changes related to inner deformations.

Seismic, Artificial Intelligence to Neural Intelligence for Advanced Interpretation

Kalachand Sain and Priyadarshi Chinmoy Kumar
Wadia Institute of Himalayan Geology, Dehradun, India

Definition

The human brain is an expert system for analyzing patterns. In other words, human or neural intelligence is quick in

demonstrating its proficiency for making qualitative analysis. When machines (or machine intelligence) are trained to work under the guidance of the human brain (or intelligence), optimum solutions to large and complex problems can be achieved with much ease. This motivates to amalgamate machine (or artificial) intelligence with human (or neural) intelligence to solve complicated nonlinear problems. Such practices have been applied to many scientific areas such as face recognition, image processing, seismic data analysis, and interpretation.

Introduction: A Motivation for Automating Interpretation

Seismic reflection data are rigorously processed for producing an appreciable image of the subsurface, which can be interpreted for geologically meaningful features related to hydrocarbon exploration, mineralized prospects, geotectonics, etc. The image can be enhanced by using advanced tools to aid interpreters for better understanding of the subsurface. The interpretation varies from a young interpreter to an experienced interpreter. Strictly speaking, an anomaly in the seismic data for a young interpreter could be a noise, whereas it may be a geologic feature to an experienced interpreter. Hence, interpreters continue to improve their skills, such that a realistic and geologically meaningful interpretation of the subsurface can be achieved.

Advanced interpretation techniques, such as seismic attribute analysis, have brought out revolutionary changes for the interpretation of subsurface. The attribute analysis workflow is one of the major steps of the subsurface interpretational sequence adopted by interpreters. Seismic attributes help in capturing every single anomalous response of the targets from the data and provide guidance to interpret the responses in terms of geological features such as faults, fractures, and folds; stratigraphic features such as pinch outs, debris, slumps, and channels; intrusive features such as sills, dykes, submarine volcanoes, and reefs. Seismic attributes have been recently used as major inputs for generating three dimensional bodies of subsurface, such that the entire tectonic architecture and geometry of these features can be imaged clearly from seismic data. The major and most important problem which agitates an interpreter is the fact that an attribute hardly ever responds to a particular geologic object of interest (Kumar and Sain 2018, 2020; Kumar et al. 2019a, b, c). Hence, the output is a mixed set of geological information overlapped with noisy or unwanted features. Thus, the final interpretation becomes erroneous and perturbs the interpreters.

A plausible way to alleviate such challenges is amalgamating artificial intelligence with neural intelligence. This amalgamation is carried out by designing meta-attributes or hybrid attributes, which are robust computer models (Kumar

and Sain 2018) that are obtained through unification of several attributes trained over interpreter's acquaintances. The meta-attribute is much more efficient than single attribute in interpreting the subsurface geological features.

Automating interpretation of seismic data has been an active area of research. However, most of these automation approaches have concentrated on improving interpretation of discontinuous structures such as the faults and gas migrations from seismic data. Aminzadeh et al. (2013), Connolly and de Groot (2016), and Singh et al. (2016) demonstrated the use of chimney technology (an automated approach) for the interpretation of gas seepages from reflections of seismic data. Kluesner and Brothers (2016) and Kumar and Mandal (2017) highlighted the use of conditioned seismic data in extracting different structural attributes and simultaneously combined them to capture the fault discontinuities from seismic data. Di et al. (2017) further advanced the multiattribute approach using the support vector machine (SVM) technique for interpreting the geologic discontinuities from 3D seismic volume. Kumar and Sain (2018) introduced a thinned fault cube meta-attribute to bring out sharp thinned fault images from seismic data. Wu et al. (2019) adopted deep neural learning approaches for improving the fault images from seismic data. Many advances in this process of interpretation include the works of Kumar et al. (2019a, b, c), where the combination of artificial intelligence and machine intelligence is incorporated for interpreting magmatic bodies, fluid migrations, volcanic systems, and submarine landslides from seismic data.

Here we present examples of a set of meta-attributes that have been designed by the unification of artificial and neural intelligences to produce geologically-meaningful subsurface images of sedimentary basins through an automated approach.

Examples of Meta-attributes

Example 1: Thinned Fault Cube (TFC) Meta-attribute

The first example is a case study performed over the Waitara 3D prospect, off New Zealand, where our objective is to generate a Thinned Fault Cube (TFC) meta-attribute from 3D time-migrated seismic data. Geologic faults are discontinuous structures, which are associated with reflector terminations, vertical disturbances, and discontinuities in seismic reflectors (Tingdahl 2003; Kumar and Sain 2018). These features are characterized with abrupt changes in the dips of seismic reflectors and are generally oriented with different geometric shapes (e.g., curve, straight, or bend) (Tingdahl 2003). The fault zones are also characterized with the loss of energy and frequency content. Seismic attributes, e.g., similarity, coherency, curvature, dip angle variance, dip magnitude, azimuth, and energy attributes, when amalgamated

and trained under interpreter's knowledge, generate a hybrid attribute called as the Thinned Fault Cube (TFC) meta-attribute. Interpreter's past acquaintances play a crucial role as he/she decides all possible locations associated with the faults and all nonfault locations devoid of structural discontinuities within the data. The TFC meta-attribute generates thinned, linear, prominent, distinct, and razor-shaped fault images from the seismic data (Fig. 1).

Example 2: Intrusion Cube (IC) Meta-attribute

The second example is a case study performed over the Kora 3D prospect, off New Zealand, where our objective is to generate an Intrusion Cube (IC) meta-attribute from the 3D time-migrated seismic data. This meta-attribute is very much suitable for interpreting submarine buried volcanic system. Buried volcanic systems are accompanied with igneous and sedimentary processes that may have both positive and negative impacts over the petroleum system, e.g., maturity of the source rocks, migration pathways for hydrocarbons, sealing and trapping mechanism, geothermal history of the basin, etc. (Kumar et al. 2019a). This type of complexities sometimes changes the porosity and permeability of the subsurface reservoirs and poses high risks for exploration and exploitation. Thus, such a complex geological system should be examined critically and investigated thoroughly for prospect evaluation. Submarine buried volcanoes have a tendency to pierce vertically through the host sedimentary succession. Internally they are associated with distorted and chaotic reflections and dissimilar seismic events. Over the crater and along the flanks, they are associated with high amplitudes due to larger impedance contrast with the surrounding sedimentary rocks (Kumar et al. 2019a). While piercing through the host geologic formations, these features tend to possess variable dips. Seismic energy, when passed through these features, gets diminished. The flanks and the crater of the volcano are linked with high coherent energy. Sills and dykes generally act as conducive pathways for the movement of magma into the overlying sedimentary units. Sills are concordant intrusive bodies, commonly subhorizontal with a gentle inclination cross-cutting the subsurface stratigraphy, and exhibit major impact on basin history and petroleum system (Thomson and Hutton 2004). On seismic section, these appear as saucer shaped, gently inclined, distinct high amplitude and discontinuous in nature. However, dykes vertically intrude into the overlying younger strata and exhibit steep dips. Thus, attributes, e.g., reflection strength, dip angle variance, energy gradient, azimuth, and similarity, when amalgamated and trained over interpreter's knowledge to capture the extension and distribution of such a complex plumbing system from seismic data, generate a meta-attribute called Intrusion Cube (IC) meta-attribute. Kumar et al. (2019a) make a first documentation of such a meta-attribute that has brought out a realistic image of the plumbing system

Seismic, Artificial Intelligence to Neural Intelligence for Advanced Interpretation, Fig. 1 The TFC meta-attribute corendered over amplitude data, in the Waitara prospect off New Zealand, shows thin and razor-shaped images (cream arrows) of subsurface faults from seismic data

(consisting of buried volcano, sill networks, dyke swarms, and magmatic ascent) from seismic data (Fig. 2).

Example 3: Sill Cube (SC) Meta-attribute

The third example is a case study performed over the Utgard prospect, Vøring Basin, off Norway, where our objective is to generate a Sill Cube (SC) meta-attribute from 3D time-migrated seismic data. This meta-attribute is very much suitable for automatic interpretation of magmatic sill complexes from seismic data. Conventionally, magmatic sills are interpreted as tabular intrusive rocks with concordant surfaces showing concave upward cross-sectional geometries and discordant limbs (Hansen et al. 2004). These are concordant intrusive bodies, commonly subhorizontal with a gentle inclination cross-cutting the subsurface stratigraphy, and exhibit major impact on basin history and petroleum system (Thomson and Hutton 2004). These geologic features help in transporting magmatic fluids into the overlying stratigraphic units. Magmatic sills exhibit high amplitude and entropy character due to larger impedance contrast with the surrounding sedimentary rocks. Moreover, they possess an appreciable contrast in comparison to the host sedimentary succession (Chopra and Marfurt 2007). Thus, these seismic characteristics make suitable attributes, e.g., reflection strength, texture contrast, and texture entropy

for amalgamation and training them under interpreter's guidance to generate a hybrid attribute, called Sill Cube meta-attribute (Kumar et al. 2019b). Figure 3 shows the meta-attribute corendered over a conventional seismic section.

Example 4: Fluid Cube (FC) Meta-attribute

The fourth example is a case study performed over the Parihaka 3D prospect, off New Zealand, where our objective is to generate a Fluid Cube (FC) meta-attribute from the 3D time-migrated seismic data. This meta-attribute is very much suitable for interpreting fluid migration (e.g., hydrocarbon fluids and magmatic fluids) through subsurface geological formations. On seismic section, these migration zones are associated with disordered reflection patterns, low similarity among seismic traces, loss in energy, and frequency and appear to have vent-like structure. Suitable attributes such as similarity, energy, and frequency variance, when amalgamated and trained over interpreter's knowledge, generate a meta-attribute called Fluid Cube (FC) meta-attribute. Kumar et al. (2019c) have brought out a realistic interpretation of such migration zones using the FC meta-attribute from seismic data. Fluids are observed to get migrated from the subsurface geological formations bounded by a system of hard-linked normal faults (Fig. 4a, b).

Seismic, Artificial Intelligence to Neural Intelligence for Advanced Interpretation, Fig. 3 (a) Amplitude section showing manually identified sills from seismic data; (b) automatic interpretation of magmatic sills using SC meta-attribute

Example 5: Mass Transport Deposit Cube (MTDC) Meta-attribute

The fifth example is a case study performed over the Karewa 3D prospect, off New Zealand, where the objective is to generate a Mass Transport Deposit Cube (MTDC) meta-

attribute from the 3D time-migrated seismic data. Mass Transport Deposits (MTDs), occurring in different tectonic and depositional settings, are generally defined as gravity induced slope failure deposits that include creeps, slides, slumps, or debris flows. These deposits are internally deformed and

Faults are shown by black solid lines. (b) 3D view of the TFC and FC meta-attributes bringing out realistic interpretation of subsurface geological scenario from 3D seismic data

Seismic, Artificial Intelligence to Neural Intelligence for Advanced Interpretation, Fig. 5 (a) The MTDC meta-attribute corendered over the amplitude section of the Karewa prospect; (b) 3D view of the MTDC meta-attribute revealing the structural geometry of the MTD in the Karewa prospect, off New Zealand

associated with variable shape and size. During slope failure, masses tend to flow downslope over a shearing surface called as the basal shear surface (BSS) that forms the base of the MTDs. Moreover, the BSS preserves the record of all erosional and deformational activities experienced by these

deposits or masses during their transportation. Their interpretation is crucial, as such deposit during transportation over the instable slope may lead to several catastrophic submarine landslides, tsunamis, and avalanches and is a precursor for subsea installation. When suitable attributes such as

similarity, dip angle variance, energy, and average frequency variance are amalgamated and trained over interpreter's knowledge, generates a meta-attribute called Mass Transport Deposit Cube (MTDC) meta-attribute. This meta-attribute reveals the detailed structural geometry of the MTD, which is very crucial for its interpretation (Fig. 5).

Conclusion

When seismic attributes (that act as corner stones) are combined suitably and trained over an interpreter's acquaintances or past knowledge through artificial intelligence, a meta-attribute is generated that augments the image of subsurface and hence its interpretation. Meta-attribute is robust and automatically derived that has brought revolutionary changes in the interpretation of 3D seismic data. The most exciting part of the meta-attribute concept is the amalgamation of artificial intelligence of neural networks and human or neural intelligence to improve the interpretation task. This concept has been applied to 3D seismic data in different geological provinces demonstrating how the seismic images can be enhanced to aid the interpretation of several subsurface features. To have more detailed information on the meta-attributes, the readers may explore the following articles, e.g., Singh et al. 2016; Kumar and Mandal 2017; Kumar and Sain 2018, 2020; Kumar et al. 2019a, b, c. This approach can be extended for the interpretation of other geophysical data also.

Seismic imaging

Definition

Seismic migration. A set of techniques for transforming recorded (elastic-wave) seismic reflection data into an image of reflecting boundaries in the earth's interior. In simplest form, these are intended to correct certain distortions present in recorded wavefields. The distortions can be caused by: diffractors inside the earth, which scatter the incident energy to a range of receiver locations; geometric effects caused by dipping reflectors; and velocity effects, which cause the seismic waves to change direction as they propagate from source to reflector to receiver. Migration is also used to estimate seismic velocity and to provide amplitudes for rock property analysis.

The migration heuristic assumes that subsurface reflectors are made up of point diffractors (Trorey 1970). The response of a reflector to input seismic energy is the sum of responses to

all the diffractors, and migration transforms this response to the actual reflector shape by collapsing each diffractor response to a point (diffraction stack). Migration can be applied both in prestack and poststack (zero-offset data) domains, and in general, the quality of migration depends on the data quality (S/N), velocity field used in migration, migration algorithm, and the type of migration (2D/3D; depth/time; prestack/poststack).

History

Mapping Using Pencil and Paper: Mechanical Migration

The first migrations were performed in the 1920s as a manual operation. A single-fold reflection profile was acquired with sources and receivers on the surface of the earth, and two-way travel times for events from a shallow dipping reflector were picked on the recorded traces. The extent of the lateral offset between source and receiver locations was neglected, which is equivalent to assuming that sources and receivers were colocated, or at zero offset. Then circular arc segments were drawn, centered at the source-receiver midpoints and with radii equal to one-half the product of the picked travel times and the velocity of propagation in the overburden. The envelope of these mapped arcs gave a rough picture of the reflecting interface (Fig. 1).

This technique reveals principles and problems of migration. First, reflection events move sideways, or *migrate*, from their picked time locations on the recording surface (the source-receiver midpoints) to subsurface locations at the reflection interface. When reflectors in the earth are not flat, the lateral position of a subsurface reflector is different from that of the recording location of the same event. Second, the assumption of colocated sources and receivers is problematic. As the use of seismic data increased, reflection profiles were typically acquired using higher fold, or

multiplicity: for each source, a spread of many receivers recorded reflection data in order to provide a greater multiplicity of observations. Some of the receivers were at considerable distance from the source locations, violating the zero-offset assumption. Later, the common-midpoint (CMP) stack (Mayne 1962) performed approximate corrections intended to shift each event on a nonzero-offset recorded trace to its zero-offset time, once again allowing the use of the zero-offset assumption in migration (poststack migration). In areas of complicated geologic structure, however, the time corrections used in the CMP stacking process are not accurate, requiring that each recorded trace be migrated using its actual source and receiver location (prestack migration). Third, if more than one reflector exists inside the earth, the various migrated events can interfere with one another as the circular arcs that build up their envelopes overlap. This problem is solved by the more recent application of wave theory to migration. This allows the rigorous migration of waveforms, with energy buildup near reflector locations, and energy cancellation away from reflector locations. Fourth, if the velocity used in the migration process is incorrect, the image of a subsurface reflector will be located incorrectly. This fundamental velocity problem persists today.

The process of swinging reflection events through arcs to construct approximate reflector segments spawned a number of mechanical devices that migrated reflection records. They allowed the migration of picked events from nonzero-offset traces. However, they were all based on the same principle of swinging events over a restricted range of angles. This process was formalized by Hagedoorn (1954).

Digital Migration

Seismic recording, processing, and migration became digital in the 1960s. Digital processing emphasized the discrete sampling of signals, in both time and space. It also allowed reflection records to be treated as wavefields, and wavefield algorithms could be applied to them. Wave-equation migration methods arose, based on differential equations, integral solutions to the wave equation, or mapping in the Fourier domain (Berkhout 1982; Yilmaz 1987). These methods are in use today. They have different realms of validity and different efficiencies. One of the methods, integral (Kirchhoff) migration, deserves mention. This technique is the direct descendant of pencil-and-paper migration. In Kirchhoff migration, samples on the recorded input traces are swung out over a range of angles. The earlier techniques could consider only isolated events, because constructing the envelopes corresponding to all reflection events of a record would produce an uninterpretable mess. However, including the wave equation as an essential part of the process allowed all samples to be swung out. Constructive and destructive interference, a natural consequence of treating the samples as components of a wavefield, caused reflection events to appear

Seismic, Migration, Fig. 1 Schematic illustration of early pencil-and-paper migration. Assuming constant velocity and zero-offset source and receiver, an event on a seismic trace is swung out along an arc of a circle. Repeating this for the corresponding event on all traces produces an image of a reflector, which lies along the envelope of all the arcs

on the image, not as envelopes, but as waveforms moved to reflector locations.

Poststack Migration

The first digital migrations were performed on computers with limited memory and processing capability. Migrating all traces of a two-dimensional (2-D) reflection survey involving hundreds of source locations, each with tens of receiver locations, would have taken months on early computers. So it became necessary to make use of the intermediate process of CMP stack to reduce the number of traces to be migrated. As mentioned above, this process performs time (“normal moveout,” or NMO) corrections to traces with nonzero source-receiver offset. These corrections are time shifts, different for each sample, intended to produce equivalent zero-offset traces to be summed, or stacked, together. The quality of the normal-moveout process depends on the stacking velocity, which determines the time shift to be applied to each sample of each nonzero-offset trace. In order to stack together traces in a domain where the velocity varies as little as possible, it is desirable to sort the input traces from their original recorded common-shot configuration to a set of records where each record has a common source-receiver midpoint – thus the term common-midpoint stack. The stacking velocity for a common-midpoint gather is taken to be the velocity at the midpoint location. This velocity can vary with time down the zero-offset trace of the record. For each value of time, it is a type of average velocity. When all the traces in a CMP gather have been NMO-corrected and summed (stacked) together, the CMP gather has been replaced with a single, zero-offset, trace. The NMO/stack process is illustrated on a single reflection event in Fig. 2.

The ensemble of zero-offset traces, from all CMP gathers indexed by their midpoint locations, is a stacked record ready to be (poststack) migrated.

The CMP stacking process makes several approximations that are incompatible with the physics of wave propagation inside the earth. For example, sorting into CMP records and assuming that the seismic velocity does not change for all traces within a record ignores the lateral variability of the actual velocity, and it assumes that the reflectors inside the earth are locally flat below each midpoint location. These approximations were not usually damaging in earlier times, when drilling prospects were in shallow, relatively simple geology. As shallow targets were drilled, leaving deeper prospects under complex overburden with complex velocity behavior, the approximations broke down. Since about 2000, migration performed without CMP stacking (prestack migration) has become commonplace.

Prestack Migration

Dropping the NMO/stack process from the migration flow eliminated some problems, but it made the velocity estimation problem more complicated. NMO velocities were useful for migration as well as stacking. These velocities were not necessarily accurate, but they provided a guide for the velocities to be used in migration. Using a rough estimate of velocity, poststack migration generates plausible migrated images, even if they lack the resolution required for interpretation of subtle targets. Accurate prestack migration, on the other hand, requires the velocity to be estimated without a prior stacking velocity analysis. New tools, consistent with wave propagation inside a geologically complicated earth, were needed for this task. These tools have been under

Seismic, Migration,

Fig. 2 NMO and CMP stack illustrated on a single reflection event

development since the 1980s, but are not yet completely satisfactory. Unlike NMO/stack, they allow arbitrary velocity structure inside the earth, and there is no “locally flat” assumption.

2-D, 3-D, Wide-Azimuth 3-D Acquisition, and Migration

Early seismic reflection profiles were acquired along 2-D lines, both land and marine. On land, a line of receivers was laid out, and shots were fired into the earth at locations along the line. As the shot locations moved along the line, receivers were picked up from the back end of the spread and placed at the front. Marine data were acquired using a vessel towing a linear array of receivers (a streamer), firing at regular locations along the line. Two-dimensional processing assumes that the subsurface of the earth is invariant in the direction perpendicular to the line direction. When this assumption is violated, “out-of-plane” reflectors (not vertically below the acquisition line) contribute energy to the reflection records; 2-D migration cannot map this energy to its correct locations. For this reason, 3-D acquisition became commonplace in the 1970s and 1980s. On land, the receivers were laid out in a 3-D pattern (patch) that could be repeated as in 2-D. Gradually, the receiver patch became larger (thousands of meters on a side), with a wider range of azimuths, or compass directions of vectors joining the source and receiver locations. Today, the recording patch often contains several thousand receivers. Wide-azimuth marine acquisition is more difficult than land because it is physically impossible for a single vessel to tow the large number of streamers required. However, adding a second vessel as a source vessel alongside the first vessel at a large lateral distance produced data over a wide range of azimuths as for land.

Moving from 2-D to 3-D enabled the accurate migration of geologically complex structures such as salt bodies and overthrust structures, and it altered the economics of migration. In the initial days of 3-D seismic data, 2-D prestack migration was available but not commonly applied because it was still too computationally expensive. A fortiori, 3-D prestack migration was not yet feasible. In 3-D, the numbers of input and output locations are increased by an order of magnitude over 2-D, increasing migration cost by two orders of magnitude. Three-dimensional migration was earlier accomplished by a two-pass migration algorithm, which migrates the data first in inline direction and then in crossline direction, using the standard 2D migration algorithms and the choice of migration algorithms was open. With the availability of greater computational facilities, the 3D migration now works in the true sense of 3D by treating the hyperboloids in the inline and crossline directions simultaneously.

Deep Crustal Imaging

Most migration projects are performed by the oil and gas industry for hydrocarbon exploration, whose target depths

rarely exceed 10 km. However, solid-earth geophysicists acquire and migrate seismic data to map crustal structures tens of kilometers deep. Imaging very deep targets with cumulative overburden effects such as wavefield scattering and absorption presents added challenges, and migration cannot be expected to be successful as often as it is for hydrocarbon exploration (Warner 1987).

Time Migration, Depth Migration

Seismic traces are recorded in time, with a particular event occurring at different times on traces with different lateral positions. The CMP stack produces a composite section, with a trace at each position. Although migration is used to image reflectors inside the earth, the CMP stack itself provides a crude image. With its collapse of many seismic records into one, and its use of redundancy (fold) to suppress noise, the CMP stack produces images that can sometimes be interpreted without migration. If the CMP stack is migrated with the depth axis on the migrated image replaced by time, events on the unmigrated stack and the migrated stack can be compared directly, helping with interpretation. Such a migration, called “time migration,” is opposed to the more natural “depth migration.”

This fact has caused a diversity of approaches to migration. Geophysical interpreters often prefer time migration, but structural geologists and engineers usually prefer depth migration. Structural geology deals with space (depth) and how space is filled with material; geologists and engineers are concerned with the physical dimensions of a potential hydrocarbon trap. Even if a migrated image is interpreted in time, in principle, it is preferable to perform the migration and display the final image in depth. In practice, however, there are valid arguments against this statement.

First, time migration is sometimes more robust than depth migration; that is, it is often easier to produce an interpretable image with time migration than with depth migration, even if the image is known not to be accurate. This is because time and depth migration treat velocity differently. Time migration, following procedures developed for NMO/stack, uses what is best called an imaging velocity field, i.e., one that best focuses the migrated image. At each image location, this velocity is an average of the seismic velocity values in the overburden above the image depth. The imaging velocity is free to vary spatially. In essence, time migration performs a constant-velocity migration at each image location, where the constant can change from point to point. The imaging velocity field that produces the best image need not be consistent with any possible field of actual velocities inside the earth, and any attempt to convert the imaging velocities to a field of geologically possible earth velocities can fail. For example, assuming that the imaging velocities are root-mean-square

velocities and using the Dix (1955) equation to invert these to interval velocities often produces physically impossible values. This inconsistent handling of velocity allows time migration to be robust. Second, the precision implied by depth migration is not always justified. A migrated image purports to show locations of reflectors and diffractors inside the earth, but often the locations are incorrect. It is easy to see that this can happen for time migration, which is not precise because of its inconsistent handling of velocity. For depth migration, the implied accurate positioning of reflectors assumes a correct migration velocity, which is an interval velocity field, i.e., a field of local velocities. Using accurate interval velocities allows depth migration to image more accurately than time migration can, but using inaccurate interval velocities can degrade image coherence that the less precise velocities of time migration often preserve.

Purposes of Migration

Structural Imaging

The primary goal of seismic migration is to correct distortions present in recorded seismic records, due to uncollapsed diffraction energy, geometric effects, or velocity effects. Even in areas of fairly flat geology, diffracted energy from abrupt fault terminations can obscure deeper reflection events, making their interpretation difficult. Therefore, collapsing unwanted diffraction energy to scatterer locations is important. Geometric and velocity effects are caused by complicated geologic structures. Familiar examples are “bowtie” signatures on stacked records converted by migration into synclines, and broad anticlinal structures converted by migration into narrower, steeper structures. Other examples include complicated water bottoms, complicated salt geometry, thrust structures, heavily faulted areas, and gas-charged sediments. In these, reflector geometries or lateral velocity variations cause wavefield distortions that must be corrected before the image can be interpreted.

Velocity Estimation

Poststack migration is performed using a velocity field that is specified beforehand. The velocity can be derived from NMO velocity analysis or from an assumed geologic model. It is difficult to analyze a poststack migrated image for velocity errors. By contrast, we can analyze prestack migration for velocity errors. To do this, one performs prestack migration separately on all the input records, with individual images that overlap considerably. In the overlap areas, the different images can be checked for consistency by sorting the migrated traces into common-image-point gathers (CIGs), which are the migration analog of NMO-corrected unmigrated CMP gathers. Within a CIG, each trace refers to a single surface location, imaged from a different input

record. As an example, Fig. 3 shows six CIG's from a land survey, referring to images below six different locations on the earth's surface. Each CIG displays migrated traces from different source-receiver offsets. If all the individual migrations have imaged one particular event at the same depth, the images are consistent at that location. That is the case in this example: except at the greatest depths, most of the events on each CIG appear flat. If the different migrations image a particular event at different depths, the images will be inconsistent, and the event will not appear flat on a CIG. In order to make the images consistent for such an event, the migration velocity will need to be adjusted in the overburden above the event location.

For prestack depth migration, the velocity estimation problem is to build an interval velocity field that makes the migrated events appear flat on all the CIGs. This is usually posed as an algebraic inverse problem, called seismic tomography, involving the interval velocity field, the reflector locations, and the raypaths from the reflectors to the source and receiver locations. This problem is solved iteratively for velocity model refinements. In order to avoid converging to an unrealistic model, tomography usually needs to be constrained, using partial knowledge of the seismic velocities

Seismic, Migration, Fig. 3 Prestack depth migration common-image-point gathers from six different locations on a survey from Western Canada. Each of the gathers contains traces from migrations of data with offsets ranging from 0 m to 4500 m. The events on the gathers are flat except at the greatest depths, indicating that the velocity field is largely correct

and reflecting horizon locations. This biases the solution, and it can result in incomplete event flattening on the CIGs. Tomography is widely used, but it usually produces velocity models with limited spatial resolution.

An attempt to circumvent the issue of velocity dependency of prestack time migration is made and the concept of common migration reflector element stacking (Dell et al. 2012) is introduced. In this scheme, a stack of common scatter point (CSP) gathers is generated, while including an automatic update of time-migration velocities. The CSP gathers are generated by a direct mapping of summed amplitude into the common offset apex of the double square root (DSR) migration operator. The DSR operator is calculated as follows:

$$t_D = \sqrt{\frac{t_0^2}{4} + \frac{(m-h)^2}{V^2(t_0)}} + \sqrt{\frac{t_0^2}{4} + \frac{(m+h)^2}{V^2(t_0)}}$$

where h is the half source-receiver offset, m is the midpoint displacement with respect to the considered CMP position, m_0, t_0 correspond to the vertical ZO two-way traveltime, and $V(t_0)$ is the time-migration velocity belonging to t_0 . The CSP gathers are generated exactly at the locations of the input traces as that of a CMP gather and so, the method does not suffer from generation of extra traces, and is more suitable for application in 3D case.

More recently, the approach of automatic migration velocity estimation (Dong et al. 2019) is becoming popular, wherein the velocity field is constructed from the common reflection point (CRP) gathers. The scheme is similar to the conventional velocity analysis, except that it is based on residual moveout and not the normal move out. The event picking is done in the common reflection point gathers, and the scheme is implemented by semblance scanning, as in conventional velocity analysis. The velocities are then picked at discrete grids using the least squares method and the spatial interpolation is carried out to create a velocity model. The principal advantage is that the velocity model can be obtained in few iterations and fitting curves of the picked events in a range of offsets prevents the scheme from entering into the local minima issue as is the case with curve fitting to a normal moveout.

Increasingly, seismic velocities are recognized as anisotropic: at each location, seismic velocity varies with direction. Including anisotropy makes velocity estimation more difficult, but anisotropy is usually needed to produce accurate images. The most common assumption for anisotropy is transverse isotropy, often with a tilted axis of symmetry (TTI), which is generally the case in presence of fractures. The issue of fracture induced anisotropy is routinely addressed using the azimuth sector migration (Peng et al. 2013) aimed at analyzing the azimuthal anisotropy and for

detecting fractures. However, these are applied to a limited offset bin sizes in the prestack data and hence suffer from low S/N. Subsequently, the aspect of considering the full-azimuth offset into consideration came into use so as to carry out anisotropic migration on basis of common offset migration (Wang et al. 2013). However, these schemes are based on assumption that the ray path can be invariantly parameterized by source-receiver offset and azimuth, which is not always the case because the ray path is continuously changing during the course of energy propagation. The anisotropic migration carried out in local angle domain was introduced by Sun and Sun (2015) and proved to be an efficient way of extracting the azimuth preserved common image gathers (CIGs), so as to retain the fracture induced amplitude responses. In case of steep dips, the spatial aliasing is quite significant and needs to be handled by increasing the spatial sampling.

Migrated Amplitude Analysis for Rock Property Determination

In the 1980s, researchers observed that careful handling of amplitude terms within migration algorithms produced migrated amplitudes that are proportional to reflection coefficient values at rock boundaries. This observation is the basis of true-amplitude migration (Bleistein 1987). Migrated amplitudes are now often analyzed in terms of angle-dependent reflection coefficients at rock boundaries. The reflection coefficients can be used to estimate the types of rock above and below each interface, and whether the rocks can bear hydrocarbons. This endeavor has had some success in areas of moderate velocity and structural complexity, but less success below areas of high complexity, such as below salt.

Imaging Conditions

The general assumptions are that the data is multiple free; the seismic velocity is known at every data sample and that there are no out of plane reflections.

Isochron Imaging

Pencil-and-paper migrations were performed by swinging reflection events to their migrated locations, which are the envelopes of all possible swing locations. Kirchhoff migration can be performed the same way, with the wave equation canceling the energy away from the envelopes and leaving only images of reflectors. The time of a sample on an input trace is the sum of time from the source to a reflector plus time from the reflector to the receiver; Kirchhoff migration acts by placing the sample at all subsurface locations (isochrons) that share the same two-way travel time.

Isochron imaging, useful in describing Kirchhoff migration, is plausible and correct, but it is not a wavefield concept,

and cannot be applied to all migrations based on the wave equation. These require more general treatment, which is different for poststack and prestack migration.

Poststack Migration: Exploding Reflector Model

The CMP stack simulates a zero-offset record, where energy has been excited and recorded at the same location. It can also be considered as a single wavefield from a far-fetched experiment. Suppose all the reflectors and diffractors inside the earth exploded at the same instant (time zero), sending energy in all directions; some of the energy would emerge at the earth's surface at later times to be recorded at the receiver locations. Suppose also that the propagation velocity of the wavefield from the exploding reflectors is exactly one-half the actual propagation velocity inside the earth. Then the recording time for an event from an exploding reflector is the same as the two-way zero-offset reflection time, with the actual velocity, from the same reflector. This thought experiment (Loewenthal et al. 1976) provides the basis for a poststack migration imaging principle, breaking migration into two parts: downward continuation and imaging. The first part expresses the wavefield at one depth in terms of the wavefield at a shallower depth. As the wavefield moves down, time decreases towards zero (the time of the explosion). The second part picks off the downward-continued wavefield at each location when the time reaches zero. The result of the process is a snapshot of the reflectors in the act of explosion.

Reflected Wavefield Amplitude Normalized by Source Wavefield Amplitude

For prestack migration, downward continuation is useful, but exploding reflectors and zero-time imaging are not. As in poststack migration, the wavefield from the many receiver locations is downward continued into the earth and backwards in time. Likewise, the wavefield from the source location is downward continued, but forward in time so that it can interact with the receiver wavefield at actual reflection times. If the two downward-continued wavefields intersect at a location at a particular time, the process has captured the instant of reflection at that point. At that location and time, the receiver wavefield amplitude equals the source wavefield amplitude times the value of the reflection coefficient at the location (possibly zero, if the location is not on an actual reflector). That is, the migrated image at that location is the receiver wavefield divided by the source wavefield.

Deconvolution and Cross-Correlation Imaging Conditions

Some migration techniques are applied in the time domain, others in the frequency (ω) domain. For frequency-domain methods, a precise statement of the prestack migration imaging principle is that reflectors exist inside the earth where downward continued source and receiver wavefields are in

phase, and the reflection strength is the ratio of the two wavefields. For a single frequency, there is complete uncertainty about the location of a reflector; only by adding the results from many frequencies can reflector positions be precisely determined. Thus, the prestack-migration imaging principle can be written as:

$$R(\mathbf{x}) = \int \frac{U(\mathbf{x}; \omega)}{D(\mathbf{x}; \omega)} d\omega, \quad (1)$$

where $R(\mathbf{x})$ is reflection strength at location $\mathbf{x}$, U is the downward-continued receiver wavefield, and D is the downward-continued source wavefield. The quotient can cause stability problems when the source wavefield D becomes weak. To overcome instability, note that if both numerator and denominator are multiplied by the complex conjugate of D , denoted D^* , the phase of the denominator will disappear (the denominator becomes a positive real number). Instability, caused by the nearly vanishing denominator DD^* , can be eliminated by replacing the denominator with a constant value, leaving the modified imaging condition:

$$R(\mathbf{x}) = \int U(\mathbf{x}; \omega) D^*(\mathbf{x}; \omega) d\omega. \quad (2)$$

Equations 1 and 2 migrate events to the same locations, but migrated amplitudes obtained using Eq. 2 are different from those obtained using Eq. 1. Imaging conditions (1) (*deconvolution*) and (2) (*cross-correlation*) were introduced by Claerbout (1971).

Migration Techniques

Integral (Kirchhoff) Migration

Kirchhoff migration is the digital embodiment of the earliest migration heuristics, and it has a basis in the downward continuation of wavefields: the wavefield at depth is an integral of the recorded wavefield (Schneider 1978). The mathematical physics of this operation requires amplitude and phase manipulations of the recorded wavefield, yielding various expressions for poststack and prestack migration with different recording configurations. For example, shot-record Kirchhoff migration is expressed as:

$$I(\mathbf{x}; \mathbf{x}_s) = \int d\mathbf{x}_r \int dt W \frac{\partial U(\mathbf{x}_r; \mathbf{x}_s; t)}{\partial t} \delta[t - (t_s + t_r)], \quad (3)$$

where $I(\mathbf{x}, \mathbf{x}_s)$ is the migrated image at location $\mathbf{x}$ due to a source at $\mathbf{x}_s$, $\mathbf{x}_r$ are the receiver locations, W is a weight function, U is the recorded wavefield, δ is the Dirac delta function, and t_s and t_r are travel times from $\mathbf{x}_s$ and $\mathbf{x}_r$ to $\mathbf{x}$.

The integral accumulates data samples from the receiver locations into the image at $\mathbf{x}$. Alternatively, Eq. 3 allows an input sample at time $t_s + t_r$ from receiver location $\mathbf{x}_r$ to be smeared out into the isochron surface.

Kirchhoff migration is flexible, allowing the accumulation of trace values from any subvolume of the recorded traces into any subvolume of the image. This has made Kirchhoff migration very popular. However, complicated velocity models used in many depth migration projects have shown its accuracy limits, which are due mostly to a reliance on asymptotic ray theory to provide travel times and amplitudes. Kirchhoff migration can be implemented in 2D and 3D data in both pre- and poststack domains.

Practical Considerations in Kirchhoff's Migration

Migration aperture: Migration aperture can be defined as the summation span of the diffraction hyperbola. In practical terms, it is defined as the number of traces involved in the computation. The shape of the hyperbola is governed by the velocity at apex and for a vertical increase in velocity, the slower velocity will have smaller aperture and the higher velocity will have wider aperture. In other words, wider apertures are needed to collapse deeper diffraction hyperbolas. Also, wider aperture means higher velocity and thereby more migration and the deeper events are migrated more than the shallow events, provided the dip is constant. The effectiveness of the migration scheme is proportional to the aperture width, i.e., wider the aperture, better the lateral resolution. On the flip side, the runtime is also directionally proportional to the aperture, meaning wider apertures will require more time for migration. Therefore, an optimum migration aperture must be used for effective migration. In general, for a specific reflection event with a constant dip θ and depth h , the aperture width d can be computed as:

$$d = h / \tan \theta$$

Too small apertures can sometimes cause total loss of steep dips, e.g., flanks of diapirs, and cause spurious subhorizontal events at deeper parts, called as “smearing.” These are especially significant at later times, where signal strength is weaker than the random noise.

Dip Limits The maximum dip can be defined in the migration scheme and is used to suppress the steeply dipping coherent noise. The flanks of theoretical hyperbolas used for summation are truncated after the allowed dip. Dip parameter is again related to the migration aperture to some extent. The narrower the migration aperture, the smaller maximum allowed dip. The effect of dip is especially significant in areas of steep dips and dip tests need to be carried out for areas of steep dip.

Velocity Field Effectiveness of the migration undisputedly depends on the velocity field used, irrespective of the migration algorithm. A slower velocity results in under migration and “frowns” occur in the final image. The inclined events are not relocated to their accurate lateral positions and bow-tie effects remain unresolved. Inversely, higher velocity causes over migration and “smiles” occur in the final image. The inclined events are migrated too much in an updip direction.

Beam Migration

In its simplest form, beam migration is a Kirchhoff migration with the integral over the recording surface broken into two stages: first, the domain of integration is divided into a number of overlapping regions; second, a directional decomposition of the data within each region is performed. This decomposition produces a set of local plane waves, over a range of angles, emerging within each region. Each of these local-plane wave data components is mapped back into the earth using raypaths sent in the directions of the emerging plane waves. A more complete description (Hill 2001) uses Green's identity to downward continue the wavefields, with Gaussian beams as Green's functions. Gray et al. (2009) provide an elementary physical explanation of this complicated method, which is generally more accurate than Kirchhoff migration because it naturally allows several arrivals from each wavefield to accumulate at any image location (which is difficult for Kirchhoff migration). It has many of the flexibilities of Kirchhoff migration, but, like Kirchhoff migration, relies on asymptotic ray theory.

One-Way Wave-Equation Migration (OWEM)

Strictly speaking, applying the term “wave-equation migration” solely to migration methods that downward-continue wavefields recursively one depth step at a time is an abuse of terminology. This usage excludes Kirchhoff and beam migrations, implying that they do not derive from the wave equation, which is not true. This usage has become entrenched.

Downward continuing a wavefield from one depth to the next requires that the wavefield is propagating either up or down, but not both at once. (The wavefield can propagate laterally, but up or down is a distinguished direction.) Further, it requires an appropriate (upgoing or downgoing) wave equation. In the simple constant-velocity case, the one-way solution can be obtained easily. The two-way wave equation for wavefield P (acoustic, ignoring elastic effects such as mode conversion) is:

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} - \frac{1}{v^2} \frac{\partial^2}{\partial t^2} \right) P = 0. \quad (4)$$

When this equation is expressed in the frequency/horizontal wave number domain, it factors into separate equations for upgoing and downgoing wavefields. Analytical solutions of

these equations provide phase shifts that perform downward continuation. Once the downward-continued wavefields have been inverse Fourier transformed from wave number back to space, they can be combined and summed over frequency using Eq. 1 or 2 to produce the migrated image (Gazdag 1978). This method, phase-shift migration, can accurately image dips up to 90° . Its only limitation is the lateral invariance of the velocity field. It has proven successful in imaging salt flanks in marine sedimentary basins. Beneath the salt flanks, where significant velocity contrast has occurred, the phase-shift image is inaccurate.

Factoring the wave equation exactly into one-way equations works only for constant velocity. When velocity varies laterally, the factoring, again with z as a distinguished direction, is approximate, incurring kinematic (time) and dynamic (amplitude) errors. A number of methods downward continue wavefields using approximate one-way wave equations. The earliest of these used finite differences to discretize the equations, using low-angle approximations (e.g., Claerbout 1970). Later methods generalized phase-shift migration to handle lateral velocity variations, and other methods combine aspects of finite-difference and phase-shift approaches. Development of these methods continues today. Because of the errors inherent in even the best one-way wave equations, none of the methods can be completely accurate.

Finite-Difference Migration

As the name indicates, the finite-difference migration is based on the numerical solution of the scalar wave equation by the finite-difference method. Its theoretical basis consists in downward continuation of the recorded wavefield, by moving the receivers downward in finite depth steps and by shortening the spread length with each step. This process will shorten the diffraction hyperbolas, and when the receiver arrives at the apex, the hyperbola is completely collapsed to a single point. An undermigration occurs if the downward continuation is completed before the source depth is reached and the hyperbola cannot be collapsed perfectly. The same situation also occurs when a slower velocity is used for the migration. Inversely, if the downward continuation is continued beyond the source depth, the mirror image of diffraction hyperbola is formed. This also happens if a faster velocity is used for migration.

Depth Step The minimum depth step size can be the same as the sampling rate of the input seismic data. Higher depth step results in undermigration and lower depth steps result in overmigration. Undermigration can sometimes lead to specific type of noise (Yilmaz 2001) called “dispersion,” along the flanks of the diffraction hyperbola. Large depth steps are incapable of collapsing the diffraction events and the dipping events, thereby are not moved to their correct lateral

position, and this becomes more prevalent if there are updipping event. Smaller depth steps are usually preferred in steeply dipping events as they are capable of producing better results. In practice, the value for depth step is between T_s and $0.5 T_s$, where T_s is the dominant period of the input dataset.

Frequency–Wave Number (f-k) Migration

In this scheme, the migration is implemented using the Fourier transform in f-k domain and also using the phase shift method in Fourier domain. The former is called Stolt migration, and the later is called Gazdag migration, in the name of their proposers. Of these, the Stolt migration does not handle the velocity variations in the horizontal and vertical directions and instead requires a constant velocity medium. Therefore, a modification is made to the method where a constant called “Stolt stretch factor” is defined so that the algorithm can be applicable to areas with complex geology, wherein the velocity varies both laterally and vertically. Before migration, the vertical axis in the f-k domain is the frequency that is transformed into wave number. Stolt migration is by far the fastest method and is mostly used in QC purposes.

Gazdag migration also works on the principle of downward continuation of the recorded wave field, like finite-difference method, but corresponds to a phase shift in the f-k domain.

Stolt Stretch Factor The crux of applying a stretch factor lies in the fact that it transforms the input data into a constant velocity section, inducing a stretch to the seismic data along the temporal axis. Subsequently, an inverse stretch is applied and final migrated section is obtained after inverse Fourier transform. The stretch factor also partially controls the aperture of migration and changes between 0 and 2. The amount of stretch depends on the ratio between the V_{rms} of the time sample and the smallest value of RMS velocity for the entire dataset. For constant velocity media, the stretch factor equals 1 and if it is greater than 1, then it indicates overmigration and less than 1 indicates undermigration.

A special case of this class of migration is the zero-order WKB approximation, which can be used in the datasets that involve both upgoing and downgoing wavefields, e.g., ocean bottom seismometer data, vertical seismic profiling data, etc. The set of equations governing the (f-k) migration are transformed to give new set of equations that govern the interaction between the up- and downgoing wave fields (Ursin 1984). The zero-order WKB approximation (consisting of neglecting all interaction between the down- and upgoing wave fields) is used to downward extrapolate both the downgoing wavefield from the source and the recorded upgoing wavefield. The ratio between the up- and the downgoing wave fields is used to compute the depth-migrated seismic trace.

Two-Way Wave-Equation Migration (Reverse-Time Migration)

Reverse-time migration (RTM) uses the full two-way wave Eq. 4. It does not operate by downward continuation of downgoing or upgoing wavefields. Instead, it takes the source and receiver wavefields at the recording surface and injects them into the earth by treating them as boundary values for the wave equation (McMechan 1983), computing full wavefields inside the earth at each time step. The source wavefield is computed forwards in time, so successive wavefield snapshots show an expanding wavefront moving into the earth and interacting with reflectors and diffractors. The receiver wavefield is computed backwards in time (beginning with the final time sample on each trace of the recorded data), so successive snapshots show reflection events moving generally downward. Imaging is performed using a temporal version of the imaging condition (1) or (2). In principle, RTM is the most accurate migration method: it does not rely on asymptotic ray theory, and it suffers from neither the steep-dip nor the kinematic and dynamic errors of OWEM. The source and receiver wavefield are reconstructed forward and backward separately at finite time steps. At each time step, the migrated image is achieved by cross-correlating the two extrapolated wave fields. The caveat is that the time steps selected must be small, so as to ensure numerical stability. Until recently, its use has been limited because it tends to be slower than other migration methods, and numerical approximations to the wave equation (e.g., low-order finite-difference approximations) produced errors (e.g., numerical dispersion) that other methods do not incur.

To overcome this drawback, RTM is implemented in time-wave number (t - k) domain, where it is relatively faster, but accounts only for vertical velocity variations. However, modern computational hardware has both the speed and the memory availability to allow very good approximations to the wave equation, and high-quality RTM images are now the norm. RTM is especially effective in areas of complex geology with steep dips, such as salt flanks, that are not sufficiently illuminated by primary reflections.

RTM can be effectively reformulated (Zhan et al. 2014) so that it can be used as a tool to filter the coherent noise. In this scheme, the migration image at a point is computed by summing the trace amplitudes over all the scattered events which in turn leads to filters that can be applied to mitigate the coherent noise and associated artifacts, like crosstalk and aliasing. However, the main drawback is that it is more memory intensive and input dependent than the conventional RTM.

Dispersion in seismic waves caused by attenuation generally degrades the resolution of the migrated images. The method of compensating for the attenuation and then applying RTM is called Q-RTM, and it effectively mitigates the amplitude/phase dispersion effects. The dispersion and attenuation

compensated operators are constructed by extrapolating the time-domain visco-acoustic wave equation (Zhu et al. 2014). The results obtained showed marked improvement in the amplitude and phase of the seismic events compared to the conventional RTM.

In a nutshell, the various types of migration can be grouped into three categories, each solving for scalar wave equation using different approaches:

- Integral or diffraction summation methods (Schneider 1978) – can handle structural dips up to ~ 90 degrees; migration cannot handle lateral velocity variations.
- Finite-difference methods (Claerbout and Doherty 1972) – can handle structural dips up to ~ 35 degrees only; migration is not affected by lateral velocity variations.
- Fourier transform methods (Stolt 1978; Gazdag 1978) – can handle dips up to structural 90 degrees; migration is not affected by horizontal and vertical velocity variations.
- Reverse-time migration (Baysal et al. 1983) – very effective in imaging the geologically complex areas.

Migration Examples

There are many reasons to migrate seismic data; we will need to be content with a few illustrations.

The first illustrates structural imaging in the presence of anisotropy. Fig. 4 shows two images of a cross section designed to mimic the structural geology of a dipping thrust sheet, simplified to isolate the effect of anisotropy on image positioning and quality. The velocity is generally simple, with a constant velocity of 2740 m/s outside the thrust sheet. The velocity complication lies in the thrust sheet, which is anisotropic (TTI), with a symmetry axis parallel to the boundaries of the sheet. In the thrust sheet, the velocity is 2925 m/s in the direction of the symmetry axis, and higher in all other directions. Both images in Fig. 4 are from prestack beam migration of the same input data set, which was generated by finite-difference elastic modeling (courtesy BP). In Fig. 4a, anisotropy was ignored, and in Fig. 4b, anisotropy was taken into account. The reflector below the dipping thrust sheet should be flat, as it is in Fig. 4b. In Fig. 4a, the flat reflector is pulled up beneath the thrust sheet and is poorly imaged. The high-amplitude flat event cutting across the entire section at shallow depths is a shear-wave artifact that has been mis-migrated by the P-wave migration program.

The second example illustrates the action of various migration methods: Kirchhoff, beam, OWEM, and RTM. Figure 5 shows four images overlaid on a geologic cross section, each obtained by migrating a single event on a single zero-offset trace through the complicated geology/velocity model shown (called Sigsbee2a). A high-velocity salt body of complex

Seismic, Migration, Fig. 4 Prestack depth migrated images from a synthetic thrust model data set. In (a), the anisotropy in the dipping thrust sheet is ignored by the migration, leading to inaccurate imaging below

the thrust sheet. In (b), the migration has accounted for the anisotropy, leading to correct structural imaging

Seismic, Migration, Fig. 5 The action of migration, illustrated on four different migration methods: (a) Kirchhoff; (b) beam; (c) one-way wave equation; (d) reverse time. In each, a single event from a single zero-

offset trace was migrated. The migration methods have interacted differently with the velocity model, producing different wavefronts. (From Etgen et al. 2009)

shape has been inserted into a set of lower-velocity sedimentary layers, and we note the effect of the geometry and velocity on the migration algorithms. The migrated images are, in effect, wavefronts modeled by the migration methods; full migrated images are formed by adding together such partial images from all samples on all traces. The Kirchhoff migrated image (Fig. 5a) shows the effect of the assumption,

made by most Kirchhoff migration programs, that at most one travel path for seismic energy connects a given upper-surface location with each subsurface location. The wavefield discontinuities in the subsalt area are physically impossible and will cause inaccurate, noisy images in areas of structural complexity. The remaining images show wavefields of greater continuity and complexity in the subsalt area. The most

complicated wavefield, produced by RTM, should produce the most accurate image. This happens in practice when the velocity field is accurate, and the input traces are free from unwanted noise such as elastic-wave mode-converted events.

The Evolving Role of Migration in Seismic Data Processing

Before seismic processing became digital, migration was a standalone process. Pencil-and-paper or mechanical migration provided a cross section that showed where to drill. Later, poststack migration was the final seismic processing step; all other processing was intended to prepare a stacked data set for migration. With prestack migration, migration has moved to a central location in the processing flow. In tomography, it is common to process the signals on a migrated stack or in a set of CIG's. In postmigration amplitude analysis, it is common to analyze and alter the migrated waveforms. In the future, when the wave equation used for migration can model earth effects more completely than at present, seismic data will undergo less processing before migration, and the migrated data will predict rock properties directly.

Selection of Migration Algorithm

Ideally, the migration algorithm should be able to handle full range of dips; preserve amplitude and phase information without generating artifacts and should be computationally efficient and fast. Poststack time migration is the simplest one and can be applied to the regions of less geological complexity, velocity variation and gentle dips. In case of greater

geological complexity, prestack time of depth migration should be applied. In both the types of migrations, the velocity plays a vital role. In areas typical of salt tectonics, the depth imaging has to be preferred. In such cases, RTM, although costly, provides good results. The most common algorithm used by industry is the Kirchhoff migration, because the shortcomings, the advantages, and restrictions of it are well understood. A comparative statement of the various migration algorithm, their applicability and computational simplicity are presented in Table 1.

Some Aspects of Migration

- Input data should be properly conditioned before migration. Missing traces/irregular fold distribution/spiky data induces artifacts in migration. So also, the input velocity should be properly interpolated and regularized before migration.
- Spatial aliasing is of two types, i.e., data aliasing and operator aliasing. Data aliasing is caused due to coarse trace spacing in the input data. Operator aliasing is caused due to the coarse sampling of hyperboloid (3D) or hyperbola (2D). Data aliasing is more pronounced in dipping events and the aliased energy is located at the negative panel in the f-k spectrum and migration treat them as reverse dipping events, causing aliased amplitudes. The distance between CDP inputs directly effects the migration output. Finer intervals give higher resolution and sharper migrated images. Data interpolation is generally required in 3D data, especially in crossline direction so as to have properly migrated images. Data aliasing can be solved either by data interpolation or by using the anti-aliasing

Seismic, Migration, Table 1 Comparative statement of migration algorithm, applicability, and computational simplicity

Type of migration	Applicability	Simplicity level (1–4, 4 is most complex)
Kirchhoff (prestack or poststack)	• Vertical and horizontal velocity variations • Steep dips ($< 80^\circ$) • Widely used • Might produce horizontal events at depth	3 (especially in depth)
Finite difference (prestack or poststack)	• Dips up to 35° • Large depth step might cause kinks, dispersion, and undermigration • Less sensitive to velocity errors	2
Stolt (only in poststack)	• Computationally efficient • Constant velocity medium • Steep dips up to 90° • Good for QC	1
Phase shift (only in poststack)	• Valid only for vertical velocity variations • Low noise in output • Steep dips up to 90°	1
RTM (prestack or poststack)	• Promising algorithm for less illuminated zones • Complex geology • Valid for vertical and horizontal velocity variations	4

filter. The operator aliasing can be avoided by removing high-frequency components.

- Borders of the input seismic line must be treated carefully, since there is no place for updip replacement of dipping events located close to the borderline. The section should be expanded in both directions by incorporating the zero-amplitude traces at the end of the data traces. This process is called zero padding.
- Tapering also needs to be carefully selected before migration in order to avoid the edge effects due to the migration aperture. Conical taper zones (narrow at time zero and wider at maximum time) can be considered since the diffraction hyperbolas (and aperture) get wider with an increase in depth. However, unnecessarily wide taper zones might induce noise in migration output.
- Mute zones have zero amplitude and cause a characteristic noise called as swings. These effects are mostly seen in the beginning of the line and also in zones which have been muted as part of trace kill, surgical mute, irregular data acquisition, etc., and hence it is important to reapply mute after migration to avoid swings.
- Migration should be carried out only in seismic lines that are long enough. Migration on short lines could be disastrous as the entire data would be consumed by edge effects.
- Spikes or the high amplitude transient noise bursts present along the seismic line at regular intervals also lead to the migration output that is completely degraded. Every single spike causes a distinct smile and in such case, it is desired to go back to preprocessing stage and remove the spike.
- Migration algorithms, although very robust, still depend a lot on the interval velocity model. Poststack migrations are less sensitive to velocity errors, but the prestack migrations, especially depth migrations are highly degraded by improper velocity input. To reduce the effect of localized velocity errors, it is preferred to smooth the RMS velocity field both in space and time before migration.
- Near surface structures may result in velocity issues in the deeper parts of the data, e.g., mass transport deposits in the shallow subsurface/near surface channel filled with low/high velocity sediment results in vertical disturbances in the deeper parts, such as velocity pull-up or push-down in deeper section. In such cases, tomography velocity model maybe used instead of the RMS velocity model.

Summary

Seismic migration has been used in prospecting for oil and natural gas since the 1920s. Since the 1970s, migration has been applied as a wave-equation process, explicitly recognizing that reflections recorded at the earth's surface are the result of wavefields propagating and reflecting inside the earth. Wavefield migration has taken several forms (time-domain,

frequency-domain; finite-difference, integral) because of the variety of ways for expressing the propagation of wavefields. All these different forms of migration are still in use because each of them has features that the others lack: flexibility, steep-dip capability, etc. When computer power was limited, migration was usually performed after NMO/stack, allowing a reduction of the size of the data volume input to migration. Nowadays most migrations are performed before stack in 3-D. Another shift has been from time to depth, bringing migration closer to the problem of estimating seismic velocities inside the earth. A separate development has been the capability of migration to preserve amplitudes for estimating rock properties near reflector locations. With migration velocity estimation and amplitude analysis, migration has moved from the final step of the seismic processing flow to a more central role. This means that an increasing amount of processing and analysis is performed on migrated gathers before they are stacked to form the final structural image.

Synonyms

Receiver functions; Scattered teleseismic waves

Definition

Receiver function. Response of the Earth's structure below seismic stations to incident teleseismic waves. Seismic discontinuities in the Earth's crust or upper mantle cause waves from distant earthquakes to be converted from P to S waves or vice versa or to be multiply reflected between discontinuities before arriving the stations. Such scattered waves carry information about the seismic structure of the lithosphere and upper mantle. Scattered waves are weak signals, and summation of many records is usually required to visualize the useful information.

Receiver Function Technique

If a seismic wave hits a discontinuity between two solid materials with different physical parameters, a part of the wave will be reflected, and another part will be transmitted. There is also mode conversion between compressional (P) waves and shear (S) waves (see ► [“Energy Partitioning of Seismic Waves”](#)). Therefore, a P wave crossing a discontinuity will generate an S wave (called Ps), which will follow the P wave with a slower speed; and an S wave will produce a P wave (called Sp), which will run ahead of the S wave with a faster speed. If these wave types are recorded at the surface and their incidence angles and the material velocities are known, the depth of the discontinuity, where they are generated, can be determined from the differential times of the two seismic phases, mother phase and daughter phase. The waveforms of both phases carry information about the structure of the discontinuity, which can be isolated by the receiver function technique. The ray path of such waves is shown in Fig. 1. Figure 2 compares incident P and S phases for a simple model with two discontinuities (Moho and lithosphere–asthenosphere boundary, LAB; see ► [“Earth's Structure, Core”](#); ► [“Lithosphere, Oceanic: Thermal Structure”](#)), which cause converted and multiply reflected phases that lead finally to the receiver functions. There are a number of processing steps required in the receiver function technique, which will be considered in the following.

Separation of P and S Waves

Since the converted daughter phase is a different wave type with different particle motion, it can be separated from the mother phase. The usual vertical, north–south, and east–west (ZNE) components of a seismic record should be rotated, for better identification of signals, into a coordinate system where P, SV, and SH wave types are on different components. Due to heterogeneities close to the station, such a coordinate system (frequently called LQT or P-SV-SH system; see Fig. 3)

depends on the local angle of incidence and back azimuth. In many cases, only the horizontal components N and E are rotated into the radial (R) and transverse (T) components. Frequently the rotation is done according to the theoretical back azimuth between receiver and source and the theoretical angle of incidence according to epicentral distance. A local ray coordinate system may be determined from the diagonalization of the covariance matrix of the ZNE recordings within a certain time window (Montalbetti and Kanasevich 1970;

Kind and Vinnik 1988). The length of the time window used plays an important role for determination of rotation angles with this technique. The influence of the free surface of the Earth is small and in most cases not considered. In Fig. 4, theoretical seismograms in the ZR and LQ coordinate system are shown, along with ray diagrams for direct Ps phase and multiple phases PpPs and PpSs.

Deconvolution

After separation of P and SV wave types on separate components, it is much easier to identify and interpret the small converted signals. In earlier times when only analog data records were available, only a few records could be searched for converted phases. With the large amount of digital data now available (see ► “Seismological Networks”), weak signals can be enlarged relatively easily by summation of many records. A number of problems need to be considered before seismic records can be summed. Different waveforms and amplitudes generated by different earthquakes are another problem, which needs to be taken into account before summation of many traces can be applied. After rotation, records of one source and many distributed stations may be summed because all records are caused by a single event with the same source

Seismic, Receiver Function Technique, Fig. 1 P receiver function geometry. The target zone below the three-component receiver is illuminated from below. The source is an earthquake at a large epicentral distance. When a plane P wave encounters interfaces below the receiver, Ps waves are generated. The incidence angle of the P wave is always bigger than that of the Ps waves. The travel path of S receiver functions (SRFs) is very similar, except that the incidence angle of the S wave is smaller than that of the Sp wave

Seismic, Receiver Function Technique, Fig. 2 (a) Sketch showing ray paths of teleseismic Ps and Sp converted waves below a station. Note that the piercing point of Sp is offset farther away from the station than that of Ps. (b) Velocity model for the calculation of P and S receiver functions. (c) Theoretical S receiver function (SRF), primary conversions arrive prior to S (which arrives at zero time and is omitted here), and crustal multiples arrive after S. (d) S receiver function (trace c) after

reversal of timescale and amplitude for better comparison with P receiver functions (PRFs). (e) P receiver functions (PRFs) of model in (b). The main difference of P and S receiver functions is that S receiver functions are free of crustal multiples at the time of the lithosphere–asthenosphere boundary (LAB) arrivals. Note that in the case of a homogeneous half-space, no signal would be contained in the above traces (Yuan et al. 2007)

Seismic, Receiver Function Technique, Fig. 3 Rotation of the radial (R) and vertical (Z) components around the angle of incidence into the L and Q system (Vinnik 1977). The P wave is in this case only on the L component, and the SV wave is only on the Q component. The SH wave remains on the T component

time function. This is the well-known delay and sum technique. However the results of such a summation will be the response function at the source region (including, e.g., depth phases) and not the “receiver function.” If we are interested in the structure beneath a seismic receiver, records from many earthquakes at this receiver with very different source time functions and magnitudes must be summed. Only in this case we will obtain as the result of the summation the response of the structure beneath a receiver. Influences of the receiver structure are common to all records and will be enhanced by summation. In contrast, influences of the source or the source structure (depth phases, conversions near the source) will be reduced. Obtaining the structure beneath a receiver is especially interesting because in contrast to sources, we can move the receivers where we need them and record teleseismic events to study the structure at nearly any location (with many problems at ocean bottom stations). The procedure used for source equalization is usually deconvolution. In the frequency domain, deconvolution of P receiver functions (PRFs) means division of the SV component by the P component, and in S receiver functions (SRFs), it means division of the P component by the SV component (Langston 1979; Gurrola et al. 1995). In time domain, a Wiener filtering approach (Kind et al. 1995) can be applied. For P receiver functions, an inverse filter can be generated by minimizing the least-square difference between the observed P waveform on the vertical component and the desired delta-like spike function. The inverse filter is then convolved with other components to obtain receiver functions. Ligorria and Ammon (1999) proposed an alternative approach to iteratively remove the source and

propagation effects. The question which type of deconvolution is carried out does not seem to be very significant. After deconvolution, amplitude normalization is applied, resulting in amplitude values of the converted phase in percent of the incident phase. Deconvolution, however, has one principal disadvantage. One entire component is considered as the source time function. For example, the entire P component over duration of perhaps 100 s is deconvolved from the SV component. This means all signals within this window on the P component are considered source. For example, P multiples within the crust at the receiver site will also be eliminated by this kind of deconvolution. In this sense, deconvolution prevents computation of the complete Green’s function (impulse response) at the receiver site (Kumar et al. 2010; Baig et al. 2005; Bostock 2004; Langston and Hammer 2001). The modification of seismic records caused by deconvolution is demonstrated in Fig. 5. Kumar et al. (2010) have shown that plain summation of many records of a seismic station results in SV component traces, which are nearly identical with deconvolved traces and P component traces are preserved. They only applied amplitude and sign equalization and summed all traces aligned along the maximum of the P signal (see Kumar et al. 2010). The only disadvantage of the new technique is that more traces are needed to obtain the same signal-to-noise ratio.

Moveout Correction and Summation

An important problem is that seismic phases travel with different velocities. This means that the differential times of seismic phases in one record depend on epicentral distances. Therefore, only records from similar epicentral distances can be summed. Traces from different distances may also be summed if the conversions arrive very closely in time to their mother phase (perhaps still possible for crustal conversions). For converted phases arriving later from greater depths, it is necessary to consider effects of their different slowness. Vinnik (1977) has solved this problem by using a delay and sum technique known from array processing and applying it to the upper mantle discontinuities. Results are displayed in a slowness-time plot (or conversion-depth-time plot; see Fig. 6). Another solution is that the distance moveout correction procedure could be applied before summation, which is very well known in applied seismics (see ▶ “[Deep Seismic Reflection and Refraction Profiling](#)”). In moveout correction, the timescale is stretched or compressed in order to parallelize the same type of travel time curves. A fixed reference slowness of 6.4 s/degree (or 67° epicentral distance) is frequently used at which the timescale remains unchanged. At smaller distances the timescale is compressed and expanded at larger distances, in order to transform the travel time curve of the converted phase under investigation into one parallel to the mother signal. After moveout correction, a

Seismic, Receiver Function

Technique, Fig. 4 (a) Effects of rotation of theoretical Z and R coordinates into the LQ system. Phases arriving as S wave (Ps, PpPs, PpSs) at the station remain on the Q component only. Phases that arrive as P waves remain on the L component (P, PpPp). (b) Ray paths of crustal multiples

number of traces may be lined up and summed into a single trace. A group of traces used for summation could be all records from either one station or records with piercing points in a certain geographical region (box) at a certain depth (common conversion point technique, Dueker and Sheehan 1997; see Fig. 7). The advantage of the moveout correction and summation technique is that single traces representing groups of traces can be easily compared. After moveout correction for direct conversions, the summation traces contain only such phases. Surface multiples are destructively superimposed because of their different slowness. Moveout corrections cannot only be applied to Ps or Sp conversions but also to other phases like multiples. In this case, the summation trace contains only a certain type of multiples (see Fig. 6). Moveout correction and summation also solve a special problem in S receiver functions. Not every precursor of S on the P component is an S-to-P conversion. Surface multiples of the

P phase can also arrive on the vertical component as precursors of S (Bock 1994). These phases have, fortunately, a different slowness and are suppressed in the delay and sum technique or the moveout correction and sum technique.

CCP Stack and Migration

Stacking by single stations is meaningful if piercing points from different stations are not overlapping in the depth range studied. If several stations are closely spaced and piercing points are overlapping at the study depth, summation by common regions of piercing points at that depth may be more meaningful (common conversion point stacking, CCP). In this case, piercing point locations for conversions at a defined depth are computed, and all traces with piercing points inside a defined area are summed (see Fig. 7).

Seismic, Receiver Function Technique, Fig. 5 (a) Deconvolved, (b) original theoretical seismograms (Kind 1985), and (c) the overlay of both for a simple crust–mantle model. All phases except P are eliminated on the deconvolved P component. The deconvolved SV (Q) component differs significantly from the theoretical SV component. The $P_M P$ phase has disappeared on the deconvolved SV component, as expected. However, the PpPs Moho multiple reflection has a significantly distorted amplitude (Kumar et al. 2010)

Stacked time domain receiver functions are not yet the goal of the processing, even if clear converted phases can be recognized. We need to know where in the three-dimensional Earth the conversion occurs. Therefore, the final goal is the migration from the time series into a depth model (see ► “Seismic, Migration”). Depth migration with a known velocity depth model is necessary for this purpose. Migration is a very well-known technique in controlled source seismics. In earthquake seismology with relatively sparse station distribution, more simple versions of migration with one-dimensional models are often used. The amplitudes of the receiver function traces are distributed along the ray path of a known velocity depth model. The Earth model is divided in boxes, and amplitudes of all rays in one box are summed. The result is an approximate two-dimensional (or three-dimensional) distribution of seismic energy in space where hopefully seismic discontinuities can be identified (see Fig. 8). In the case of P receiver functions, such images are blurred with multiples from the surface, which produce

apparent discontinuities. One of the first examples of receiver function depth migration is given by Kosarev et al. (1999). A more sophisticated development is given, e.g., by Bostock (2002).

The results of the processing steps described so far indicate the great similarity with steep angle-controlled source techniques. The topography of seismic discontinuities in the interior of the Earth is displayed either in the time or space domain. Distance moveout corrections and depth migration are the most important common steps. The main differences are the frequency content (which determines the resolution) and depth penetration. Steep angle seismics uses frequencies of many Hertz, whereas the teleseismic signals have periods from one to many seconds. Steep angle seismics does not always reach the Moho, whereas receiver functions have practically unlimited depth penetration since the signals are incident from below. Ryberg and Weber (2000) conclude from computations of theoretical seismograms of two-dimensional models that a station spacing of a few kilometers is required if structures with a few kilometer scale length need to be resolved (see Fig. 9). A station density of a few kilometers has so far been achieved only in very few deployments (e.g., Hansen and Dueker 2009).

Waveform Modeling

The above described processing steps for receiver functions lead to the detection and location of discontinuities in the interior of the Earth and their topography, ranging from the base of the sedimentary layers to the upper mantle transition zone between 410- and 660-km depth. A frequently applied additional step in receiver functions is the inversion of the waveforms over the entire length of the receiver function at a station into a one-dimensional velocity depth model (e.g., Ammon et al. 1990; Kind et al. 1995). Such an inversion technique has the capability of fitting the data nearly perfectly. However, problems involved are the nonuniqueness of the inversion and the assumption that seismic phases, which have been generated by a three-dimensional Earth, can be transformed into a one-dimensional model (Ammon et al. 1990). Although the nonuniqueness problem has been improved recently by using long-period signals (Jacobsen and Sverningsen 2008), even a perfect fit of the observed waveforms with theoretical waveforms encounters the problem of fitting three-dimensional effects and possible noise into a one-dimensional model.

Somewhat closer to reality seems to be the inversion of isolated waveforms of conversions from individual discontinuities in P or S receiver functions (e.g., Moho or LAB). An example is given by Li et al. (2007) (see Fig. 10). They summed about 8000 S-to-P converted signals from the LAB (S receiver functions) in the western USA and inverted the

Seismic, Receiver Function Technique, Fig. 6 Theoretical P receiver functions in original form and moveout corrected. A velocity model is needed to apply the moveout correction. (Bottom

left) Delay and sum technique developed by Vinnik (1977). Delays are computed for a number of assumed depths of conversion

width of the summed signal in terms of thickness of the LAB gradient. They obtained a transition zone of not more than 20 km. However, determinations of the size of the velocity jump and of the thickness of the LAB from summation traces may depend on focusing and defocusing effects of the topography within the region of piercing points and erroneous transform topography into the vertical velocity structure. Therefore, this 20-km gradient must be considered as an upper limit in this case. Another example is given by Mohsen et al. (2005) in Fig. 11. They show how each one of the observed seismic phases may be modeled with good accuracy with a relatively simple model.

Two Data Examples

In Fig. 12 are shown P, S, and SKS receiver functions in time domain from a seismically quiet station in northern Canada. The interesting point in these data is that in S and SKS receiver function (SKSRF), a clear negative phase is observed at 12–13 s, which corresponds to a depth of about 110 km. A negative signal indicates a low velocity zone. Such a zone in that depth may be caused by the LAB. However, from surface wave studies, a much larger depth of the LAB is expected in this region. These contradicting results pose very interesting questions about the structure of the upper

Seismic, Receiver Function Technique, Fig. 7 Cartoon showing receiver function rays in a simple Earth model. Single-station summation is useful for shallower studies or for averages over larger regions in greater depths. In case of dense deployments of several stations, common depth summation (CCP) may be used

mantle beneath old cratons. In Fig. 13 is shown an excellent example of depth migrated P receiver functions beneath a subduction zone (Kawakatsu et al. 2009). The subducting oceanic lithosphere is completely visible, including upper and lower boundary of the oceanic crust and the lower boundary of the oceanic lithosphere (see ► [“Lithosphere, Oceanic”](#)).

New Technical Development of the S-Receiver Function Method

The question of sidelobes in the receiver function technique caused by the data processing has frequently been asked but not satisfyingly been answered so far. A new method was suggested which avoids sidelobes completely and leads in some geological regions to surprising new results.

The traditional S-receiver function (SRF) method uses several acausal processing steps. The first of such steps is the deconvolution which may cause significant precursors of

Seismic, Receiver Function Technique, Fig. 8 Principle of depth migration of seismic records (theoretical seismograms in this case). Each ray from each station is back projected into an assumed model of the Earth. The amplitudes of the seismogram are distributed along this ray path. In the left figure it is assumed that all energy in the seismogram

originates from direct conversions; in the other figures, it is assumed that all energy is caused by multiples. Migration can, like moveout correction, only be done for one wave type at a time. The energy of the other phase type is migrated to the wrong depth and not focused

Seismic, Receiver Function Technique, Fig. 9 (a-d) Migrated theoretical 1-Hz receiver functions of a dome structure with different receiver spacing. A spacing of 5 or less kilometers is required to obtain

a good image of the structure. (e-f) Effects of illuminating the structure from limited back azimuths (see *arrows*, Ryberg and Weber 2000). Station spacing is 1 km

Seismic, Receiver Function Technique, Fig. 10 Modeling of the LAB summation phase in the western USA (Li et al. 2007, Fig. 8). (a) Models with different sharpness and velocity contrast of the LAB. Dashed line: LAB as a first-order discontinuity; solid line: LAB as a 20-km thick gradient transition zone and dotted line: LAB as a 40-km thick gradient transition zone. (b) Waveforms of data and synthetic S receiver functions. The thick gray line is the summation of all the

S receiver function stacks for each station after an alignment of the LAB phase. A 3–20-s bandpass filter is applied prior to alignment and summation for a better phase correlation. Synthetic S receiver functions correspond to the models shown in (a). The large positive swing in the data at less than 5 s is the averaged Moho signal, which is not computed in the synthetic seismograms

the SV signal. The second step is the definition of the reference time. The reference time is usually chosen at the time of the maximum of the deconvolved SV signal. Summation of different traces along these reference times causes always significant sidelobes. Applying acausal filters contributes also to sidelobes.

In the new method, deconvolution is avoided and the causal onset time of the SV signal is chosen as reference time. We correct for the sign of the SV onset and normalize the amplitudes by the maximum of the SV wave group. Also unfiltered broadband records are used. The new causal method is described by Kind et al. (2019). A comparison of a profile across the northern part of the United States computed with the traditional acausal method and the new causal method is shown in Fig. 14. The same data from the USARRAY are used in both techniques. The main difference is that the mid-Lithospheric discontinuity (MLD) in the traditional acausal deconvolution method (marked MLD in Fig. 14b) has completely disappeared in the causal method (Fig. 14a). The signal marked LAB (Lithosphere-Asthenosphere Boundary), in Fig. 14a, b, is identical in both methods. This indicates that this signal is physically existing and may be interpreted as LAB of the tectonic active western USA.

A new signal marked X appears in the causal method (Fig. 14a), which is overwhelmed by the sidelobes in the acausal method. This signal was interpreted by Kind et al. (2019) as indication of low-angle fossil subduction below nearly the entire Superior Craton. More geologically significant new findings of the new method in the USA are shown by Kind et al. (2019) and in China by Shen et al. (2019).

Summary

Receiver functions or converted waves belong to a class of small secondary scattered waves generated by a relatively strong main phase like P or S. Similar scattered phases are precursors of other main phases like PP, SS, or P'P', which have the great advantage to cover areas that are difficult to access, like oceans (see ► [“Body Waves”](#); ► [“Seismic Phase Nomenclature: The IASPEI Standard”](#)). These techniques are since about 30 years the main tools to study discontinuities of material properties in the Earth. The other main seismic tool is tomography, which is sensitive to smooth changes of material properties. The success of the scattered wave techniques was made possible by the great extension of high-quality seismic networks in the last decades. Permanent and mobile networks supplement each other. Especially studies of the lithospheric plates and the mantle transition zone have gained much from the new techniques. Many more detailed results can be expected when much denser networks will be used in future.

A recent review of the receiver function technique has been given by Rondenay (2009). A number of additional processing steps are the use of multiples to determine average crustal properties (e.g., Zhu and Kanamori 2000), the role of anisotropy (e.g., Levin and Park 1997; Schulte-Pelkum et al. 2005), or three-dimensional inversion (e.g., Bostock 2002).

Reflection matrix method

Definition

Reflectivity method is a semi-analytic method for computing synthetic seismograms in layered elastic media. The method has now been extended to anisotropic and laterally varying media.

The Reflectivity Method

Introduction

Synthetic seismograms are now used routinely for interpretation of field seismic data and evaluating the performance of seismic processing algorithms. Generation of synthetic seismograms essentially involves solution of the partial differential equation (PDE) for seismic wave propagation.

Different forms of the PDE are available for different earth models (e.g., acoustic, isotropic, elastic, anisotropic, homogeneous, laterally inhomogeneous, etc.). Brute force numerical methods such as finite differences and finite elements can, in principle, handle models of any complexity. However, they are limited by the speed of computation and computer memory. Even with our latest computer technology, generation of realistic 3D synthetic seismograms is not possible within reasonable clock time.

Much effort has been invested over the years in developing methods that are fast and accurate. We are left with three choices:

- Approximate the earth model and generate analytic or semi-analytic solutions
- Derive approximate (asymptotic) solutions for realistic heterogeneous models
- Derive pure numerical solutions for general heterogeneous models

Figure 1 provides a fairly complete list of the methods currently available for seismic modeling. Pure numerical methods based on finite difference (Virieux 1984; Liu and Sen 2009) and finite element (Marfurt 1984; Komatitsch and Tromp 1999, DeBasabe and Sen 2007; Vamaraju et al. 2020) approaches generate complete solutions but these methods become prohibitively expensive at high frequencies. The ray-based methods generate asymptotic solutions at infinite frequency and can be applied to models of general complexity as long as rays can be traced through the medium (Cerveny 2001). Although the original WKB method is valid for layered media, its extension to laterally varying media is the Maslov method (Chapman and Drummond 1982).

The methods such as the reflectivity (Fuchs and Mueller 1971) or Cagniard-deHoop method (e.g., Aki and Richards 2000) are included in the category of non-asymptotic analytic method. They were originally proposed for layered (1D) isotropic media and are still commonly used in such media although some extensions of these methods to anisotropy and lateral heterogeneity have indeed been reported. Although I included these methods in the category of “analytic method,” their final evaluation is done numerically. Thus, strictly speaking, they should be included in the category of “semi-analytic” methods. The speed of computation of these methods can be improved by using an asymptotic approximation at the final stage of evaluation of an oscillatory integral.

The primary goal of this entry is to provide an overview of the reflectivity method – perhaps the most popular method of seismogram synthesis. In the following sections, I will summarize the theory and numerical methods pertaining to reflectivity and provide some numerical examples. Finally, I will discuss an extension of the reflectivity method to laterally inhomogeneous media.

Seismic, Reflectivity Method, Fig. 1 A table showing different methods for computing synthetic seismograms: the reflectivity method is a semi-analytic method that is generally valid for layered earth models

Plane Waves

The plane waves are fundamental to understanding wave propagation. It has been demonstrated that a point source response can be generated by a weighted sum of individual plane wave responses (e.g., Aki and Richards 2000). In a homogeneous medium, plane waves propagate without spreading. In a stratified medium, plane waves remain planar during their propagation. However, as they propagate through a stack of flat layers (Fig. 2), they undergo changes in amplitude and phase.

- The amplitude changes can be accounted for by imposing boundary conditions of continuity of displacement and stress resulting in expressions for the so-called plane wave reflection and transmission coefficients.
- Travel time changes can be computed using individual layer velocities for locally linear ray paths.
- Changes in propagation angle can be computed by imposing Snell's law of preservation of horizontal slowness.
- In a stratified medium, an incident plane wave generates converted waves and internal multiples with appropriate amplitudes given by reflection and transmission coefficients.

Figure 2 displays a stack of layers in which each layer is characterized by its elastic moduli (P-wave and S-wave velocities in an elastic isotropic medium), density, and thickness. An incident plane P-wave characterized by a ray (normal to the plane) given by the angle it makes with the vertical axis is shown in the top layer. At the first layer boundary, it generates a reflected P-wave and a reflected SV-wave (converted). It

Seismic, Reflectivity Method, Fig. 2 A stack of layers in which each layer is characterized by its elastic moduli, density, and layer thickness: As an incident plane wave propagates through the stack of layer, it undergoes mode conversion and changes in amplitude due to reflection and transmission

also generates several reverberations with the top free surface (not shown in the figure). As the plane wave enters the second layer, it changes its propagation direction and similarly generates several converted waves and multiples. The primary task in generating synthetic seismograms is to keep track of all of these paths and account for all these amplitude and phase changes. The reflectivity method does exactly that. However, before we look into the details of the reflectivity method, let us first examine some simple cases with a few rays.

Simple Plane Wave Synthetics

It is fairly straightforward to generate plane wave synthetic seismograms for a layered medium for a few rays or plane waves. Two fundamental parameters involving plane wave seismograms are the ray parameter or horizontal slowness denoted by p and vertical delay time denoted by τ . They are defined as follows

$$p = \frac{\sin \theta}{v}, \quad q = \frac{\cos \theta}{v} \quad (1)$$

where θ is the vertical angle of the ray, q is called the vertical slowness, and

$$\tau = 2hq, \quad (2)$$

where h is the layer thickness.

Now referring to Fig. 2, the PP reflection delay time for layer 1 is

$$\tau_1^{PP} = 2h_1 q_1^P, \quad (3)$$

and the PS reflection delay time is

$$\tau_1^{PS} = h_1 (q_1^P + q_1^S). \quad (4)$$

In the above equations, the subscript represents the layer and the superscript represents the wavemode under consideration. The plane wave response of the primary PP mode from

the interface between layer 1 and layer 2 can be written down in the frequency-slowness domain as

$$R(\omega, p) = R_1^{PP} \exp(i\omega 2h_1 q_1^{PP}), \quad (5)$$

where R_{1PP} is the PP plane wave reflection coefficient for interface 1. Similar expression can be written down for the PS mode primary reflection.

$$R(\omega, p) = R_1^{PS} \exp(i\omega h_1 (q_1^P + q_1^S)). \quad (6)$$

To include the reflection from the second layer, we simply need to add a term appropriate for the second layer (similar to Eq. 3) resulting in the following expression

$$R(\omega, p) = T_{1D}^{PP} R_2^{PP} T_{1U}^{PP} \exp(i\omega (2h_1 q_1^{PP} + 2h_2 q_2^{PP})), \quad (7)$$

where we include the effects of transmission using downgoing (with subscript D) and upgoing (with subscript U) transmission coefficients. Expressions similar to Eq. (7) can also be written down for mode-converted waves.

Examples of plane wave and point source synthetic seismograms are shown in Fig. 3; these are generated for a vertical point force and only the traces of vertical component of displacement are shown. The upper panel shows the plane

wave seismograms in τ - p domain while the lower panel shows the corresponding x - t domain synthetic seismograms. The left panel shows seismograms for primary PP reflections only. Note two distinct reflections from the two-layer boundaries. The right panel shows seismograms that include primary PP , PS , and internal multiples from the second layer.

It is fairly straightforward to compute seismograms for a few selected phases for a few layers. In reality, we have many layers and an infinite number of rays paths – these are not easy to count. The reflectivity method offers an elegant algorithm for computing full response without having to count rays. Of course, we may choose to compute a few selected phases under reflectivity formulation as well, if desired.

Theory

Detailed developments of the theory of the reflectivity method for isotropic media can be found in Fuchs and Mueller (1971) and Kennett (1983). Derivations for an anisotropic layered medium can be found in Booth and Crampin (1983) and Fryer and Frazer (1984). The method has been used in a wide variety of applications in global and near surface seismology (e.g., Piera and Zanzi 1993). We start with the two fundamental equations in seismology, namely, the constitutive relation and the equation of motion given by

Seismic, Reflectivity Method,

Fig. 3 Examples of plane wave and point source synthetic seismograms for a model comprising two elastic layers over a half space: These were generated for a vertical point force and only the traces of vertical component of displacement are shown. The upper panel shows the plane wave seismograms in τ - p domain while the lower panel shows the corresponding x - t domain synthetic seismograms. The left panel shows seismograms for primary PP reflections only. The right panel shows the seismograms that include primary PP , PS , and internal multiples from the second layer

$$\tau = \mathbf{C} : \nabla \mathbf{u}, \quad (8)$$

$$\rho \omega^2 \mathbf{u} = \nabla \cdot \tau + \mathbf{f}, \quad (9)$$

where τ is a second rank stress tensor, $\mathbf{C}$ is the fourth rank elastic stiffness tensor, $\mathbf{u}$ is the displacement vector, ω is the angular frequency, and $\mathbf{f}$ is a body force term. Note that the above equations are in frequency domain.

The fundamental assumption in reflectivity is that the medium is layered and therefore, we can apply transformations over x and y coordinates to horizontal wavenumbers K_x and K_y or horizontal slowness p_x and p_y . For isotropic and layered transversely isotropic media, we can make use of cylindrical symmetry and transform to radial ray parameter p and azimuth ϕ . For a general anisotropic medium, we simply apply Fourier transforms over x and y coordinates to transform Eqs. (8) and (9) into horizontal wave numbers or ray parameter domain. Once that is achieved, all the analytic developments are done in the frequency ray-parameter domain.

The equation of motion and the constitutive relation are thus transformed into the following system of ordinary differential equations in depth z , by applying a Fourier transform in x and y

$$\mathbf{b} = i\omega \mathbf{A} \mathbf{b} + \mathbf{f} \quad (10)$$

where $\mathbf{b} = [u_x \ u_z \ u_y \ \tau_{xz} \ \tau_{zz} \ \tau_{yz}]^T = \mathbf{b}(\omega, \mathbf{p})$ is the stress-displacement vector which is a function of frequency ω and horizontal slowness $\mathbf{p}$, $\mathbf{A}(\omega, \mathbf{p})$ is the system matrix that is a function of elastic coefficients, and $\mathbf{f}$ is a body force term. The stress-displacement vector for isotropic and transversely isotropic media, the Eq. (10) decouples into two systems, namely, a P-SV (4X4) system and an SH (2X2) system. The solution of the ODE (Eq. 10) can be carried out by a propagator matrix method (Gilbert and Backus 1966). It is well known that the propagator matrix is generally unstable due to

growing exponentials (e.g., Jensen et al. 1993). Stable solutions can be obtained by one of the three methods:

- A global matrix approach (Schmidt and Tango 1986).
- Compound matrix approach where we define a new system of ODE in which the elements of the new system matrix are the minors of the original system matrix. The original 4X4 P-SV system maps into a 6X6 system (Dunkin 1965, Phinney et al. 1987).
- An invariant imbedding or a reflection matrix approach (Kennett 1983).

Of the three methods listed above, the compound matrix and the reflectivity methods have been widely used in seismology. Table 1 summarizes the two methods. The reflectivity method has been very popular because of its ray-interpretation and easy generalization to azimuthally anisotropic media. In the unconditionally stable reflection matrix approach (Kennett 1983), the propagation uses the eigenvalues and eigenvectors of the system matrix $\mathbf{A}$; the eigenvalues are the vertical phase functions. These eigenvalues and eigenvectors are used to define four upgoing and downgoing reflection and transmission coefficient matrices, $\mathbf{R}_D$, $\mathbf{T}_D$, $\mathbf{R}_U$, and $\mathbf{T}_U$. These are propagated through the stack of layers to obtain a composite reflection matrix that includes the effects of reflection, transmission, mode-conversion, and internal multiples. Kennett (1983) derived the following iteration equation (Kennett 1983, p. 127), which can be used to compute the R/T matrices of a zone AC when those of zones AB and BC are known (Fig. 4):

$$\begin{aligned} \mathbf{R}_D^{AC} &= \mathbf{R}_D^{AB} + \mathbf{T}_U^{AB} \mathbf{R}_D^{BC} [\mathbf{I} - \mathbf{R}_U^{AB} \mathbf{R}_D^{BC}]^{-1} \mathbf{T}_D^{AB} \\ &\quad \mathbf{T}_D^{AC} + \mathbf{T}_D^{BC} [\mathbf{I} - \mathbf{R}_U^{AB} \mathbf{R}_D^{BC}]^{-1} \mathbf{T}_D^{AB} \\ \mathbf{R}_U^{AC} &= \mathbf{R}_U^{BC} + \mathbf{T}_D^{BC} \mathbf{R}_U^{AB} [\mathbf{I} - \mathbf{R}_D^{BC} \mathbf{R}_U^{AB}]^{-1} \mathbf{T}_U^{BC} \\ &\quad \mathbf{T}_U^{AC} + \mathbf{T}_U^{AB} [\mathbf{I} - \mathbf{R}_D^{BC} \mathbf{R}_U^{AB}]^{-1} \mathbf{T}_U^{BC} \end{aligned} \quad (11)$$

Seismic, Reflectivity Method, Table 1 Reflection matrices or compound matrices?

Reflectivity approach	Compound matrix approach
Unconditionally stable	Unconditionally stable
For the P-SV case, the algorithm evaluates four 2X2 complex reflection/transmission matrices and iteration equations for each frequency and ray-parameter.	For the P-SV case, the algorithm fewer floating-point operations than the reflectivity method. The method is computationally faster than the reflectivity method.
Derivatives or differential seismograms can be computed analytically for isotropic and VTI media	Derivatives or differential seismograms can be computed analytically for isotropic and VTI media
Derivatives can be computed by semi-analytic approach for general anisotropic media	—
Requires VERY CAREFUL coding	Coding is very EASY
Most efficient for general anisotropic media	Very slow for general anisotropy
Ray-interpretation is possible. Selected rays and selected number of multiples can be included. The algorithm is VERY FLEXIBLE	Complete solution is derived

Seismic, Reflectivity Method, Fig. 4 Zones AB and BC from a stack of layers; if the upgoing and downgoing reflection/transmission matrices for these two zones are known, those for the entire stack AC can be generated using the iteration equations

Equation (11) is the most fundamental development of the reflectivity formulation. Given the R/T matrices (which include layer propagation and interaction terms) of two consecutive regions AB and AC, we can compute the response of region AC using Eq. (11). Thus, we can propagate through the stack of layers resulting in an unconditionally stable algorithm.

Let us examine the downward reflection matrix in Eq. (11) in slightly more detail. Using the matrix identity

$$(\mathbf{I} - \mathbf{A})^{-1} = \mathbf{I} + \mathbf{A} + \mathbf{A}\mathbf{A} + \mathbf{A}\mathbf{A}\mathbf{A} + \dots, \quad (12)$$

we can write

$$\begin{aligned} \mathbf{R}_D^{AC} &= \mathbf{R}_D^{AB} + \mathbf{T}_U^{AB} \mathbf{R}_D^{BC} [\mathbf{I} - \mathbf{R}_U^{AB} \mathbf{R}_D^{BC}]^{-1} \mathbf{T}_D^{AB} \\ &= \mathbf{R}_D^{AB} + \mathbf{T}_U^{AB} \mathbf{R}_D^{BC} \mathbf{T}_D^{AB} + \mathbf{T}_U^{AB} \mathbf{R}_D^{BC} \mathbf{R}_U^{AB} \mathbf{R}_D^{BC} \mathbf{T}_D^{AB} \\ &\quad + \dots \end{aligned} \quad (13)$$

Figure 5 clearly shows that Eq. (13) includes all the internal multiples and mode converted waves. We may also choose to retain a few terms in the expansion and thus compute exact response of a few rays.

While computing the up/downgoing reflection/transmission matrices through the stack of layers, we need to save the appropriate matrices through the source, receiver layers and the free surface. Finally, one can compute the entire stress/displacement vector comprising the components of displacement and traction at any receiver location. Combining these R/T matrices through one can obtain the required displacement or traction components.

Note that we obtain our solution in the frequency-ray parameter domain. An inverse temporal Fourier transforms results in $(\tau-p)$ seismograms. Synthetics in the offset-time domain can be obtained by plane wave synthesis of the (ω, p) or $(\tau-p)$ seismograms. A general flow chart for computing synthetic seismograms by the reflectivity method is shown in Fig. 6. Note that the ray-parameter, layer and frequency loops can be interchanged depending on the application. As stated earlier, intermediate results in $(\tau-p)$ domain are very useful for understanding wave propagation and amplitude effects since they are devoid of spherical spreading loss (Fryer 1980).

Computational Issues

It has been demonstrated that the reflectivity algorithm reviewed in this entry is unconditionally stable (Kennett 1983). However, one must incorporate some practical strategies in computing noise-free synthetic seismograms (e.g., Mallick and Frazer 1987).

- **Spatial aliasing:** Generation of offset synthetics from plane wave seismograms requires evaluation of an oscillatory integral. The integrand becomes more and more oscillatory with increase in offset and frequency. Thus, a practical strategy would be to use a frequency-dependent sampling interval in ray-parameters. Alternatively, one can use the minimum ray-parameter increment appropriate for the highest frequency and the largest offset of interest. We also need to use smooth tapers at the high and low ends of the ray-parameter window to avoid truncation phases.
- **Temporal aliasing:** Temporal aliasing can be avoided either by using a very large time window or adding a small imaginary part in the frequency following a method outlined in Phinney (1965)
- **Parallelization:** For high frequency and large offset calculation, the reflectivity calculation may be computationally intensive especially for azimuthally anisotropic media where reflectivity calculation needs to be performed for a large number of ray parameters. Note that (Fig. 6) almost the entire reflectivity computation can be done in parallel resulting in an algorithm that may be termed “embarrassingly parallel.” One of the simplest ways to parallelize is to distribute the computation of ray-parameter traces equally to the available nodes of a computer (e.g., Roy et al. 2005). The master node collects all the ray parameter traces (note that there is no communication in between the nodes required for the calculation of ray parameter trace). This results in an almost linear speedup as a function of the number of nodes. MPI can be used for parallelization; the reflectivity code can also be parallelized using simple compiler directives, if coded carefully.
- **Attenuation:** In order to include attenuation, we need to specify Q values for P- and S- waves for each layer. For

Seismic, Reflectivity Method,

Fig. 5 A demonstration of how the iteration equation includes all the reflection and transmission effects

**General Flow chart**

- Loop over ray-parameter
 - Loop over layer
 - Compute R/T (up going and downgoing) for all the interfaces
 - loop over frequency
 - evaluate iteration equation
 - end loop over frequency
 - end loop over layer
 - inverse FFT for (tau-p) seismograms
- End loop over ray-parameter
- Sum the plane wave responses to compute point source synthetics

Seismic, Reflectivity Method, Fig. 6 A general flow chart for developing a reflectivity code

frequency-dependent attenuation, the velocities are complex and dependent on frequency. In such cases, the layer loop (Fig. 6) becomes the deepest loop.

Applications

Exploration scale Modeling: Numerous applications of reflectivity synthetic seismograms for exploration can be found in literature. This algorithm is often used to generate synthetic seismograms from well logs and then used in calibrating a seismic gather at the well location and well tie (e.g., Sen 2006). Figure 7a shows V_p , V_s , density, and VTI anisotropy parameters ϵ and δ derived from a well log as a function of two-way time. The plane wave synthetics for an isotropic and VTI model and their differences are shown in Fig. 7b. Note that for isotropic calculations, ϵ and δ values were set equal to zero; for VTI calculations, V_p and V_s logs were treated as vertical P and S velocities. Offset synthetics for isotropic and VTI models and their differences are shown in Fig. 7c. As expected, the effect of anisotropy is more pronounced at large offsets or ray-parameters.

Modeling anisotropy in the core-mantle transition zone (D''): For modeling at regional and teleseismic distances, we need to apply earth flattening transformation to the models prior to computing synthetic seismograms using a reflectivity code. An example of such modeling is given in Pulliam and Sen (1998) in which attempts were made to model shear wave splitting observations of S-wave phases that propagate nearly horizontally through the core-mantle transition zone. Figure 8

shows the data and the corresponding synthetic seismograms for a station at Hockley from earthquakes from Tonga-Fiji. The model used for reflectivity calculation includes transversely isotropic layers with a horizontal axis of symmetry within the D'' zone.

Modeling in azimuthally anisotropic media (comparison with FD): An example of comparison of azimuthally anisotropic reflectivity synthetic seismograms with those computed by a 3D azimuthally anisotropic finite difference code is shown in Fig. 9 (Bansal and Sen 2008). The synthetics computed by the two methods are in excellent agreement.

Extension to Laterally Heterogeneous Media

Extension of the reflectivity method to two dimensions, where the velocities and densities are allowed to vary laterally as well, is nontrivial. Koketsu et al. (1991) and Sen and Pal (2009) developed extended reflectivity methods for the case of homogeneous layers separated by irregular or curved interfaces which do not cross each other. Lateral media variations within a layer cannot be easily taken into account in a reflectivity-type formalism because the concept of an interface is inherent in it except using the concepts of pseudo-differential operators and Fourier Integral operators (McCoy et al. 1986).

Across a flat surface, the horizontal slowness p is conserved according to Snell's law. However, across an irregular interface, an incident ray with a particular p is scattered into different plane waves with slownesses p' . This is mathematically equivalent to Fourier transforming the dependence of z on x to the scattered set of p' or k' (wavenumber). Now the coefficients $\mathbf{R}_D(p)$, $\mathbf{R}_U(p)$, $\mathbf{T}_D(p)$, $\mathbf{T}_U(p)$ become functions of both p and p' . The 2D extension of the method as proposed by Koketsu et al. (1991) involves explicit evaluation of boundary conditions that results in a matrix formulation involving several matrix inversions in the coupled ray-parameter domain; numerous numerical artifacts are caused by such matrix operations. An alternate asymptotic approach was proposed by Sen and Pal (2009) by examining a tangent-plane or Kirchhoff formulation in the plane wave domain to replace the exact boundary condition evaluation (Sen and Frazer 1991). All other reflectivity operations such as the invariant imbedding or iterative computation of reflection, transmission, multiple and mode conversions can be readily applied even under this approximation. This new algorithm computes noise-free

Seismic, Reflectivity Method, Fig. 10 (a) A model with two homogeneous layers over a half space; (b) τ - p - p' synthetic seismograms for the model shown in (a): note the shift in p value for the reflection from

the dipping interface; (c) shot gathers for the model shown in (a) – asymmetry in the reflection pattern from the second interface is modeled very well

seismograms even with coarse sampling of the interfaces and ray-parameters. Approximate calculation of reflection/transmission coefficients, however, does not include multiple interaction of a plane wave with an interface.

Sen and pal (2009) performed computations in the coupled slowness domain and thus, multiple shot-receiver data can be synthesized rapidly. Intermediate results in the coupled slowness space provide important insight into understanding wave propagation in heterogeneous media. Figure 10 shows synthetic seismograms for a model with two homogeneous layers over a half space (Fig. 10a) such that the top interface is flat and the second interface is dipping with a constant dip. Figure 10b shows synthetic seismograms in (τ - p - p') domain; note that for the flat layer the scattered p is the same as the incident ray-parameter and the same for the dipping reflector is different from the incident ray-parameter. Synthetic shot

gathers for three shot locations shown in Fig. 10a are shown in Fig. 10c. These were all computed using a 2D reflectivity code in which internal multiples were not included. Similarly, in Fig. 11, I show synthetic seismograms for a two layer over half space model where both the interfaces are curved. Note the triplicated arrivals in the seismograms in both τ - p - p' domain (Fig. 11b) and shot gathers (Fig. 11c). Note the triplicated arrivals in the seismograms due to curved interfaces.

Summary

Seismic modeling is crucial to understanding seismic wave propagation and interpreting field seismic records. Several methods for seismic modeling are available; they vary in

Seismic, Reflectivity Method, Fig. 11 (a) A model with two homogeneous layers over a half space; (b) τ - p - p' synthetic seismograms for the model shown in (a); note the shift in p values and triplications for the

reflection from the curved interfaces; (c) shot gathers for the mode shown in (a) – triplications in the reflections modeled very well

accuracy, model assumptions, and computational speed. Of these, the reflectivity method is perhaps the most popular. The original reflectivity formulation is valid for 1D elastic media. It is capable of computing a complete response of a layered earth model. If needed, this can also be designed to compute responses of a few selected phases. The cost of computation grows with the number of layers, increase in frequency, and offset. Most isotropic models can now be computed fairly rapidly on standard desktop workstations of personal computers. Azimuthally anisotropic models require computations in two wave numbers and therefore can be computationally demanding. Parallel algorithms can be easily developed for rapid computation of reflectivity synthetic seismograms for large models. For 1D full waveform inversion, the reflectivity forward modeling is invoked a large number of times where a parallel reflectivity algorithm is also essential. The reflectivity

algorithm has been used in a wide variety of applications including seismic modeling in exploration and whole earth scales. Full waveform inversion methods based on reflectivity forward modeling are becoming increasingly popular (e.g., Sen and Roy 2003). The method has also been extended to modeling in laterally heterogeneous media and in electromagnetic modeling in layered media (Sena et al. 2008).

Dhahran, Saudi Arabia

Definition

Super-virtual refraction interferometry (SVI) is a seismic data processing method that enhances the signal-to-noise ratio (SNR) of head-waves generated from different sources and recorded by many receivers. The enhancement of the SNR can be equal to the square root of N , where N is the number of postcritical sources.

Introduction

Seismic interferometry estimates the detailed properties of the Earth by analyzing the interference patterns of seismic waves. These patterns are constructed by correlating or convolving traces, and then summing pairs of seismic traces to robustly image the Earth's elastic properties (Schuster 2009).

The reciprocity equation of correlation type for a two-state system (Schuster 2009) is given as

$$G(y|x) - G_o(x|y)^* = \int_{S_o} \left[G_o(x|s)^* \frac{\partial G(y|s)}{\partial n_s} - G(y|s) \frac{\partial G_o(x|s)}{\partial n_s} \right] d^2s, \quad (1)$$

where x and y represent receiver positions, s represents the location of the physical shot, $G(b|a)$ is the Green's function for the actual Earth model in the frequency domain for a source located at a and a receiver located at b , and S_o is the

integration boundary. Here, the receiver line should be slightly below the source line, while the integration along the free surface vanishes because both Green's functions are zero. $G_o(x|y)$ is the acausal Green's function, and n is an outward pointing unit vector normal to the boundary.

The far-field approximation to eq. (1) is given as

$$G(y|x) - G_o(x|y)^* \approx 2ik \int_{S_o} G(y|s) G_o(x|s)^* dx^2. \quad (2)$$

An important property of the correlation is that the phases in the spectral product are subtractive, so that subtracting the traveltimes leads to shorter traveltime and earlier events with shorter raypaths. On the contrary, temporal convolution leads to the spectral product with additive phases. This means that the resulting trace has a longer traveltime and, hence, the new event has a longer raypath. For more information on seismic interferometry, see Schuster (2009) and Wapenaar et al. (2010).

The integration boundary should completely surround the receivers at x and y , however, for practical reasons, this is not possible; hence, artifacts may occur due to incomplete cancellation of nonphysical events. However, eq. 2 is considered acceptable for seismic interferometry since the approximation does not affect the phase (Wapenaar et al. 2010).

One of the major benefits of seismic interferometry is that velocity model or statics are not required for the redatuming because the data act as natural wavefield extrapolators. Actually, the scatterers in the medium have the effect of virtually enlarging the aperture of the recording array, which leads to what is known as super-resolution of the image (Leroy et al. 2007).

Interferometry helps in the surface-wave inversion of earthquake data (Gerstoft et al. 2006), surface-wave prediction and elimination (Halliday et al. 2007), trace interpolation (Hanafy and Schuster 2014) and extrapolation, refraction interferometry (Dong et al. 2006), passive seismic imaging (Draganov et al. 2004), and super-illumination (He et al. 2006) of the subsurface. In this entry, we will discuss the enhancement of the noisy signals through the use of natural Green's functions, which is known as super-virtual refraction interferometry (SVI).

Virtual Refraction Interferometry

In a refraction acquisition experiment where the sources and receivers are located on the ground surface, assume that the subsurface seismic velocities are homogenous, then the first arrival traveltime from a source located at s to a receiver located at x (left panel of Fig. 1a) is a head wave and can be approximated by

$$u(s, x) = A(s, x) e^{i\omega(\tau_{ss'} + \tau_{s'x})} \quad (3)$$

The amplitude term $A(s, x)$ in equation (3) accounts for both the geometrical spreading and the source wavelet, $\tau_{ss'}$ is the traveltime of the seismic wave that propagates from the surface source (s) to a point x' along the refractor with angular frequency ω , and $\tau_{s'x}$ is the traveltime from x' to the surface receiver located at point x .

Dong et al. (2006) redatum the surface sources (s) to the refractor by cross-correlating two nearby traces; here, the source is redatumed to the refractor at point x' (eq. 4 and Fig. 1a),

Super-virtual Refraction Interferometry

a) Crosscorrelation and stacking to generate virtual refractions

b) Convolution and stacking to generate super-virtual refractions

Seismic, Super-Virtual Refraction Interferometry, Fig. 1 (a) The two traces $u(s, x)$ and $u(s, y)$ recorded at the receivers in the left and middle velocity models are cross-correlated to generate the virtual trace $D_s^v(x, y)$ (see right velocity model). To enhance the SNR we stack over different source positions to generate the virtual trace $d^v(x, y)$. (b)

The virtual trace $d^v(x, y)$, recorded at y in the middle model, is now convolved with the recorded trace $u(s, x)$ in the left model, to generate the super-virtual refraction trace $D_s^{sv}(s, y)$ recorded at y in the right model. To enhance the SVI trace, we stack the traces for all locations (x) which are between s and y

$$\begin{aligned}
D_s^v(x, y) &= u(s, y)u(s, x)^*, \\
&= |A(s, x)|^2 e^{i\omega(\tau_{sx'} + \tau_{x'y} - \tau_{sx} - \tau_{x'y})}, \\
&= |A(s, x)|^2 e^{i\omega(\tau_{x'y} - \tau_{x'x})}, \tag{4}
\end{aligned}$$

where $D_s^v(x, y)$ is a virtual trace recorded at the physical receiver y and excited at a virtual source with unknown location x' ; the unknown excitation time is equal to the negative of the time for waves to propagate from point x' to point x . Here, we assume that the amplitude terms are roughly the same for each receiver position. The $\tau_{x'y}$ and $\tau_{x'x}$ terms in equation 4 represent the traveltime difference between a direct wave measured at x and a refraction arrival at y for a buried source located on the refractor at x' (Fig. 1a). The traveltime calculated by equation (4) is the same for any source position s located at the surface that generates head waves at receivers x and y from the same refractor. Therefore, these correlated traces for different source positions can be stacked together to give an N -fold stacked trace to enhance the signal-to-noise ratio (SNR), i.e.,

$$\begin{aligned}
d^v(x, y) &= \sum_{s=1}^N D_s^v(x, y), \\
&= e^{i\omega(\tau_{x'y} - \tau_{x'x})} \sum_{s=1}^N |A(s, x)|^2, \tag{5}
\end{aligned}$$

where $d^v(x, y)$ is the stacked virtual interferometry trace for a virtual source located at x' and arrivals recorded by a receiver located at y (Fig. 1a). Equation 5 shows an enhancement of the SNR equal to $\sqrt{N}$, where N is the number of stacked traces.

To avoid the artifacts due to a limited recording aperture and discrete sampling, Dong et al. (2006) suggested windowing about the first arrival traveltimes so that only the head-wave arrivals are correlated with one another.

Advantages. The advantage of the virtual refraction interferometry is that the correlated traces show improvement in the SNR equal to $O(\sqrt{N})$.

Limitations. The virtual refraction interferometry method suffers from the following limitations: (a) the source location is redatumed to the unknown position in the subsurface (Fig. 1a, right panel), (b) the excitation time of the correlated trace is unknown, the new excitation time after the redatuming step is equal to the negative traveltime from point x to point x' (the dashed line shown on Fig. 1a, right panel), and (c) the length of the raypath of the correlated trace is shorter than the original lengths of the input traces, which decreases the depth of penetration. These problems can be remedied by selecting the time of a visible refraction arrival

and adjusting the times of the SVI traces so that the virtual sources are automatically redatumed to the surface.

Super-Virtual Refraction Interferometry (SVI)

Bharadwaj and Schuster (2010) and Mallinson et al. (2011) suggested an alternative solution to the problem associated with the unknown excitation time and unknown source location, where they convolved the virtual traces $d^v(x, y)$ in equation 5 with the real trace $u(s, x)$ recorded at x excited by a source located at s (Fig. 1b),

$$\begin{aligned}
D_x^{sv}(s, y) &= u(s, x)d^v(x, y), \\
&= |A(s, x)| e^{i\omega(\tau_{sx'} + \tau_{x'y})} e^{i\omega(\tau_{x'y} - \tau_{x'x})} \sum_{s=1}^N |A(s, x)|^2, \\
&= |A(s, x)| \sum_{s=1}^N |A(s, x)|^2 e^{i\omega(\tau_{sx'} + \tau_{x'y})}, \tag{6}
\end{aligned}$$

The SVI head-wave arrivals, $D_x^{sv}(s, y)$ given by equation 6, are kinematically identical to those seen in traces with a high SNR and recorded by a receiver at y with a source at s . This process can be repeated for all M postcritical positions of x which are located between s and y ; hence, a total of M traces for the same source and receiver positions are generated. Then, similar to the virtual refraction interferometry, we stack these traces to enhance the output trace which has a known surface source position, and an enhanced SNR compared to the recorded trace (Bharadwaj et al. 2012, Fig. 1b):

$$\begin{aligned}
d^{sv}(s, y) &= \sum_{x=1}^M D_x^{sv}(s, y), \\
&= \sum_{x=1}^M |A(s, x)| \sum_{s=1}^N |A(s, x)|^2 e^{i\omega(\tau_{sx'} + \tau_{x'y})}, \tag{7}
\end{aligned}$$

The output of equation 7 is the “*super-virtual*” head-wave refraction arrival at y for a source located at s , as shown in Fig. 1b. Here, the location of the source point is known and located at point s , and the source excitation time is now equal to zero (Hanafy et al. 2011; Alshuhail et al. 2012).

Advantages. The SVI approach is an alternative solution to the limitations of the virtual refraction interferometry: (a) The source location is now redatumed back to the ground surface at point s , (b) the excitation time of the SVI is equal to zero, and (c) the lengths of the raypaths associated with the SVI traces are the same as the original raypath lengths of the input traces. In addition, the SNR of the SVI traces is

improved by an additional $\sqrt{M}$, where M is the number of stacked traces in the convolution step.

Limitations. The limitations of the SVI include: (a) we need to mute around the expected first-arrival traveltimes because the smaller the window the better the SVI result and (b) SVI is valid only in the case of head waves. However, it can also work if the velocity gradients only generate diving that does not dip too steeply.

SVI in Practice

The SVI method can be summarized (as shown in Fig. 2a–c) in the following steps:

1. On the raw data (Fig. 2a), a time window is identified that includes the head waves at both the near- and far-offset traces.
2. Mute the arrivals outside the window selected in step 1 (Fig. 2b), so that only the head wave arrivals are correlated with one another. This step is essential in order to suppress unwanted artifacts related to the correlations between reflections, direct arrivals, and refractions. The length of the window should be 2–3 periods long.
3. Generate the virtual interferometry data set by cross-correlating the muted traces together (eq. 4); the two

correlated traces must be from the same shot point (s), and the head waves must propagate along the same refractor (Fig. 1a).

4. Stack the virtual traces that share the same virtual source (x') and same receiver point (y) to enhance the virtual refractions (eq. 5).
5. Convolve the stacked virtual interferometry data set with the recorded traces to produce the super-virtual refraction interferometry (SVI) data set (eq. 6). The convolved traces must share the same virtual source point (x'), and the associated head waves must refract along the same refractor (Fig. 1b).
6. Stack the SVI traces that share the same source (s) and same receiver point (y) to enhance the SNR of the SVI arrivals (Fig. 2c and eq. 7).

For refractions propagating along from more than one refractor, the data are divided into subsections, and each subsection contains traces refracted from only one refractor. Then the SVI method is applied to each subsection separately, and the SVI data sets of all sections are blended together to get the final SVI data set.

In general, the SVI traces are more ringy than the raw traces because the amplitude spectrum of the wavelet (eq. 7) is raised to the third power. This might lead to ambiguous

Seismic, Super-Virtual Refraction Interferometry, Fig. 2 A field example from the Qademah data set recorded 20 km north of KAUST, Saudi Arabia: (a) raw CSG; (b) same as (a) after muting around the first

arrival traveltimes; (c) the result of SVI, 1st iteration; and (d) the result of the ISVI after three iterations. The red arrows point to the location of the first arrival traveltimes. (Modified from Fig. 7, Al-Hagan et al. 2014)

identifications of the first arrivals (Fig. 2c). To solve this problem, the raw traces with high SNR are used as guidance for better identification of the first arrival traveltimes in the SVI traces (Note red arrows in Fig. 2b, c).

The SVI method has been tested using synthetic and field 3D data set (Lu et al. 2014, Edigbue and Al-Shuhail 2016). There are several differences between the 2D and 3D SVI approaches, where the stationary positions of the source-receiver pairs could be any place along the x-y plane, also the SNR enhancing effect could be limited due to the limited number and irregularity of the survey lines and azimuthal range of arrivals. Lu et al. (2014) suggested integrating along the source or receiver lines, which enhances the SNR without the requirement of knowing the stationary locations. In addition, the amplitudes SVI traces are largely strengthened by integration, which is helpful to further enhance the SNR.

Iterative Super-Virtual Refraction Interferometry

There are some cases where the SNR enhancement from SVI is insufficient for accurate picking of noisy far-offset arrivals. This noise might result from weak sources shooting into distant receivers, and the area is polluted with environmental noise, etc. In such cases, Al-Hagan et al. (2014) suggested that the SVI traces can be used as an input to another round of SVI processing (eq. 8), and the output will be traces with an increase in SNR (Fig. 2d). They called this procedure iterative super-virtual refraction interferometry (ISVI),

$$d^{(k+1)} = L[d^{(k)}] \quad (8)$$

where $L[]$ represents the normalized super-virtual interferometry operations of summed correlation and convolution in equations 5 and 7, where $d^{(0)}$ at $k = 0$ represents the raw windowed traces and the output ($d^{(1)}$) is the super-virtual data obtained by the sequential application of equations 5 and 7. Then, the input to the 2nd SVI iteration at $k = 1$ is the SVI output $d^{(1)}$ to produce $d^{(2)}$, and this procedure is repeated until acceptable convergence.

Al-Hagan et al. (2014) recommended that the number of iterations should not exceed 3 ($k \leq 3$). For large number of iterations, the ISVI data become overly smoothed.

Advantages. ISVI shares the same advantages as the SVI, except it produces a higher SNR.

Limitations. ISVI also shares the same limitations as the SVI, and it also shows more ringing in the ISVI traces by increasing the number of iterations (note red arrows in Fig. 2d). To partially solve this problem, we can use a deconvolution filter (Snieder and Safak 2006, Vasconcelos and Snieder 2008; Al-Hagan et al. 2014), which is applied to the virtual traces after the correlation step to reduce the ringing in the first arrivals.

Very Noisy Data

In case of very noisy traces, it could be very difficult to identify a small (2–3 periods) window around the first arrival traveltimes. In these cases, Hanafy (2019) suggested the use of a 2-stage ISVI procedure.

1. In the first stage a very large window is identified to make sure that the first arrival traveltime is included. Then the ISVI with 2-iterations is applied on the windowed data. The result of the first stage shows ISVI data with slightly improved SNR, however, the SNR is not good enough for the first arrival traveltime picking.
2. In the second stage we use the ISVI data set of the first stage to identify a smaller window around the first arrival traveltimes. The updated window is now used to mute around the first arrival traveltime in the raw data, and then the ISVI is applied again to the muted-raw data using the small window. In this case, we use 2 or 3 ISVI iterations.

Summary

Super-virtual refraction interferometry (SVI) is used to enhance the SNR of noisy head waves recorded at the far offsets. The SVI starts with correlating nearby traces to generate the virtual refraction data traces, which are then convolved with the recorded data to generate the SVI data set. The SVI enhancement can be as large as $O(\sqrt{M})$, where M is the number of stacked traces in the convolution step. SVI procedure can be applied iteratively to enhance very low SNR data, however, a maximum of three iterations is recommended in this case. SVI is valid in case of head waves, and it can be applied to data recorded at any velocity model; however, it fails if the first arrival traveltimes mainly consist of diving waves with steep arrival angles. Traces from different refractors need to be handled separately to decrease the artifacts in the final SVI data set.

Seismic, Velocity, and Density Relationships

Kalachand Sain
Wadia Institute of Himalayan Geology, Dehradun, India

Definition

Seismic velocity is defined as the speed with which a seismic wave travels through a medium and is measured in km/s. The density is the mass per unit volume and is expressed in g/cc.

The relationship between seismic velocity and density is very much required for subsurface geological interpretation

and reservoir characterization. As a rock property, density plays an important role for the identification of lithologies, delineation of pore fluids, estimation of porosity and overburden stress, and prediction of well planning. It is possible to derive velocity-depth function from seismic data, but the density variation along a well path can be hardly obtained from gravity data until a well is drilled. Hence, density is calculated from seismic velocities using a set of relationships (Birch 1961; Gardner et al. 1974; Lindseth 1979), if the well information is not available.

Types of seismic waves: The *body wave* and the *surface wave* are the main seismic waves. The body waves are the longitudinal (P) and the shear (S) waves in which the particles vibrate parallel and perpendicular to the direction of wave propagation, respectively. The velocities of P-wave (V_P) and S-wave (V_S) are related to the density, ρ as

$$V_P = \sqrt{\frac{\kappa + \frac{4}{3}\mu}{\rho}} \quad (1)$$

$$V_S = \sqrt{\frac{\mu}{\rho}} \quad (2)$$

Where κ and μ are the bulk and rigidity moduli, respectively. It appears that the seismic velocity and density are inversely related, but the denser rocks are characterized by higher velocities compared to lighter rocks, as the density also depends on κ and μ . The halite with low density of 1.8 g/cc and high V_P of 4.5 km/s shows an exception. Generally, velocities and densities increase with depth. The inversion of this trend is also observed due to pore pressure, fluids, or sediments below volcanic rocks.

General Relation Between Velocity and Density

- (a) Birch's law – To fit measurements from crustal and mantle rocks, Birch (1961) established a linear relationship between V_P and ρ as

$$V_P = a + b\rho \quad (3)$$

Where a and b are empirical parameters. This relation was tested at high pressure by Campbell and Heinz (1992).

- (b) Gardner relation – Gardner et al. (1974) conducted field and laboratory measurements on saturated sedimentary rocks from a wide-range of basins, ages, and depths and established the velocity-density relation as

$$\rho = aV_P^b \quad (4)$$

Where $a = 0.31$ and $b = 0.25$ are Gardner coefficients. Though many sedimentary rocks (Shale, Sandstone,

Limestone, and Dolomite) fall within a narrow corridor around the Gardner curve, Coals, Anhydrite, Salts, etc. exhibit large deviations from this trend. The deviation increases with porosity and becomes higher for lower densities.

- (c) Based on data of Gardner et al. (1974), Lindseth (1979) proposed an empirical relation between V_p and acoustic impedance to extract the density from the reflectivity as

$$V_p = 0.308 \rho V_p + 3460$$

Krasovsky (1981) showed that the Gardner equation is non-unique for many sedimentary basins in the world, and suggested for local calibration to improve the accuracy of rock property prediction. As a way forward, Ojha and Sain (2014) and Nwozor et al. (2017) used the well logs data in the Kerala-Konkan (India) and Niger Delta (Egypt) basins, respectively, to derive the lithology-specific Gardner coefficients for geological analyses accurately. The sands usually trend lower densities than shales of corresponding velocity due to their different mineral composition, and shales are more responsive to compaction than sands. Though the Gardner coefficients are calibrated from sonic and density well log information, but in the absence of these, Gardner coefficients are still used in petroleum exploration.

Estimation of seismic velocity and density from surface measurements provides important inputs in understanding the structure and tectonics of a geotectonic province. Since gravity is a potential field, velocity structure is often used to constrain the gravity modeling (Barton 1986; Ravat et al. 1999; Behera et al. 2004; Boore 2016; Emudianughe and Ahmad 2019) by converting the velocity into density based on a relationship. Use of Ludwig (1970) formula to relate V_p with ρ is also very common in crustal studies.

Waveform inversion

Definition

Tomography. A seismic inversion method to produce slicing image of the internal structures of an object, by recording seismic wavefield propagating through and scattered-refracted-reflected back from the object and observing the difference in the effects on the wave energy impinging on those structures.

Introduction

Seismic waveform tomography is an imaging technology using seismic data to reconstruct the Earth subsurface physical properties, represented by seismic velocity, attenuation coefficient, etc. It is usually formulated as an inverse problem (Wang 2016). Many seismic tomography methods use the arrival time or amplitude information extracted from the waveform recordings as the input data to an inversion process. These methods are generically referred to as travel time or amplitude tomography (Wang 2003). Comparing to either travel time or amplitude tomography, waveform tomography has at least two major features. First, the input data consist of the seismic waveforms themselves, as opposed to travel times, amplitudes, or some other secondary attributes of the recorded data. This makes waveform tomography a better resolution than travel time or amplitude tomography. Second, the underlying numerical method is based on the full-wave equation, as opposed to a ray approximation or a Born approximation. This makes waveform tomography more accurate than the travel time or amplitude counterpart. These two features also make the inverse problem of waveform tomography more difficult to solve.

However, as field seismic data usually lack low-frequency information, travel time or amplitude tomography may provide a reliable starting model for the iterative waveform inversion. If waveform tomography is implemented in the frequency domain, the inversion process proceeds from low- to high-frequency components. In the time domain, a band-pass filter can be applied to the seismic data, and inversion uses band-pass filtered data with low frequencies first and proceeds to higher frequencies (Rao and Wang 2017). Even for the frequency-domain implementation, in order to suppress the low signal-to-noise ratio effect of frequency data and to make the inversion procedure robust, waveform tomography usually uses a group of frequencies simultaneously in an iterative inversion and proceeds from low- to high-frequency groups, generating a high-resolution image of the subsurface model (Wang and Rao 2006).

Waveform tomography has been used successfully on transmission data, such as crosshole seismic data, and to wide-angle reflection/refraction seismic data with a certain degree of success. It has also been used for regional-scale studies on the crustal and upper mantle velocity structure, using scattering waves, surface waves, and SH-waves from either exploration seismic data or broadband teleseismograms. In addition, there is a good progress on its application to seismic reflection data with limited source-receiver offsets (Wang and Rao 2009). The seismic reflection method is a routine practice in the hydrocarbon exploration, and the data dominated by the precritical reflection energy, reflected back from subsurface contrasts in physical parameters, are well suited for seismic migration for the structural image. Applying the waveform tomography

technique to these reflection data can quantitatively extract the geophysical parameters, for identifying different lithologies and different fracture characteristics and even for indicating the hydrocarbon distribution directly.

Waveform Modeling

Waveform modeling is the key engine in seismic waveform tomography. Seismic wave propagation satisfies both Newton's second law and Hook's law and can be expressed by the following five simultaneous first-order differential equations for a two-dimensional (2D) case:

$$\begin{aligned}\rho \frac{\partial u}{\partial t} &= \frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{xz}}{\partial z}, \\ \rho \frac{\partial w}{\partial t} &= \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{zz}}{\partial z}, \\ \frac{\partial \tau_{xx}}{\partial t} &= c_{11} \frac{\partial u}{\partial x} + c_{13} \frac{\partial w}{\partial z} + c_{15} \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right), \\ \frac{\partial \tau_{zz}}{\partial t} &= c_{31} \frac{\partial u}{\partial x} + c_{33} \frac{\partial w}{\partial z} + c_{35} \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right), \\ \frac{\partial \tau_{xz}}{\partial t} &= c_{51} \frac{\partial u}{\partial x} + c_{53} \frac{\partial w}{\partial z} + c_{55} \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right),\end{aligned}\quad (1)$$

where u and w are the particle velocity components in the horizontal and vertical direction, respectively; τ_{xx} , τ_{xz} , and τ_{zz} are stress components; ρ is density; and

$$\begin{bmatrix} c_{11} & c_{13} & c_{15} \\ c_{31} & c_{33} & c_{35} \\ c_{51} & c_{53} & c_{55} \end{bmatrix}\quad (2)$$

are the elastic constants in Hook's law relating stress to strain in the 2D case. The first two equations are derived from Newton's second law and the last three from Hooke's law for an elastic medium. Eliminating stress components, these five simultaneous equations can be coupled into two equations:

$$\begin{aligned}-\rho \frac{\partial^2 u}{\partial t^2} + \frac{\partial}{\partial x} \left(c_{11} \frac{\partial u}{\partial x} + c_{15} \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial x} \left(c_{15} \frac{\partial u}{\partial z} + c_{13} \frac{\partial w}{\partial z} \right) \\ + \frac{\partial}{\partial z} \left(c_{51} \frac{\partial u}{\partial x} + c_{55} \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial z} \left(c_{55} \frac{\partial u}{\partial z} + c_{53} \frac{\partial w}{\partial z} \right) = 0, \\ -\rho \frac{\partial^2 w}{\partial t^2} + \frac{\partial}{\partial x} \left(c_{51} \frac{\partial u}{\partial x} + c_{55} \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial x} \left(c_{55} \frac{\partial u}{\partial z} + c_{53} \frac{\partial w}{\partial z} \right) \\ + \frac{\partial}{\partial z} \left(c_{31} \frac{\partial u}{\partial x} + c_{35} \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial z} \left(c_{35} \frac{\partial u}{\partial z} + c_{33} \frac{\partial w}{\partial z} \right) = 0,\end{aligned}\quad (3)$$

which are defined in terms of horizontal wave component u and vertical wave component w . These equations are

valid for the Earth media with arbitrary anisotropy and heterogeneity.

In the forward modeling of seismic wave propagation based upon either five or two simultaneous equations, there has been a steady development in the finite-difference implementations. As the time derivatives are approximated by $\partial u/\partial t \approx -(u_{i+1} - u_i)/\Delta t$ and $\partial^2 u/\partial t^2 \approx (u_{i+1} - 2u_i + u_{i-1})/\Delta t^2$, where i is the time index, $t_i = i\Delta t$, and Δt is the step size in time; the wavefield u_{i+1} at the current time can be calculated based on the previous wavefield: $u_{i+1} = f(u_i)$ or $u_{i+1} = f(u_i, u_{i-1})$. This is an explicit finite-difference scheme (Alford et al. 1974; Kelly et al. 1976). For the spatial derivatives, a second-order staggered grid scheme is widely used for numerical stability (Virieux 1986) and can also be extended to a fourth-order scheme for greater accuracy (Levander 1988).

In the frequency domain, the two simultaneous equations become

$$\begin{aligned} \omega^2 \rho u + \frac{\partial}{\partial x} \left(c_{11} \frac{\partial u}{\partial x} + c_{15} \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial x} \left(c_{15} \frac{\partial u}{\partial z} + c_{13} \frac{\partial w}{\partial z} \right) \\ + \frac{\partial}{\partial z} \left(c_{51} \frac{\partial u}{\partial x} + c_{55} \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial z} \left(c_{55} \frac{\partial u}{\partial z} + c_{53} \frac{\partial w}{\partial z} \right) = 0, \\ \omega^2 \rho w + \frac{\partial}{\partial x} \left(c_{51} \frac{\partial u}{\partial x} + c_{55} \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial x} \left(c_{55} \frac{\partial u}{\partial z} + c_{53} \frac{\partial w}{\partial z} \right) \\ + \frac{\partial}{\partial z} \left(c_{31} \frac{\partial u}{\partial x} + c_{35} \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial z} \left(c_{35} \frac{\partial u}{\partial z} + c_{33} \frac{\partial w}{\partial z} \right) = 0, \end{aligned} \quad (4)$$

where ω is the angular frequency. This system of equations can be solved in parallel for individual frequencies, using also a finite-difference method. Once all frequency components of the wavefield at any spatial position are obtained, performing inverse Fourier transform, with respect to the frequency variable, will produce a time-domain seismic trace at this spatial position.

However, the frequency-domain implementation is much more time-consuming, compared to its counterpart in the time domain. This is because the frequency-domain calculation involves the solution of linear algebraic equations as the follows. Using a finite-difference method, Equation (4) may be presented in a vector-matrix form as

$$\mathbf{M}\mathbf{u} = \mathbf{s}, \quad (5)$$

where $\mathbf{M}$ is a matrix approximating the partial differential operators, $\mathbf{u}$ is a vector representing the two components of the wavefield at all grids, and $\mathbf{s}$ is a vector representing the source term, which is zero everywhere except at the location of the source (added to the right-hand side of the wave equations). To obtain wavefield $\mathbf{u}$, one needs to solve the inverse matrix $\mathbf{M}^{-1}$. This is therefore an implicit finite-difference scheme.

The matrix $\mathbf{M}$ represents a significant storage requirement, which is largely determined by the numerical bandwidth of $\mathbf{M}$ and by the manner in which the structural sparsity of the matrix is maintained in any solution method. The bandwidth of the differencing matrix is determined by the number of nodes needed for a spatial derivative. A minimal, rotated computational star is a scheme that can minimize the bandwidth of the matrix and meanwhile improve the accuracy for finite-difference modeling. It does not require any new grid points as used in a second-order finite differencing but can produce an equivalent of fourth-order accuracy in finite differencing (Štekl and Pratt 1998).

While it is feasible to calculate the inverse matrix $\mathbf{M}^{-1}$ for a small, 2D model, in many practical problems such as 3D seismic modeling, the system $\mathbf{M}\mathbf{u} = \mathbf{s}$ with a large, sparse matrix is solved iteratively rather than directly. An approximate solution $\tilde{\mathbf{u}}$ is first obtained by solving using a related, preconditioning matrix. This preconditioner is chosen such that it is related to the true matrix but is much faster to invert. The approximate solution $\tilde{\mathbf{u}}$ from the preconditioner is then substituted into the true matrix equation to discover the effective source, $\tilde{\mathbf{s}} = \mathbf{M}\tilde{\mathbf{u}}$. The difference $\mathbf{s} - \tilde{\mathbf{s}}$ between this effective source and the true source can then be treated as an actual source for the next iteration. The final solution $\mathbf{u}$ to the original matrix equation is found if the difference is sufficiently small.

Figure 1 shows the snapshot of wave propagation through an anisotropic medium. The elastic coefficients are summarized as $c_{11} = 29.26$, $c_{33} = 23.98$, $c_{55} = 4.29$, $c_{13} = c_{31} = 17.27$, $c_{15} = c_{51} = 1.98$, and $c_{35} = c_{53} = 2.53$ (Gpa), and the density of the medium is a constant of 2.5 g/cm^3 . The source is a Ricker wavelet with dominant frequency of 10 Hz. The snapshot shows clearly qP -wave front propagating in difference directions with different velocities. S-wave front can also be observed in these figures.

Waveform modeling uses an elastic wave equation, for the generality, and produces a wavefield presented as particle velocity components. In a homogeneous, isotropic media, $c_{11} = c_{33} = \lambda + 2\mu$, $c_{13} = c_{31} = \lambda$, and $c_{55} = \mu$, where λ and μ are Lamé parameters, and $c_{15} = c_{51} = c_{35} = c_{53} = 0$. In an acoustic assumption, $c_{11} = c_{33} = c_{13} = \lambda$ and $c_{55} = c_{15} = c_{35} = 0$. With the acoustic assumption, most field seismic records are pressure data. According to Newton's second law, the relationship between particle velocity (u, w) and pressure P is

$$\rho \frac{\partial u}{\partial t} = -\frac{\partial P}{\partial x}, \quad \rho \frac{\partial w}{\partial t} = -\frac{\partial P}{\partial z}. \quad (6)$$

Structural complexities such as the fluctuations of subsurface interfaces significantly influence seismic wavefields. For instance, fluctuating interfaces have both focusing and defocusing effects on seismic amplitudes. These interface-

Seismic, Waveform Modeling and Tomography,

Fig. 1 Snapshot of wave propagation in an anisotropic medium: (a) horizontal component and (b) vertical component

related amplitude effects can be exploited to reconstruct the interface geometry by inverting the seismic amplitudes (Wang and Houseman 1994, 1995; Wang and Pratt 2000; Wang et al. 2000) and are also included implicitly in the waveform inversion of seismic reflection data. Seismic reflection data, which are dominated by precritical reflected energy from subsurface contrasts in physical parameters, are suitable for structural imaging following seismic migration. However, these data can also be utilized in waveform inversions to quantitatively reconstruct velocity models for the subsurface of the Earth.

To conduct an accurate waveform modeling for seismic waveform tomography, it is necessary to have an accurate representation of the subsurface interfaces within the numerical model, as the contrast in elastic properties across an interface has a dominant impact on the seismic wavefield. A straightforward and cost-effective waveform modeling method is the finite-difference method with quadrilateral grids. A body-fitted gridding scheme can be adopted to partition each horizontal layer that is confined by two fluctuating interfaces in the model. The grids should be coincided with fluctuations of the irregular surface and interfaces while satisfying the pseudo-orthogonality condition. This pseudo-orthogonality condition is necessary to effectively avoid any scattering caused by artificial stair-type grids used within conventional rectangular gridding (Rao and Wang 2013; Zhang et al. 2014).

However, for a fluctuating interface, it is difficult to simultaneously adjust grids on both sides of the interface and to ensure that grids across the interface satisfy the pseudo-orthogonality condition. Then, a summation-by-part (SBP) discretization approach can be effective for the finite-difference implementation of the wave equation (Strand 1994; Mattsson and Nordström 2004; Svärd et al. 2005; Mattsson 2012). The SBP discretization satisfies the SBP

identity in Abel's lemma that guarantees the stability of the finite-difference scheme. This SBP finite-difference method can cope with non-rectangular meshes in the vicinity of a fluctuating interface and consequently achieve a desirable accuracy for the waveform modeling (Rao and Wang 2018).

Inverse Method

Seismic waveform tomography is an inverse problem (Wang 2016). Its objective can be defined as

$$\phi(\mathbf{m}) = [\mathbf{P}(\mathbf{m}) - \mathbf{P}_{\text{obs}}]^H \mathbf{C}_D^{-1} [\mathbf{P}(\mathbf{m}) - \mathbf{P}_{\text{obs}}] + \mu [\mathbf{m} - \mathbf{m}_0]^H \mathbf{C}_M^{-1} [\mathbf{m} - \mathbf{m}_0], \quad (7)$$

where $\mathbf{m}_0$ is a reference model; $\mathbf{m}$ is the model to invert for; $\mathbf{P}(\mathbf{m})$ is a modeled data set based on model $\mathbf{m}$; $\mathbf{P}_{\text{obs}}$ is an observed data set; $\mathbf{C}_D$ is the data covariance matrix with units of $(data)^2$, defining the uncertainties in the data set; $\mathbf{C}_M$ is the model covariance matrix with units of $(model\ parameter)^2$; and μ is a scalar that controls the relative weights of the data fitting term and the model constraint in the objective function. In Equation (7), the superscript H denotes the complex conjugate transpose.

For minimizing the objective function, a gradient method can be used. It starts with the differentiation of the objective function with respect to the model parameters:

$$\frac{\partial \phi}{\partial \mathbf{m}} = 2(\mathbf{F}^H \mathbf{C}_D^{-1} \delta \mathbf{P} + \mu \mathbf{C}_M^{-1} \delta \mathbf{m}), \quad (8)$$

where $\delta \mathbf{m} = \mathbf{m} - \mathbf{m}_0$ is the model perturbation, $\delta \mathbf{P} = \mathbf{P}(\mathbf{m}) - \mathbf{P}_{\text{obs}}$ is the data residual, and $\mathbf{F}$ is a matrix of the Fréchet derivative of $\mathbf{P}(\mathbf{m})$ with respect to the model $\mathbf{m}$. The first term in Equation (8) is the gradient direction of the data misfit:

$$\hat{\mathbf{g}} = \mathbf{F}^H \mathbf{C}_D^{-1} \delta \mathbf{P} = \mathbf{F}^H \delta \hat{\mathbf{P}}, \quad (9)$$

where $\delta \hat{\mathbf{P}} = \mathbf{C}_D^{-1} \delta \mathbf{P}$ is a weighted data residual. Setting $\partial \phi / \partial \mathbf{m} = 0$ in Equation (8), one obtains the following equation:

$$\delta \mathbf{m} = -\alpha \mathbf{C}_M \hat{\mathbf{g}}, \quad (10)$$

where α is a update step length that needs to be determined.

In order to evaluate the gradient $\hat{\mathbf{g}}$ using Equation (9), one needs to know the Fréchet matrix $\mathbf{F}$, which is obtained from the following linear formula:

$$\delta \mathbf{P} = \mathbf{F} \delta \mathbf{m}. \quad (11)$$

This is the first term in a Taylor's series for $\delta \mathbf{P}$ and relates the data perturbation $\delta \mathbf{P}$ to the model perturbation $\delta \mathbf{m}$. However, a direct computation of $[\mathbf{F}]_{ij} = \partial P_i / \partial m_j$ is a formidable task when P_i are seismic waveforms. The action of matrix $\mathbf{F}^H$ on the weighted data residual vector $\delta \hat{\mathbf{P}}$ can be computed by a series of forward modeling steps, summarized as follows (Tarantola 1984, 1987).

The frequency-domain acoustic wave equation for a constant density medium with velocity $c_0(\mathbf{x})$ is

$$\left(\nabla^2 + \frac{\omega^2}{c_0^2(\mathbf{x})} \right) P_0(\mathbf{x}, \omega) = -S(\omega) \delta(\mathbf{x} - \mathbf{x}_0), \quad (12)$$

where $\mathbf{x}$ is the position vector, $\mathbf{x}_0$ locates the source position, $S(\omega)$ is the source signature of frequency ω , and $P_0(\mathbf{x}, \omega)$ is the (pressure) wavefield of this frequency, and we drop off the frequency reference in the following discussion. If the velocity is perturbed by a small amount, $\delta c(\mathbf{x}) \ll c_0(\mathbf{x})$, that is, $c_0(\mathbf{x}) \rightarrow c(\mathbf{x}) = c_0(\mathbf{x}) + \delta c(\mathbf{x})$, then the total wavefield is correspondingly perturbed to $P_0(\mathbf{x}) \rightarrow P(\mathbf{x}) = P_0(\mathbf{x}) + \delta P(\mathbf{x})$. Following Equation (12), δP approximately satisfies

$$\left(\nabla^2 + \frac{\omega^2}{c_0^2(\mathbf{x})} \right) \delta P(\mathbf{x}) = 2\omega^2 P_0(\mathbf{x}) \frac{\delta c(\mathbf{x})}{c_0^3(\mathbf{x})}. \quad (13)$$

Considering $2\omega^2 P_0(\mathbf{x}) \delta c(\mathbf{x}) / c_0^3(\mathbf{x})$, the term on the right-hand side, as a series of "virtual sources" over $\mathbf{x}$ the integral solution for $\delta P(\mathbf{x})$ can be expressed as

$$\delta P(\mathbf{x}) = - \int_{\Omega} \delta c(\mathbf{x}') \frac{2\omega^2}{c_0^3(\mathbf{x}')} P_0(\mathbf{x}') G(\mathbf{x}, \mathbf{x}') d\mathbf{x}', \quad (14)$$

where $G(\mathbf{x}, \mathbf{x}')$ is the Green's function for the response at $\mathbf{x}$ to a point source at $\mathbf{x}'$ for the original velocity field. Note that in the acoustic case where one assumes density to be constant and defines the model by the velocity field only, $\mathbf{m} \equiv \mathbf{c}$. Then,

comparing Equation (14) against the matrix-vector form of Equation (11), one can see that the Fréchet matrix is defined with element, $F(\mathbf{x}, \mathbf{x}') = -[2\omega^2 / c_0^3(\mathbf{x}')] P_0(\mathbf{x}') G(\mathbf{x}, \mathbf{x}')$. Substituting this Fréchet kernel into Equation (9), one obtains

$$\hat{\mathbf{g}}(\mathbf{x}) = \left(\frac{2\omega^2}{c_0^3(\mathbf{x})} \right)^* \int_D P_0^*(\mathbf{x}') G^*(\mathbf{x}, \mathbf{x}') \delta \hat{P}(\mathbf{x}'). \quad (15)$$

Replacing the integral over the data space with a summation over source and receiver pairs, denoted by s and g , respectively, as the source and receiver position are inherently discrete and finite in number, one can obtain

$$\begin{aligned} \hat{\mathbf{g}}(\mathbf{x}) &= \left(\frac{2\omega^2}{c_0^3(\mathbf{x})} \right)^* \sum_s \left(P_0^*(\mathbf{x}; \mathbf{x}_s) \sum_r G^*(\mathbf{x}, \mathbf{x}_r) \delta \hat{P}(\mathbf{x}_r; \mathbf{x}_s) \right) \\ &= \left(\frac{2\omega^2}{c_0^3(\mathbf{x})} \right)^* \sum_s (P_0^*(\mathbf{x}; \mathbf{x}_s) P_b^*(\mathbf{x}; \mathbf{x}_s)), \end{aligned} \quad (16)$$

where

$$P_b(\mathbf{x}; \mathbf{x}_s) = \sum_r G(\mathbf{x}, \mathbf{x}_r) \delta \hat{P}^*(\mathbf{x}_r; \mathbf{x}_s) \quad (17)$$

representing the wavefield generated by a series of virtual sources $\delta \hat{P}^*(\mathbf{x}_r)$, corresponding to a single source $\mathbf{x}_s$. Note that wavefield $P_b(\mathbf{x}; \mathbf{x}_s)$ is not calculated directly from Equation (17) but is computed using the same forward modeling scheme as used for Equation (12) with the virtual sources $\delta \hat{P}^*(\mathbf{x}_r)$. This procedure is referred to as data residual backpropagation.

In summary, waveform tomography is performed iteratively. For each iteration, the inversion procedure may be divided into four steps:

1. For a given model estimate, calculating the synthetic wavefield $P_0(\mathbf{x}; \mathbf{x}_s)$ at space position $\mathbf{x}$ corresponding to a source point at $\mathbf{x}_s$
2. Using the weighted data residual $\delta \hat{\mathbf{P}} = \mathbf{C}_D^{-1} \delta \mathbf{P}$ as virtual sources to generate a so-called back propagation wavefield $P_b(\mathbf{x}; \mathbf{x}_s)$
3. Cross-correlation of the original wavefield $P_0(\mathbf{x}; \mathbf{x}_s)$ and the backpropagation wavefield $P_b(\mathbf{x}; \mathbf{x}_s)$ to get the gradient direction $\mathbf{g} = \mathbf{C}_M \hat{\mathbf{g}}$, where $\mathbf{C}_M$ is the model covariance matrix with units of $(\text{model parameter})^2$
4. Estimating the model update $\delta \mathbf{m} = -\alpha \mathbf{g}$, where α is the optimal step length that can be found by using the linear approximation or simply line search for a minimum of the objective function

In a time-domain implementation of waveform inversion, the gradient direction is calculated by

$$\hat{\mathbf{g}}(\mathbf{x}) = \frac{2}{c_0^3(\mathbf{x})} \sum_s \int \left(\frac{\partial}{\partial t} p_0(\mathbf{x}; \mathbf{x}_s) \frac{\partial}{\partial t} p_b(\mathbf{x}; \mathbf{x}_s) \right) dt, \quad (18)$$

where $\partial p_0(\mathbf{x}; \mathbf{x}_s)/\partial t$ denotes the time derivative of the time-domain forward-propagated wavefields and $\partial p_b(\mathbf{x}; \mathbf{x}_s)/\partial t$ is the time derivative of the backprojected residual waveforms in the time domain. Zero-leg correlation of these two wavefields provides us the gradient direction for model updating.

Shot-Encoded Waveform Tomography

Seismic waveform tomography often demonstrates high resolution and high accuracy. However, the computational cost obstructs the wide application of this inversion technology, especially for the inversion of seismic reflection data, which is routinely acquired during exploration geophysics. As described in the previous section, the subsurface model is updated iteratively following the negative direction of the gradient. This gradient vector is the first-order derivative of the objective function with respect to the unknown model parameters and is computed for each shot separately. The gradient vector is formed by cross-correlation between the incident wavefield and the adjoint wavefield, and these two wavefields are simulated for each seismic shot individually. Thus, this process requires a very high operational speed, particularly for practical 3D seismic data with thousands of shots.

In seismology, a shot gather refers to a group of seismic traces recorded by a series of receivers for which the recorded wavefield has originated from a single source. To reduce the number of wavefield simulations in the inversion process, the shot gathers are multiplied by either +1 or -1 randomly and are then stacked into a super-shot gather. Equivalently, the source signatures are multiplied by random codes and are subsequently excited simultaneously to simulate forward wave propagation. For the calculation of the gradient, the residual of the waveform between the shot-encoded synthetic wavefield and the shot-encoded observed wavefield is backward propagated and cross-correlated with the forward wavefield. Note that the cross-correlation will exhibit a cross talk effect between different shots, which can directly deteriorate the quality of tomographic imagery.

For typical shot-encoded waveform tomography, seismic shots are assigned into different super shots. The shots contained within a super shot should be randomly encoded rather than simply superimposed so that the cross talk effect can be offset by the randomness of encoding. The objective

function for the shot-encoded waveform tomography is defined in terms of the weighted wavefields according to the weights in the encoding procedure. Then, the gradient of the objective function consists of both the ordinary gradient (without shot encoding) and an extra term representing the cross talk between different shots. Fortunately, this cross talk effect can be effectively suppressed by increasing the randomness of the shot encoding (Rao and Wang 2017). The quality improvement occurs because the weights w_i used in the encoding procedure are randomly generated values of +1 and -1 and the sum of a large number of $w_i w_j$ (i.e., the multiplication between different encoded shots) in the cross talk term has an expectation of zero.

The inversion algorithm used in the shot-encoded waveform tomography must be stochastic. Because the model update procedure is stochastic, both gradient-based and Newton-type methods used in conventional deterministic inversions must be properly adjusted to fit within a shot-encoded framework. The restarted L-BFGS algorithm described in the next section exploits the features of shot encoding and of the L-BFGS algorithm and uses these features to enhance the computational efficiency and the image quality of waveform tomography by mitigating the cross talk effect.

The Restarted L-BFGS Algorithm

Shot encoding in waveform tomography will induce instability in the inversion regardless of whether it uses a robust limited-memory BFGS (L-BFGS) algorithm. Rao and Wang (2017) proposed a restarted L-BFGS algorithm which is both stable and efficient. This breakthrough ensures the applicability of waveform tomography methods to 3D seismic field data. In a standard L-BFGS algorithm, if the shot encoding remains unchanged, it will generate a cross talk effect between different shots. This cross talk effect can only be suppressed by employing sufficient randomness in the shot encoding. Therefore, the implementation of the L-BFGS algorithm is restarted at every segment. Each segment consists of a number of iterations; the first few iterations use an invariant encoding, while the remainder use random re-coding. This restarted L-BFGS algorithm balances the computational efficiency of shot encoding, the convergence stability of the L-BFGS algorithm, and the inversion quality characteristic of random encoding in waveform tomography.

In waveform tomography, the subsurface model is updated iteratively, and the model update is defined by the gradient according to a precondition of the inverse Hessian matrix in the form of

$$\mathbf{m}_{k+1} = \mathbf{m}_k - \alpha_k \mathbf{B}_k \hat{\mathbf{g}}_k, \quad (19)$$

where k is the iteration number, α_k is the step length, and $\mathbf{B}_k$ is the inverse Hessian matrix. Since it exploits the inverse Hessian matrix, in contrast to Equation (10), this is a quasi-Newton method.

In a BFGS algorithm, the inverse Hessian matrix $\mathbf{B}_k$ is derived recursively from $\mathbf{B}_{k-1}$ using the following relation:

$$\mathbf{B}_k = \left(\mathbf{I} - \frac{\mathbf{z}_{k-1} \mathbf{y}_{k-1}^T}{\mathbf{y}_{k-1}^T \mathbf{z}_{k-1}} \right) \mathbf{B}_{k-1} \left(\mathbf{I} - \frac{\mathbf{y}_{k-1} \mathbf{z}_{k-1}^T}{\mathbf{y}_{k-1}^T \mathbf{z}_{k-1}} \right) + \frac{\mathbf{z}_{k-1} \mathbf{z}_{k-1}^T}{\mathbf{y}_{k-1}^T \mathbf{z}_{k-1}}, \quad (20)$$

where $\mathbf{I}$ is the identity matrix, $\mathbf{y}_{k-1}$ is the difference in the gradient between two consecutive iterations, and $\mathbf{z}_{k-1}$ is the model difference. Because of its recursive nature, $\mathbf{B}_{k-1}$ does not need to be stored, and $\mathbf{B}_k$ can be calculated quickly and adaptively based on the gradient differences $\{\mathbf{y}_{k-1}, \mathbf{y}_{k-2}, \mathbf{y}_{k-3}, \dots\}$ and the model differences $\{\mathbf{z}_{k-1}, \mathbf{z}_{k-2}, \mathbf{z}_{k-3}, \dots\}$ from the previous iterations. Therefore, Equation (20) represents the limited-memory version of the BFGS algorithm (i.e., L-BFGS).

If $\mathbf{y}_{k-1}^T \mathbf{z}_{k-1} > 0$, the inverse Hessian matrix $\mathbf{B}_k$ is positive definite. This is because in the following formula

$$\mathbf{v}^T \mathbf{B}_k \mathbf{v} = \left(\mathbf{v} - \frac{\mathbf{z}_{k-1}^T \mathbf{v}}{\mathbf{z}_{k-1}^T \mathbf{y}_{k-1}} \mathbf{y}_{k-1} \right)^T \mathbf{B}_{k-1} \left(\mathbf{v} - \frac{\mathbf{z}_{k-1}^T \mathbf{v}}{\mathbf{z}_{k-1}^T \mathbf{y}_{k-1}} \mathbf{y}_{k-1} \right) + \frac{(\mathbf{z}_{k-1}^T \mathbf{v})^2}{\mathbf{y}_{k-1}^T \mathbf{z}_{k-1}}, \quad (21)$$

if $\mathbf{B}_{k-1} > 0$, both terms on the right-hand side are nonnegative, while the first term is zero only if $\mathbf{v} = 0$ and the second term is zero only if $\mathbf{z}_{k-1}^T \mathbf{v} = 0$. This positive definite property ensures that the update $-\mathbf{B}_k \hat{\mathbf{g}}_k$ is in a descent direction and consequently the model update during the inversion will converge. If shots are re-coded at each iteration, two gradients $\hat{\mathbf{g}}_k(\mathbf{m}_k, \mathbf{w}_k)$ and $\hat{\mathbf{g}}_{k-1}(\mathbf{m}_{k-1}, \mathbf{w}_{k-1})$ are calculated from the objective functions with different sets of encoding, which are $\mathbf{w}_{k-1}$ and $\mathbf{w}_k$. For the gradient difference

$$\mathbf{y}_{k-1} = \hat{\mathbf{g}}_k - \hat{\mathbf{g}}_{k-1}, \quad (22)$$

even if the step length α_{k-1} is sufficiently small, the condition $\mathbf{y}_{k-1}^T \mathbf{z}_{k-1} > 0$ is difficult to satisfy. Therefore, shot encoding will induce instability and potentially non-convergence during waveform tomography.

The restarted L-BFGS algorithm (Fig. 2) contain the following three distinguishing features:

1. Structurally, the L-BFGS calculation is restarted after every ℓ iterations. The total number of L-BFGS iterations

Seismic, Waveform Modeling and Tomography, Fig. 2 The restarted L-BFGS algorithm. The implementation of the L-BFGS algorithm is restarted after a number of iterations (ℓ). Within the segment between two starts, only the coding of the first few iterations (m) is kept unchanged (yellow) and is the same as the previous one (orange). The shots for the rest of the iterations (gray) are re-coded with a sufficient randomness to suppress cross talk effects. Within a restarted segment, the gradient differential is given by the secant equation $\mathbf{y}_{k-1} = \mathbf{H}_{k-1} \mathbf{z}_{k-1}$ except for the first iteration where $\mathbf{y}_0 = \mathbf{g}_1 - \mathbf{g}_0$. Both $\mathbf{H}_{k-1} \mathbf{z}_{k-1}$ and $\mathbf{B}_k \mathbf{g}_k$ are calculated using the limited-memory formulas

is divided into a series of segments, and each segment consists of ℓ iterations. The recursive L-BFGS calculation is only based on the gradient differences $\mathbf{y}_k$ and model differences $\mathbf{z}_k$ within the individual segment. Therefore, the segment interval ℓ is also referred to as the storage length in the L-BFGS algorithm (i.e., for storing the vectors $\mathbf{y}_k$ and $\mathbf{z}_k$).

2. Within a segment, shot encoding of the first few iterations is kept invariant (yellow) and is the same as the previous iteration (orange). A new reassignment of the weights (either +1 or -1) is triggered for the remainder of the iterations (gray). We denote m as the number of iterations that employ invariant coding. Generally, $2 \leq m < \ell$, which

maximizes the overall randomness of shot encoding to effectively suppress the cross talk effect. Meanwhile, maintaining the weights of coding as invariant for a few of iterations, rather than re-coding at every iteration, will significantly improve the convergence speed and stability during the inversion.

3. For the first iteration, the gradient difference is calculated by $\mathbf{y}_0 = \mathbf{g}_1 - \mathbf{g}_0$. For the rest of the iterations, the gradient difference is calculated based on the following secant equation:

$$\mathbf{y}_{k-1} = \mathbf{H}_{k-1} \mathbf{z}_{k-1}, \quad (23)$$

where $\mathbf{H}_{k-1} = \nabla^2 \phi(\mathbf{m}_{k-1})$ is the Hessian matrix in the $k-1$ -th iteration. Equation (23) represents the gradient differential rather than the gradient difference. Using the gradient differential will improve the accuracy and, in turn, the stability of convergence of waveform tomography.

Note that the secant equation in Equation (23) differs slightly from the conventional secant equation used in the BFGS algorithm. The latter imposes a condition wherein $\mathbf{H}_k$ is close to the current matrix $\mathbf{H}_{k-1}$ and presents the following approximation as the secant equation:

$$\mathbf{y}_{k-1} = \mathbf{H}_k \mathbf{z}_{k-1}. \quad (24)$$

This approximation can be justified because

$$\mathbf{y}_{k-1} \equiv \mathbf{g}_k - \mathbf{g}_{k-1} = \frac{\mathbf{g}_k - \mathbf{g}_{k-1}}{\mathbf{m}_k - \mathbf{m}_{k-1}} (\mathbf{m}_k - \mathbf{m}_{k-1}), \quad (25)$$

wherein the fraction can be treated as either a forward difference or a backward difference, i.e.

$$\frac{\mathbf{g}_k - \mathbf{g}_{k-1}}{\mathbf{m}_k - \mathbf{m}_{k-1}} \approx \mathbf{H}_k \approx \mathbf{H}_{k-1}. \quad (26)$$

However, the approximated secant equation in Equation (24) cannot be used to directly calculate $\mathbf{y}_{k-1}$, as it depends on $\mathbf{H}_k$ and not $\mathbf{H}_{k-1}$. Rao and Wang (2017) suggested use Equation (23) to calculate $\mathbf{y}_{k-1}$.

To calculate the Hessian matrix, we use the DFP (Davidon-Fletcher-Powell) method, which represents the Hessian matrix based on the gradient difference and the model difference as follows:

$$\mathbf{H}_k = \left(\mathbf{I} - \frac{\mathbf{y}_{k-1} \mathbf{z}_{k-1}^T}{\mathbf{y}_{k-1}^T \mathbf{z}_{k-1}} \right) \mathbf{H}_{k-1} \left(\mathbf{I} - \frac{\mathbf{z}_{k-1} \mathbf{y}_{k-1}^T}{\mathbf{y}_{k-1}^T \mathbf{z}_{k-1}} \right) + \frac{\mathbf{y}_{k-1} \mathbf{y}_{k-1}^T}{\mathbf{y}_{k-1}^T \mathbf{z}_{k-1}}. \quad (27)$$

Exploiting its recursive characteristic, we can derive the following formula:

$$\begin{aligned} \mathbf{H}_k &= \mathbf{V}_{k-1}^T \mathbf{V}_{k-2}^T \cdots \mathbf{V}_1^T \mathbf{H}_0 \mathbf{V}_1 \cdots \mathbf{V}_{k-2} \mathbf{V}_{k-1} \\ &+ \rho_1 \mathbf{V}_{k-1}^T \mathbf{V}_{k-2}^T \cdots \mathbf{V}_2^T \mathbf{y}_1 \mathbf{y}_1^T \mathbf{V}_2 \cdots \mathbf{V}_{k-2} \mathbf{V}_{k-1} \\ &\vdots \\ &+ \rho_{k-2} \mathbf{V}_{k-1}^T \mathbf{y}_{k-2} \mathbf{y}_{k-2}^T \mathbf{V}_{k-1} \\ &+ \rho_{k-1} \mathbf{y}_{k-1} \mathbf{y}_{k-1}^T, \end{aligned} \quad (28)$$

where $\rho_k = 1/\mathbf{y}_k^T \mathbf{z}_k$ and $\mathbf{V}_k = (\mathbf{I} - \rho_k \mathbf{z}_k \mathbf{y}_k^T)$. According to the secant equation, where $\mathbf{H}_k \mathbf{z}_k = \mathbf{y}_k$, we define the initial Hessian matrix $\mathbf{H}_0$ as

$$\mathbf{H}_0 = \mathbf{y}_0 \mathbf{y}_0^T [\mathbf{z}_0 \mathbf{y}_0^T]^{-1} \approx \frac{\mathbf{y}_0 \mathbf{y}_0^T}{\mathbf{z}_0^T \mathbf{y}_0} \mathbf{I}. \quad (29)$$

Equation (28) does not need to store matrices and is a limited-memory version of the DFP formula. This equation is similar to the L-BFGS formula, which uses the same recursive form as Equation (28) for the inverse Hessian matrices $\mathbf{B}_k$, for $k = 0, 1, \dots$, and does not need to store these matrices as well. Therefore, in shot-encoded waveform tomography, we use the L-BFGS and DFP algorithms and calculate $\mathbf{B}_k \mathbf{g}_k$ and $\mathbf{H}_k \mathbf{z}_k$ based only on the vectors $\mathbf{y}_k$ and $\mathbf{z}_k$, which are stored within the segment of ℓ iterations.

The computational efficiency of waveform tomography is determined by the actual number of wavefield simulations required. These wavefield simulations include wave back-propagation and step-length calculations for every iteration. Figure 3 shows the number of wavefield simulations required to achieve convergence in a synthetic test, in which a multi-scale inversion method is adopted and seismic data have been divided into four frequency bands: 2–4, 4–6, 6–8, and 8–10 Hz. Therefore, the inversion procedure consists of four stages. The total number of simulations in the restarted L-BFGS algorithm ($<0.25 \times 10^4$, shaded region in Fig. 3) is substantially less than that in the standard L-BFGS algorithm (7×10^4). Therefore, the restarted L-BFGS algorithm fully reflects an accelerated shot-encoding inversion procedure. Compared with waveform tomography without shot encoding, the restarted L-BFGS algorithm significantly reduces computational costs.

As the restarted L-BFGS algorithm can improve image quality by suppressing the cross talk effect and can simultaneously reduce computational costs and storage requirements, shot-encoded waveform tomography is shown to be applicable to cases involving 3D data sets, as demonstrated in Fig. 4. The size of the actual 3D overthrust SEG/EAGE model is $4.65 \times 20 \times 20 \text{ km}^3$. The model is partitioned into $93 \times 401 \times 401$ grids with a cell size of $50 \times 50 \times 50 \text{ m}^3$. The source signature is a Ricker wavelet with a domain frequency of 7 Hz. There are 400 shots spread out over the surface at an interval of $1 \times 1 \text{ km}^2$. Each shot gather consists of 32,761 traces. In the inversion, every 100 shots are assembled into a super shot.

Seismic, Waveform Modeling and Tomography,

Fig. 3 Convergence rates of waveform tomography without shot encoding (purple dashed lines) and of shot-encoded waveform tomography using a restarted L-BFGS algorithm (red solid lines within the shadowed zone). The horizontal axis denotes the number of wavefield simulations, and the vertical axis is the normalized residual. Each line segment corresponds to an inversion of a data set for a particular frequency band

Seismic, Waveform Modeling and Tomography, Fig. 4

(a) Velocity slices at a depth of 1 km. (b) Velocity slices at a depth of 1.5 km. (c) Velocity slices at a depth of 2 km. The left column is the true velocity model, and the right column is the velocity model reconstructed using shot-encoded waveform tomography

The initial model is a Gaussian smoothed version of the true velocity model. For the inversion of each of four frequency bands, 100 iterations are executed, and the restarted L-BFGS algorithm is used with $\ell = 5$ and $m = 2$. Figure 4 displays the resulting velocity slices at different depths to compare the true velocity model and the reconstructed velocity model. At depths of 1.0 and 1.5 km, the morphology of an ancient channel is clearly reconstructed. At a depth of 2 km, the main body of the channel can also be inverted, although there is limited wave coverage.

Preprocessing for Field Data Waveform Tomography

Let us demonstrate the application of waveform tomography to a real, marine seismic data set (Fig. 5). This example profile shows the structure along the section. However, the input to waveform tomography is shot records which should be subject to some necessary processing, such as multiple attenuation and transformation of the original point sources to equivalent line sources, before they are used in tomography.

Figure 6a is a sample shot record, consisting of 120 traces with a minimum source-receiver offset of 337.5 m and a maximum source-receiver offset of 1825 m. We investigate the feasibility of reflection seismic tomography within such a narrow source-receiver offset range.

Waveform tomography usually does not include free-surface multiples. Otherwise including seismic multiples bouncing back and forwards within the water layer in the tomographic inversion will increase the nonlinearity of the problem. As the number of multiples increases, the errors in model (and in turn in synthetics) will also increase. We use a narrow-offset shot record in multiple attenuation, also to

avoid the wide-angle refraction of the water bottom and their multiples, as the current methodology for free-surface multiple prediction cannot properly model the refraction multiples. As marked in Fig. 6a, the most difficult part of multiple attenuation is where the refraction wave just starts appearing. Figure 6b displays a shot record and the one after free-surface multiple attenuation, using a multiple prediction through inversion (MPI) method (Wang 2004, 2007). The real shot record is generated by a point source, but Fig. 6c is an equivalent line-source shot gather, after partial compensation.

Before input to waveform tomography, a shot record of real seismic data needs to be partially compensated, to become a gather generated from a line source. The 2D Green's function is

$$G_{2D}(\mathbf{r}, \mathbf{r}_s, \omega) = \left(\frac{c}{i 8 \pi \omega R} \right)^{1/2} \exp \left(-i \omega \frac{R}{c} \right), \quad (30)$$

where $R = |\mathbf{r} - \mathbf{r}_s|$ is the distance from the source and c is the acoustic velocity of the media. For a 3D case, Green's function is

$$G_{3D}(\mathbf{r}, \mathbf{r}_s, \omega) = \frac{1}{4 \pi R} \exp \left(-i \omega \frac{R}{c} \right). \quad (31)$$

Comparing the 2D and 3D, Green's functions produces a partial compensation operator as

$$W = \sqrt{\frac{2 \pi R c}{i \omega}}. \quad (32)$$

In the time domain, the operator W shows the following behavior (in the far-field)

Seismic, Waveform Modeling and Tomography, Fig. 5 An example profile of marine seismic data which shows the structure along a section. However, the input to waveform tomography is shot records which should be subject to some necessary processing

Seismic, Waveform Modeling and Tomography, Fig. 6 A marine seismic data example. (a) A sample shot record with 120 traces. (b) The shot record after multiple attenuation. (c) The same shot record after partial compensation

$$W(t) = D_{-1/2}(t)\sqrt{2\pi Rc}, \quad (33)$$

where $D_{-1/2}(t)$ is a half integrator, defined as the inverse Fourier transform of $(i\omega)^{-1/2}$ (Deregowski and Brown 1983). For a narrow-offset, reflection geometry, one can assume $2R \propto ct$ and obtain

$$W(t) \propto D_{-1/2}(t) c(t)\sqrt{t}. \quad (34)$$

Therefore, this partial compensation may be implemented in two steps: scaling $c(t)\sqrt{t}$ in the time domain and multiplication $(i\omega)^{-1/2}$ in the frequency domain.

Figure 7 closely compares a seismic trace from a point source (solid curve) and a trace after partial compensation (dash curve). With the application of the operator $(i\omega)^{-1/2}$, wavelets in the trace from an equivalent line source are broader than those actually generated from a point source.

Alternatively, one could use a 2.5D wave modeling and inversion scheme for waveform tomography. But as it involves integration along the infinite line-source direction that is perpendicular to the source-receiver profile, a 2.5D scheme would take a much longer running time, compared to the 2D wave modeling and inversion.

The frequency ω can also be complex-valued, to include an exponential function either for the amplitude attenuation or compensation. The attenuation used in wavefield $P(t)$ is for suppressing the wraparound effect in the Fourier transform domain. An opposite sign with an exponential increase in $P(t)$ could also be used to boost the energy of deep reflections. In the latter case, the real data should be balanced with an automatic gain control.

Seismic, Waveform Modeling and Tomography, Fig. 7 (a) Comparison between a seismic trace from a point source (solid) and the trace after partial compensation (dash curve). Wavelets in a trace from a line source (i.e., after partial compensation) are broader than those from a point source. (b) Comparison of amplitude spectra of seismic traces from a point source and a line source

Seismic Reflection Waveform Tomography

In the seismic reflection data, there is no significant energy recorded at low frequencies less than 6 Hz. A travel time inversion is often performed to generate the initial velocity model for the iterative waveform tomography. Referring to

Seismic, Waveform Modeling and Tomography,

Fig. 8 Waveform tomography. (a) The initial velocity model built from travel time tomography. (b) The velocity model of waveform tomography using frequencies in the range of 6.9–7.5 Hz. (c) The velocity model of waveform tomography using frequencies in the range of 6.9–13.8 Hz. (d) The final velocity model obtained from the waveform tomography using all frequencies in the range of 6.9–30 Hz

the stack section (Fig. 5), we pick the travel times of two reflections from the pre-stack seismic data and run a travel time inversion to generate a layered velocity model with two interfaces (Fig. 8a). The first layer is a water layer with

velocity 1500 m/s. The second layer has a linear velocity of 2200 m/s at one end and 2000 m/s at distance 23 km.

In the frequency-domain waveform tomography, we use a group of three frequencies simultaneously in each iterative

inversion. Using a group of neighboring frequencies in the input can suppress the noise effect in the real data, and also more data samples used in an inversion means a much better determined inverse problem. In this example, there are 26 groups of frequencies in total in the range of 6.9–30 Hz with an interval of 0.3 Hz. The first group includes frequencies 6.9, 7.2, and 7.5 Hz and the last 29.4, 29.7, and 30 Hz. Figure 8b, c are the velocity models from waveform tomography using frequencies in ranges of 6.9–7.5 Hz and 6.9–13.8 Hz, respectively, where Fig. 8d is the final velocity model obtained from waveform tomography using all frequencies in the range.

Although the starting model generated by travel time tomography generates a smooth boundary for the water bottom, waveform tomography produces a sharp geometry with a spatial variation close to that shown in the seismic section (Fig. 5). The tomography image shows clearly a stratified structure underneath the water layer. In the second layer, at the distance between 0 and 10 km, there is a high-low-high vertical velocity variation immediately underneath the water bottom, between depth of 350 and 700 m at the left end of the profile, and a high-low-high-low vertical variation above the second interface. At the distance between 17 and 23 km, there is also a low-high-low vertical velocity variation within the second layer.

Most significantly, in the third layer, high-low-high velocity channels appear immediately underneath the second interface and cross the entire section. This thin-layer separation could not be generated by any conventional travel time tomography. Beneath that, the velocity pattern in the depth between 1.2 and 1.6 km varies laterally between 0–5, 5–17, and 17–23 km in distance.

Seismic reflection is generated due to the contrast in impedance which is the product of density and velocity. In the inversion example here, however, the density is assumed to be constant. Therefore, for a more accurate quantitative interpretation of the high velocity variation within the top-most thin layer immediately underneath the water layer, a density contrast between the water and water bottom sediment needs to be compensated.

Figure 9 compares a sample frequency slice (at 9.3 Hz) of real data input to waveform tomography and synthetic data generated from the inversion result. The vertical axis is the shot position in the surface, and the horizontal axis is the source-receiver offset. The data displayed are the amplitudes of complex-valued samples in the frequency domain and are normalized based on their RMS values. For the far-offset seismic traces, there are strong amplitudes for post-critical angle reflections, which play an important role in the

Seismic, Waveform Modeling and Tomography, Fig. 9

(a) A sample amplitude slice of real seismic data at frequency 9.3 Hz. (b) The amplitude slice of synthetics at the same frequency, obtained from the waveform tomography result

inversion for the shallow part of model. There is also a good fit at near-offset traces, which influence the high wavenumber perturbations of the velocity field.

Summary

Waveform tomography uses the original waveform recordings and wave equation modeling to extract high-resolution tomographic images from seismic data. Waveform tomography uses a group of frequencies simultaneously in an iterative inversion and proceeds from low to high frequencies. For seismic data with multiple sources, shot encoding which encodes all shots randomly and sums them into one super shot is an effective strategy to reduce the computational cost significantly by reducing the number of wavefield simulations in the inversion. However, this process will induce instability in the iterative inversion regardless of whether it uses a robust L-BFGS algorithm. The restarted L-BFGS algorithm is both stable and efficient. Even for seismic reflection data with limited source-receiver offsets, the waveform tomography also can potentially image subsurface features with detailed spatial variation at sub-wavelength scales.

Seismicity, Intraplate

Paul Bodin

Pacific Northwest Seismic Network (PNSN), University of Washington, Seattle, WA, USA

Definition

Intraplate Seismicity refers to earthquakes that take place on faults other than those that form the boundaries between Earth's tectonic plates.

Historical Context

From the inception of plate tectonics as a simple set of unifying concepts, Earth scientists recognized that the notion of completely rigid plates should not be taken to be rigorous or complete. Deformations of Earth's crust and upper mantle, and the earthquakes that generally accompany them, must take place off of recognized plate interfaces. This fact was evident theoretically because in order for plate tectonics to operate on timescales greater than one Wilson cycle, new plate boundaries must form within plates, so deformation must take place off of existing plate boundaries. In addition, it was unassailable observationally because seismicity off of recognized plate boundaries clearly *does* take place, albeit at a relatively trivial pace compared to Earth's total earthquake production.

Two generations later, despite the fact that they obviously exist, intraplate earthquakes remain enigmatic and challenging; fitting subjects for special study. The dominant questions about these earthquakes not only reveals our incomplete understanding of earthquake physics in general, but also highlights a number of issues specific to active tectonics and seismic hazard in intraplate settings.

Definitions and Classification

We may define interplate earthquakes as being those that rupture parts of faults that connect directly mechanically to the globe-girdling system of recognized boundaries between tectonic plates. Intraplate earthquakes break faults that do not so connect. The difference is one of ultimate slip. Because interplate faults form a network within which new plates may be created and old plates consumed, slip on them is unbounded. On the other hand, the total slip on intraplate faults must terminate at the ends of the fault. So increasing slip comes at the cost of increasing strain in the surrounding rocks which, itself being presumably limited, caps how much any given fault can slip. Therefore, intraplate faults may be expected to slip generally more slowly, and less far, than interplate faults, and this possibly to have some consequence on the characteristics of earthquakes on the two types of faults.

It is customary for Earth scientists to distinguish further between intraplate earthquakes that break faults within *mobile zones* and those that take place within *stable zones*. Mobile zones are regions that, although not directly on recognized plate boundary fault, have been experiencing regional deformation distributed over a broad area near a plate boundary. An example is the active faulting across China, Tibet, and Mongolia, the deformations of which may be clearly related to three-dimensional complexities in the plate boundary framework. Stable zones are not only sufficiently remote from plate boundaries to be insensitive to their geometric complexities, but also are stable in the sense that significant tectonic events

have not affected them during the Cenozoic Era (~66 million years). They are generally expected to be areas of cold, thick continental lithosphere. Earthquakes in stable continental regions, often designated SCR earthquakes, are particularly enigmatic.

Reasons to Distinguish Intraplate Earthquakes

One reason to study intraplate earthquakes (and particularly SCR earthquakes) as a class involves a practical consequence: they strike the most unwary victims. Because of the long recurrence intervals between intraplate earthquakes, the threatened populace is generally unprepared and the structures they build are particularly vulnerable. It has recently been noted that this argument is becoming less restrictive to intraplate earthquakes as population growth within plate boundary regions has taken place so quickly of late that even these regions are becoming less prepared as a whole (Bilham 2009). Nevertheless, the argument remains applicable in plate interiors where the building stock may be not only not up to modern seismic codes, but is generally older.

In part, SCR earthquakes remain especially enigmatic not merely because they are rare, but also because their recurrence may be so long that (1) the sizes and sometimes locations of previous earthquakes are not well known, even for those that have occurred in historical times, and (2) it is usually not possible to ascertain what their recurrence is with certainty. This leads to great uncertainty about the seismic hazards in intraplate regions. Is damaging earthquake shaking possible anywhere (albeit with small probability within any 50-year time period)? Or are even SCR earthquakes restricted to occur in places with discernible (and hence predictable) characteristics? This is tantamount to a question of whether the entirety of Earth's crust at critical stress levels such that only small fluctuations or differences in fault strength control the occurrence of earthquakes.

With such long recurrence intervals, seismological observations are sparse and we rely on the paleoseismic evidence contained within the geological record to try to understand them. It is clear that plate tectonics is accurate to first order and that intraplate deformation takes place very slowly, which makes them a challenge for even modern high-precision geodetic techniques. It seems likely that progress in understanding intraplate earthquakes will remain slow for the time being.

Another reason they are of special interest is that they may reveal clues about elusive earthquake physics. While Earth scientists believe that nearly all tectonic earthquakes are caused by sudden slip on a fault driven by stresses in the surrounding rock (the elastic rebound theory), the specific mechanisms that localize rupture initiation and growth of a rupture remain obscure. Systematic differences between fault,

stress, and geological characteristics of intraplate faults discussed below may be exploited to test hypotheses of the important controls of earthquake fault rupture.

Do Intraplate and Interplate Earthquakes Scale Differently?

Because intraplate earthquakes, and particularly those in stable zones, have longer recurrence intervals, it is often hypothesized that their host faults will have longer time to “heal” between earthquakes (e.g., Scholz 2002). Fault healing here refers to a set of hypothesized fault processes such as the formation of minerals that bind the sides of the fault together making them stronger over time. Thus, intraplate earthquakes may be expected to break under higher loads – at higher stress levels – than their cousins that break more active plate boundary faults. The anticipated result is that they “scale” differently: that is, big earthquakes differ from small earthquakes in systematically different ways in interplate as opposed to intraplate regions. Specifically, intraplate earthquake ruptures will slip more in an earthquake per unit of fault area, relieve more stress (have a larger “stress drop”) and produce more seismic energy for their size, than the earthquakes we are more familiar with at plate boundaries. Thus seismologists expect, and arguably observe, that intraplate earthquakes tend to have higher stress drops than interplate earthquakes. Seismological evidence suggests that as a class their stress drops may be a factor of 2–5 higher than plate boundary earthquakes (Kanamori and Allen 1986). But because observations are so few, much uncertainty remains about this issue.

Source scaling studies are further hindered by systematic differences between seismic wave propagation in intraplate regions and that in more mobile or active zones. Because rock surrounding plate boundaries is often less intact and hotter than in plate interiors, seismic wave energy is more strongly absorbed, or attenuated, than in the cold hard hearts of plates. So, per unit of energy released at their source, the effects of intraplate earthquakes are more widely distributed – they have a longer reach.

What Drives Intraplate Earthquakes?

Probably the most critical enigma of intraplate seismicity concerns the source of driving stresses. It is easy to invoke “left over” or residual stresses originating from geometric irregularities or variations in frictional properties on the master plate boundary faults to explain the origin of mobile zone intraplate earthquakes. Remote from plate boundaries, occasionally sources of localized stresses may be recognized. One clear example is from intraplate regions experiencing uplift from glacial rebound, as ice sheets retreat with global

warming. This mechanism well explains the seismicity pattern of Sweden, for example (e.g., Möner 2009). Swarms of seismicity often accompany geothermal activity, even at sites in the remote interior of tectonic plates (e.g., Ibs-von Seht et al. 2008). Where such sources of localized stress are not evident, however, it is more problematic to assign the provenance of seismic stress. Modeling studies suggest that stresses within plates may be best explained as a combination of resolved stresses originating at plate boundaries (although they may be thousands of kilometers distant) plate bending due to a plate’s travel over a non-spherical Earth, or forces arising from convective patterns in Earth’s mantle.

Many scientists presume that intraplate earthquakes take place at sites where crustal rocks have been significantly weakened compared to those in surrounding rocks. In this model, seismicity should be associated with reactivated fault zones. Big intraplate earthquakes are thought to be restricted to areas that have previously been faulted, say within failed continental rift systems (e.g., Johnson 1996).

One intriguing idea is that the strength of faults could be reduced by high pore-fluid pressure. Fluids (which could include water or even carbon dioxide or hydrocarbons) that occupied the internal portion of a fault could become pressurized and reduce the frictional resistance of the fault to slipping. That would imply that seismically active faults in intraplate regions are those that contain significant quantities of fluids at high confining stress. Sufficient stress to drive earthquakes could indeed be present everywhere within plate interiors, and the conditions to release the stress controlled by something external.

Examples

The moment magnitude (M_w) = 6.8 “Nisqually” earthquake of January 23, 2001 in Washington state, USA, provides an example of an intraplate earthquakes breaking a fault within the crust of the subducting ocean plate (Ichinose et al. 2006). The earthquake resulted from slip on a normal fault driven by bending stresses as the downgoing slab flexes in its descent. On a larger scale, the Cascadia subduction zone provides an interesting example of the interplay between inter- and intraplate earthquakes in that while the master plate boundary megathrust fault is broken about every 500 years with large subduction thrust events (e.g., Satake and Atwater 2007), there appears to be no current seismicity on the plate boundary fault. Rather all earthquakes either historical or instrumentally recorded are either intra-slab events or crustal earthquakes within the overriding North America plate. These events are interplate by our definition. However, they are clearly associated with a nearby subduction interface and are driven by residual stresses that the plate boundary is unable to completely relieve.

The May 13, 2008 $M_w = 7.9$ Wenchuan earthquake in the Szechuan Province of China is an earthquake in the tectonically mobile zone of Asia, and is part of the escape of material from Asia and the uplifting of the Himalaya due to the collision of the Indian subcontinent with Asia. About 300 km of a fault on the boundary between the Longmenshan orogenic belt and the Szechuan basin broke in the earthquake (Burchfiel et al. 2008). With a high overall stress drop of 17 MPa and localized patches of up to 53 MPa (Zhang et al. 2009), the Wenchuan earthquake had large slip and disastrous effects on a populace that was largely unaware of the potential for, and unprepared for, this long-recurrence-interval (2,000–10,000 years) intraplate earthquake.

The January 26, 2001 $M_w = 7.6$ Bhuj earthquake took place ~400 km from the rather diffuse onshore portion of the left-lateral strike-slip Makran boundary between India and the Arabian and Eurasian plates, but within the western part of the peninsular Indian shield. It broke the deeper part (~5 to ~40 km) of a previously unknown reverse fault. It was located within ~100 km of a similar-sized (though shallower) earthquake in 1835 that generated a surface rupture – the Allah Bundh in the Great Rann of Kachchh. The stress drop was a high, but not extreme ~16–20 MPa, but the earthquake was very powerful, with the source lasting only about 7 s. Widespread liquefaction and secondary effects were observed, but the large death toll (~30,000) was apparently not the result of extreme ground motions, which could have been engineered for, but rather of poor construction and preparation.

Controversy

One particularly illustrative and significant example of SCR interplate seismicity concerns the New Madrid Seismic Zone that threatens a 7-state region surrounding the lower Mississippi River valley in the south central USA (e.g., Johnson and Schweig 1996). The region was the site of at least three major earthquakes during the winter of 1811–1812. While at the time thinly populated and rural, a return of these earthquakes today would affect ten million people and put at risk numerous cities, commerce, and transportation and communication infrastructure. The 1811–1812 earthquakes were accompanied by a host of surface effects (liquefaction, landslides, surface deformation) that remain visible in the landscape today. Ground motions from the earthquakes were also reported to be felt as far away as Charleston, South Carolina (~950 km) and even Boston, Massachusetts (~1600 km). There is a complex zone of active microearthquakes producing several $M < 3$ earthquakes each week. Early research based on ground-shaking intensities derived from historical reports proposed that the three largest earthquakes in the series exceeded M_8 . The ~100-km long zone of active microseismicity, which many presume to represent the active faults,

seems much too small to host even a single M_8 earthquake, let alone three, unless stress drops, and therefore slip per unit length, were extremely large. The earthquakes occupy a shallow basin formed atop a failed continental rift, formed in latest Precambrian time and briefly reactivated (but once again failed) in the Cretaceous. The faults are oriented such that they are nearly optimally oriented to be reactivated as thrust and strike-slip fault in the current compressional mid-plate stress regime.

Subsequent reexamination of the historic intensity data, and taking into account the feeble attenuation of seismic waves within rocks in the plate interior, have yielded generally smaller estimates of magnitudes, as low as M_7 for the three largest 1811–1812 earthquakes. In the absence of new information, however, it might be best to admit that while these earthquakes were undoubtedly large, their magnitudes will remain forever moot. Paleoseismic studies of earthquake-induced liquefaction features in surface deposits reveal at least four repeated episodes of strong shaking (as strong as what took place in the early nineteenth century), often in clusters like the 1811–1812 events, with an average recurrence interval of ~500 years. The geological evidence for recurrent large earthquakes is balanced by the lack of primary surface faulting, or even the prominent topographic relief one would expect if much slip had taken place at the rates paleoseismic evidence infers for the past several thousand years. So either the big events are really a good deal smaller than the largest estimates of their size or seismic activity in the zone was initiated only a few thousand years ago.

Geodetic evidence, from repeated campaign surveys and continuous GPS studies show that deformation surrounding the active seismic zone (Smalley et al. 2005) is very slow, with some (e.g., Newman et al. 1999) arguing that it is not different from zero. However, given the lack of a mid-plate fault model it is not clear what deformation pattern one should expect. So there is no general agreement about what the lack of observed active deformation means, and the interpretations remain contentious. Some suggest that either the largest earthquakes to be expected from the seismic zone are not so terrifyingly large as previously thought, or perhaps that, however large they were, they are not being recharged with stress and are not to be feared. Others hold that the paleoseismic, historical, and microseismic evidence point to the likelihood of future damaging earthquakes just like the historical ones, albeit driven by processes that are still beyond our ken.

Summary or Conclusions

Intraplate seismicity is a catchall phrase that encompasses a wide variety of seismogenic phenomena; essentially all earthquakes that do not occur on plate bounding faults. Locales

hosting intraplate earthquakes range from broad deformation zones that surround some plate boundaries to areas that lie within the cores of continents. Larger earthquakes – especially those in what are otherwise tectonically stable cold continental crust – appear to be associated with faults that formed in an earlier tectonic setting but are reactivated by the stress field applied currently. Not all faults are so reactivated, so it is likely that some as-yet-unclear weakening mechanism causes only certain faults to fail. Localized deformation, say glacial rebound or geothermal stresses can be responsible for interplate earthquakes, but does not explain all of them. As a class of faults, intraplate faults usually slip more slowly and less far than interplate faults, and this leads to longer intraplate earthquake recurrence intervals. Also, and probably related to this, intraplate earthquakes may generally be expected to have larger stress drops. Although less frequent than plate boundary earthquakes, intraplate seismicity is very dangerous because the population and infrastructure at risk from them is less prepared than in more seismically active areas. The study of intraplate seismicity is an endeavor that, because of its low rate is best done by integrating across different source regions and combining different Earth science disciplines.

RCPEV, Graduate School of Science, Tohoku University, Sendai, Japan

Definition

- | | |
|------------------------|---|
| Subduction zone | Consuming plate boundary where the oceanic plate subducts into the mantle beneath the continental plate. |
| Interplate earthquakes | Earthquakes that occur along the plate boundary. In case of the subduction zone, they occur at the shallow portion of the boundary between the subducting plate and the overriding plate. |
| Intraslab earthquakes | Earthquakes that occur within the subducted plate, that is, within the slab. |
| Shallow earthquakes | Earthquakes that occur at depths shallower than 60 km. Focal depths of interplate earthquakes in subduction zones are usually shallower than 60 km, and so they are shallow earthquakes. |
| | Earthquakes that occur at depths of 60–300 km. |

Intermediate-depth earthquakes

Deep earthquakes Earthquakes that occur at depths deeper than 300 km. Both intermediate-depth and deep earthquakes occur only within the subducted plate, and so they are intraslab earthquakes.

Introduction

There are seismically active and inactive areas on the Earth. Most of Earth's seismic activity is concentrated in narrow continuous belts that wrap around it. Plate tectonics proposes that the Earth's entire surface is comprised of somewhat more than ten large, rigid, mosaic-like plates, and that the relative movement of these plates causes tectonic activity at their boundaries. Consequently, most earthquakes are concentrated at plate boundaries, forming narrow, belt-shaped seismic zones.

Oceanic plates are generated at mid-ocean ridges by the upwelling of mantle material. Since the Earth's surface area is constant, the surface area does not expand with the generation of the oceanic plate. Instead, the same amount of material moves back down into the mantle. The generation of plates is balanced by the consumption of other plates elsewhere at consuming plate boundaries. Subduction zones are where oceanic plates plunge downward into the mantle. At subduction zones, two plates collide with each other; the heavier plate is overridden by the lighter one and sinks down into the mantle. Thus, the heavier oceanic plate subducts beneath the lighter continental plate. The subduction of the oceanic plate causes high seismic activity. In fact, it is in these subduction zones that most of the world's large earthquakes occur.

Mainly four types of earthquakes take place in subduction zones. The first type is interplate earthquakes that occur along the interface between the subducting oceanic plate and the continental plate (A in Fig. 1). The second type of events occur in the trench-outer rise region of the subducting plate (B in Fig. 1). The third is shallow inland earthquakes that occur in the shallow portion of the overriding continental plate (C in Fig. 1). The last is intraslab earthquakes that occur at depths more than about 60 km within the subducted oceanic plate (D in Fig. 1).

Interplate Earthquakes

In subduction zones, the denser oceanic plate sinks down into the mantle underneath the lighter continental plate. The shallow portion of the plate boundary is locked by friction, and in order to release accumulated stress, occasional slips at the plate boundary occur and cause earthquakes (A in Fig. 1). Most of the world's large, shallow earthquakes are interplate

earthquakes caused in this way. Interplate coupling occurs only within a specific range of depths, which seems to be primarily determined by the temperature of the plate interface.

Oleskevich et al. (1999) estimated the thermal structures of plate interfaces in several subduction zones, and compared them with the updip and downdip depth limits of source areas of large interplate earthquakes. The results show: (1) the updip limit of the depth of interplate earthquakes corresponds with the depth at which the temperature of the plate boundary reaches 100–150 °C and (2) the downdip limit approximately matches the depth at which the temperature reaches 350 °C (Fig. 2). In the shallowest part of plate interfaces, smectite clays, which are clay minerals distributed in the sediments there, prevent interplate coupling by producing stable sliding. The temperature rises with increasing depth, and when it reaches 100–150 °C, dehydration decomposition occurs and the smectite clay turns into illite and chlorite. This transformation is considered the onset of interplate coupling.

Then, deeper, where the temperature exceeds 350 °C, interplate coupling ceases and stable sliding takes place again. Figure 2 shows that the transition zone from unstable sliding to stable sliding occurs at depths where the temperature ranges from 350 °C to 450 °C. In the case where the depth at which the temperature of the plate interface reaches 350 °C is deeper than the depth at which it contacts the Moho of the upper plate, the contact zone with the Moho is considered to be the downdip limit. The reason the downdip is limited to the Moho contact zone is that stable sliding prevails where the mantle of the upper plate contacts the oceanic plate because the mantle may be serpentinized by water supplied by the dehydration of the subducting oceanic plate. It is considered that interplate earthquakes do not occur any more under those conditions (Hyndman et al. 1995). In some subduction zones, such as in northeast Japan, the upper plate's mantle is not serpentinized, since the seismic wave velocities there show normal values of non-serpentinized mantle materials. In such cases, the downdip limit is once again determined by the plate interface temperature of ~350 °C.

The degree of interplate coupling can be indicated by how much interplate slip is accounted for by earthquakes. This index is called "seismic coupling" and denotes the percentage of the seismic slip among all slip amounts occurring at the "seismogenic zone" in Fig. 2. If seismic coupling is 1, all slip occurring in that area is caused by earthquakes. In contrast, if it is 0, it means that all slip occurring in that area is aseismic stable sliding. Seismic coupling differs from one subduction zone to another.

Interplate coupling along the seismogenic zone is heterogeneous both in space and time; the seismogenic zone is not fully locked, as mentioned above, and some portions of it will slide stably during interseismic periods. Seismic waveform inversions of large interplate earthquakes have revealed spatially heterogeneous seismic slip along the seismogenic zone,

Seismicity, Subduction Zone,

Fig. 1 Schematic illustration of subduction zone seismicity. Earthquakes are shown by open circles on a cross-arc vertical cross section of a typical subduction zone. Arrows attached to open circles indicate dominant focal mechanisms; two parallel arrows in opposite directions show seismic slip along the plate interface, two arrows pointing outward show normal faulting and those pointing inward thrust faulting. Low-velocity zones in the crust and the mantle wedge of the upper plate and in the uppermost portion of the subducting plate are shown by shaded areas

**Seismicity, Subduction Zone,**

Fig. 2 Sketch of the subduction plate boundary seismogenic zone. (Oleskevich et al. 1999, copyright by the American Geophysical Union)

and backslip inversions of geodetic data, which estimate spatial distribution of interplate coupling, have confirmed spatially heterogeneous strain accumulation along the zone during the interseismic period. A conceptual model of frictional properties on the fault surface based on laboratory-derived fault constitutive laws (Fig. 3) explains the observed heterogeneous interplate coupling along the seismogenic zone. It involves patches of frictionally unstable fault surface surrounded by stable and conditionally stable fault surfaces. Frictionally stable portions of the fault are subject to steady aseismic sliding, whereas frictionally unstable patches (asperities) remain locked during the interseismic period. Then they finally fail, as evidenced by the occurrence of

earthquakes. Conditionally stable portions typically slide stably, but may fail and slide dynamically if loaded at high strain rates by the seismic slip of a neighboring asperity. Earthquakes nucleate only in the unstable patches, and once an earthquake occurs in an unstable patch, its seismic slip propagates throughout the patch, with some penetration into the neighboring conditionally stable areas. This conceptual model indicates that the larger the area occupied by the frictionally unstable patches in the seismogenic zone, the larger the seismic coupling of that subduction zone is.

A comparative study of the recent three great mega-thrust earthquakes, 2004 Sumatra-Andaman (Mw 9.2), 2010 Chile (Mw 8.8), and 2011 Tohoku (Mw 9.0), showed systematically

Seismicity, Subduction Zone, Fig. 3 A conceptual model of frictional properties on the subduction plate boundary. (Originally from Bilek and Lay (2002) and modified by Dixon and Moore (2007), copyright by the Columbia University Press)

varying rupture properties with depth on the plate interface (Lay et al. 2012). At very shallow depths shallower than ~15 km, sediments and high pore pressure cause slow rupture expansion as tsunami earthquakes. At shallow depths from ~15 to ~35 km, large and relatively uniform frictionally unstable patches are distributed, and they generate large earthquake slip but modest amount of short-period seismic radiations upon failure. At ~35 to ~55 km depths, smaller isolated unstable patches are distributed, and these areas are surrounded by conditionally stable areas. When these areas fail, coherent short-period radiations are produced which brings local strong ground motions. Deeper than that, only stable aseismic sliding occurs. However, the cause is not known so far why such a systematic variation of rupture properties with depth is commonly found. Further studies are needed to understand it.

Trench-Outer Rise Intraplate Earthquakes

The oceanic plate is bent downward as it sinks from the trench into the interior of the Earth. In order to release the stress caused by this bending deformation, earthquakes occur in the shallow portion of the subducting oceanic plate (B in Fig. 1). They are called trench-outer rise earthquakes because they occur in the outer rise region seaward of the trench which is a topography high formed with the bending deformation of the oceanic plate.

In the northeast Japan subduction zone, the trench-outer rise earthquakes form two parallel upper and lower planes separated by 25–30 km from each other (Gamage et al. 2009). Earthquakes in the upper plane have normal-fault type focal mechanism, while those in the lower plane show reverse-fault focal mechanism. This is opposite to the direction of the stress

field of the double seismic zone at depths of 70–150 km within the subducted plate (see section “[Intermediate-Depth Earthquakes](#)”). Such formation of the two parallel seismic planes in the outer rise region can be understood if we take finite depth of brittle layer of the oceanic plate into consideration. Since temperature increases with depth, only the upper half of the oceanic plate has brittle properties and the remaining lower half exhibits ductile properties. Therefore, associated with the downward bending deformation of the oceanic plate, a tensile stress is applied at the upper end of the brittle upper half of the plate and a compressive stress at its lower end. This causes the formation of the two parallel seismic planes; one at the upper end of the brittle upper half of the plate with normal-fault focal mechanism (upper plane) and the other at the lower end with reverse-fault mechanism (lower plane).

Shallow normal-fault type earthquakes, that is, upper plane events, are found to occur in outer rise regions of many other subduction zones. In addition, as in the northeast Japan subduction zone, lower plane events with reverse-fault mechanism have been also found in several subduction zones. Seno and Yamanaka (1996) pointed out that, in such subduction zones, intermediate-depth earthquakes form a double seismic zone in a subducted oceanic plate, suggesting a causative relationship between the two parallel shallow seismic planes in the outer rise region before the plate subduction and the double seismic zone of intermediate-depth events after the subduction.

Shallow Inland Intraplate Earthquakes

Convergence of two plates at subduction zones causes stress accumulation also in the overriding continental plate,

producing deformation in it well beyond the trench axis. Usually, this deformation is compressional crustal shortening, which partially accommodates the plate convergence. Shallow earthquakes occur in the crust of the overriding plate (C in Fig. 1), reflecting this ongoing compression. Focal mechanisms of these earthquakes are thrust fault or strike-slip fault with compressional axis oriented nearly in the plate convergence direction. Recurrence intervals of these types of earthquakes are much longer than those of interplate thrust earthquakes. However, once they occur, it often causes serious damages in lives and societies due to the shallow hypocenter and proximity to inhabited areas.

In most cases, these shallow inland earthquakes occur in the depth range between 1–3 and 10–20 km, forming the seismogenic zone mainly in the upper crust of the overriding plate. Deformation is made by aseismic ductile flow at shallow depths above the upper bound because of the presence of unconsolidated granular material, and at large depths below the lower bound because of the onset of plasticity at a critical temperature (Scholz 1998). This critical temperature is considered to be about 300–400 °C, and so the lower bound of the seismogenic zone varies depending on the local thermal gradient. Active faults, which are surface traces of repeated fault movements by earthquakes, show locations where in the seismogenic zone of the overriding plate large shallow earthquakes have occurred in the recent past, the Quaternary Period. Surveys of active faults further provide information on history of earthquakes, including their magnitudes and the time of the last event, which is basic and important for long-term earthquake forecast of shallow inland intraplate earthquakes.

Although we can learn from active faults where large earthquakes have occurred, it is difficult to understand why earthquakes occur in those locations. Recent investigations based on dense GPS and seismic observation network data in Japan have provided some information on this problem. Analyses of GPS data showed the existence of belt-like zones with concentrated crustal shortening in the overriding plate, along which many large shallow earthquakes have occurred or active faults are distributed (Sagiya et al. 2000; Miura et al. 2004). Seismic tomography studies revealed prominent low seismic velocity zones in the lower crust to the uppermost mantle right beneath these concentrated deformation zones (Nakajima et al. 2001; Nakajima and Hasegawa 2007). The low seismic velocities are inferred to reflect the existence of aqueous fluids, which are perhaps supplied from the subducted slabs. These observations suggest that the fluids weaken the surrounding crustal materials and cause the concentrated deformation there, leading to large shallow inland earthquakes (Iio et al. 2004; Hasegawa et al. 2005). Increase in pore fluid pressure along the fault planes should contribute to the occurrence of these shallow inland earthquakes by decreasing the fault strength (Sibson 2009). If this is the

case, places to which aqueous fluids are supplied intensively from the mantle wedge below are considered to be locations where large shallow earthquakes occur.

Intraslab Earthquakes

Earthquakes that occur at depths of more than about 60 km are found only in subduction zones. That is because these earthquakes occur in subducting oceanic plates or slabs (D in Fig. 1). They are distributed in an inclined plane in the mantle, which is called “deep seismic zone” or “Wadati–Benioff zone,” after its discoverers. The frequency distribution of earthquakes for each depth range throughout the world (Fig. 4) shows that depths from 0 to 50–60 km have the greatest occurrence frequency. Proceeding deeper, the frequency decreases nearly monotonically until a depth of about 300 km, then starts to increase with depth from that point, reaching a local maximum at 500–600 km deep. The earthquake depth range can be divided into three zones: shallow (0–60 km), intermediate depth (60–300 km), and deep (deeper than 300 km). Of these, intermediate-depth earthquakes and deep earthquakes occur within the slab, so they are called intraslab earthquakes (or slab earthquakes).

In many cases, the focal mechanisms of intraslab earthquakes are classified as either downdip compression (DC) earthquakes, in which the compressional axis is oriented in the dip direction of the slab, or downdip extension (DE) earthquakes, in which, on the contrary, the tensional axis is oriented in the dip direction of the slab. There is a systematic tendency in the depth distribution of focal mechanisms that depends on the age of the subducting plate. That is, as indicated in Fig. 5: (1) DE-type earthquakes dominate in young plate subduction zones such as in Central America, in which intraslab earthquakes occur only to a depth of about 250 km. (2) Intraslab earthquakes occur to a depth of about 650 km in old plate subduction zones such as Tonga and the Izu-Bonin arc, and the DC-type focal mechanism dominates at all depths in those areas. (3) Subduction zones such as the Kermadec and Kuriles areas have characteristics intermediate between (1) and (2); DE-type earthquakes dominate in shallow reaches while DC-type earthquakes dominate deeper. (4) In subduction zones like Chile and the New Hebrides areas, in which intraslab earthquakes do not occur at depths between 300 and 500 km, the DE-type dominates at shallow depths while the DC-type dominates deeper.

Slab mineralogy studies have shown that depth perturbations of phase transformation boundaries resulting from thermal anomalies within the slabs generate positive and negative buoyancy forces depending on depth, and so are major contributors to stress fields in the slabs (e.g., Bina et al. 2001). Figure 6 shows a diagram of the mineralogy in a subducting slab. Since the slab is colder than the surrounding mantle, the

Seismicity, Subduction Zone,

**Seismicity, Subduction Zone,**

Fig. 5 Global summary of stress states within subducting slabs (Isacks and Molnar 1971, copyright by the American Geophysical Union). Open and solid circles show downdip compression and downdip extension, respectively. Crosses indicate that neither the compression nor tension axis is approximately parallel to the slab dip

α -olivine to β -spinel phase transformation at 410 km depth and the β -spinel to γ -spinel phase transformation at 550 km depth become shallower, whereas decomposition of γ -spinel to perovskite+magnesiowustite at 660 km depth becomes

deeper than in the ambient mantle. Moreover, the olivine to β -spinel transition must be kinetically hindered within the cold slab, since the relatively colder temperatures in the slab inhibit reaction rates. A wedge-shaped zone of metastable

peridotite thus formed in the cold core of the slab persists to the depth shown by the shaded area in Fig. 6 (Kirby 1995).

Upward deflections of the olivine to β -spinel transition at 410 km and the β -spinel to γ -spinel transition at 550 km yield negative buoyancy forces by stabilizing the dense higher pressure phases in the slab surrounded by the less dense lower pressure phases in the ambient mantle. On the contrary, the downward deflection of the γ -spinel to perovskite +magnesiowustite transition at about 660 km yields positive buoyancy forces. Moreover, the metastable olivine wedge yields positive buoyancy forces. Downdip compression at depths deeper than about 300 km, observed for all the subduction zones (Fig. 5), can be well explained by the compressional stress generated by the combination of the buoyancy forces produced by the metastable olivine wedge and by the downward deflection of the perovskite-forming transition, and the force resisting slab penetration into the lower mantle

(Chen et al. 2004). It is expected that the downdip compressional stress caused by the metastable olivine wedge is smaller for warm (young) and slow slabs. Chen et al. (2004) found a good correlation between the thermal parameter of the slab and the nature of the downdip stress at depths shallower than about 300 km in accordance with this expectation: warm, slow slabs tend to have tensional stress; and cold, fast slabs tend to have compressional stress.

Intermediate-Depth Earthquakes

It is known that intermediate-depth intraslab earthquakes form a double seismic zone in several subduction zones. This was first clearly found beneath northern Honshu, in northeast Japan (Fig. 7), where the deep seismic zone is composed of two planes at depths of 70–150 km that are

Seismicity, Subduction Zone, Fig. 6 Schematic diagram of the mineralogy within a subducting slab (Kirby 1995, copyright by the American Geophysical Union)

Seismicity, Subduction Zone, Fig. 7 Double seismic zone and dehydration loci of oceanic crust and mantle for central Tohoku, northeast Japan, projected on an across-arc vertical cross section (Yamasaki and Seno 2003, copyright by the American Geophysical Union). The solid

line and broken and dotted lines show the dehydration loci of the crust and mantle, respectively. Dots denote earthquake hypocenters. Medium thick and thin lines are the upper plate interface and isotherm contours, respectively

parallel to each other and separated by about 30 km (Hasegawa et al. 1978). Upper-plane earthquakes, most of which occur in the crust of the slab, have DC-type focal mechanisms, while lower-plane ones, occurring in the mantle of the slab, are characterized as DE-type earthquakes. Engdahl and Scholz (1977) explained the formation of such a double-planed deep seismic zone by the unbending of the subducting oceanic plate at this depth range. Later studies showed, however, that DC-type upper-plane and DE-type lower-plane events are not always seen and that in some subduction zones both the upper and lower planes have DC stress. These observations indicate that the unbending force may not be the main cause of the formation of the double seismic zone, although it must be acting on the plate.

Similar to ordinary shallow earthquakes, most intermediate-depth and deep earthquakes have double couple radiation patterns and little or no isotropic component (Frohlich 2006). However, it has been thought that intermediate-depth and deep earthquakes are mechanically different from shallow earthquakes that are generated by brittle fracture. This is because normal stress on the fault becomes too high to cause ordinary brittle shear faulting. At depths of 60–650 km, the overburden produces confining pressures of 2–23 GPa, yielding the strength of the fault of about the same order of magnitude. Earthquake occurrence requires a shear stress exceeding that strength, but it is unlikely that such a high shear stress is actually produced at such depths in the slab. Even if some process in the slab can produce such a high shear stress, it cannot be maintained because ductile flow will occur. Therefore, some special mechanism is necessary to generate earthquakes at such great depths.

One possible mechanism that decreases the strength of the fault for intermediate-depth earthquakes is dehydration embrittlement (Raleigh and Paterson 1965; Green and Houston 1995). Before its subduction, the oceanic plate contains a considerable amount of water as hydrated minerals. The temperature and pressure of the plate rise as it subducts and decompose the hydrated minerals and discharge water. The water reduces the effective normal stress and enables brittle fracture. Dehydration embrittlement also seems to explain the formation of the double seismic zone as discussed below.

If dehydration embrittlement is the mechanism generating intermediate-depth intraslab earthquakes, intraslab earthquakes should not be expected to occur everywhere in the slab, but only where hydrated minerals exist, particularly at facies boundaries where the water content changes. It has become increasingly clear that intermediate-depth intraslab earthquakes do seem to occur in such areas.

In order to examine whether or not dehydration embrittlement is the cause of intraslab earthquakes, we need to know the location within the slab where the hydrated minerals are decomposed and the water is discharged. Yamasaki and Seno (2003) determined the locations in the slab where the

dehydration decompositions of serpentinized slab mantle and metamorphosed slab crust occur based on experimentally obtained phase diagrams of rocks. They compared these locations with the spatial distribution of intraslab earthquakes. The result for the Pacific slab under northeast Japan is shown in Fig. 7. The estimated dehydration loci of the crust and mantle roughly correspond to the location of the upper and lower planes of the double seismic zone. They obtained the same results for the other five subduction zones. This explains well why double seismic zones are formed and why earthquakes in the lower plane have a planar distribution near the center of the slab mantle.

Recent studies in Japan have shown a more detailed spatial distribution of upper-plane earthquakes and revealed its clear relationship with the slab structure. This, as described below, can be explained well if the cause of intraslab earthquakes is dehydration embrittlement.

As indicated by the pale-pinked zones in Fig. 8a, earthquakes in the upper plane of the double seismic zone beneath Tohoku, northeast Japan form a remarkable belt-like seismic zone at depths between 70 and 90 km, parallel to iso-depth contours of the upper surface of the Pacific slab. If the cause of intraslab earthquakes is dehydration embrittlement, this concentration of seismicity is expected to correspond to the location in the slab crust where hydrated minerals are present, particularly around the facies boundary where dehydration occurs. Estimated location of the facies boundary based on the phase diagram of mid-oceanic ridge basalt and the geotherm showed that this expectation is almost true (Kita et al. 2006).

This belt-like seismicity indicated by the pale-pinked zones is not parallel to iso-depth contours, but is oblique to them and deepens locally in Kanto (Fig. 8a). This local deepening is thought to be caused by the shield effect of the Philippine Sea slab, which is located immediately above the Pacific slab. The two slabs are in direct contact under Kanto, and the contact zone between the two is indicated as an area enclosed by two broken lines in the figure. The downdip end of the contact zone is parallel to the belt-like seismicity beneath Kanto, which is oblique to the iso-depth contours of the upper plate interface. Such a clear correspondence indicates that under Kanto, the Philippine Sea slab prevents the Pacific slab from being heated up by the mantle wedge and delays the phase transformation in the slab crust, resulting in the locally deepened belt-like seismicity in that area.

Phase transformation of the slab crust causes an increase in seismic wave velocity. Therefore, we can verify from seismic tomography whether the phase transformation is the cause of the belt-like seismicity. Distribution of S-wave velocity in the slab crust (Fig. 8b) shows that the low-velocity layer persists down to about 80 km depth in Tohoku; deeper than that, S-wave velocity becomes high. On the other hand, in Kanto, the depth range of the low-velocity layer deepens locally in the zone of contact with the Philippine Sea slab. This means

Seismicity, Subduction Zone,

Fig. 8 (a) Earthquake epicenter distribution and (b) S-wave velocity distribution in the subducting Pacific slab crust beneath northeast Japan (Nakajima et al. 2009, copyright by the American Geophysical Union). Pale-pinked zones in (a) show the belt-like seismic zone. S-wave velocity perturbations on a curved plane 5 km below the upper surface of the slab are shown in (b) by the color scale at the bottom. Iso-depth contours of the upper surface of the slab are shown by broken curves. The zone of contact with the overlying Philippine Sea slab is enclosed by green broken lines

the distribution of S-wave velocity also confirms the prediction that the phase transformation is delayed.

The above results support the hypothesis that dehydration-derived aqueous fluids cause intermediate-depth intraslab earthquakes. It is also possible that the initiation of earthquake rupture is caused by local excess pore fluid pressure, and subsequent ruptures propagate through shear heating instability (Hasegawa and Nakajima 2017). In either case, slab-derived aqueous fluids play an important role in generating intermediate-depth events. However, generation mechanism for lower-plane earthquakes is still debated. Whether hydrated minerals actually exist at depths where lower-plane earthquakes occur (the deeper part of the mantle that lies at a maximum of about 40 km below the upper slab boundary) is a point of contention. In this regard, further validation is necessary for the generation of lower-plane events.

Deep Earthquakes

As described in previous sections, seismic observations seem to support the dehydration embrittlement hypothesis for the generation of intermediate-depth earthquakes, at least those in the crust of the slab. Focal depth distribution of global seismicity (Fig. 4) shows that the frequency of earthquakes, after a nearly monotonic decrease from shallow depths, recovers at a depth of about 300 km and gradually increases until the local maximum at 500–600 km. This may suggest that a different mechanism is working for the generation of deep earthquakes.

Several hypotheses have been proposed for the generation of deep earthquakes. There exists the difficulty in generating deep earthquakes as already described in section “Intermediate-Depth Earthquakes”. Three mechanisms out of those proposed so far seem to overcome the difficulty. One is the shear heating instability of creep (Griggs and Handin 1960; Ogawa 1987). Plastic creep of minerals produces heat, while high temperatures promote creep. Therefore, positive feedback promoting creep would arise if the creep of a thin layer occurs at a higher rate than the heat produced by the creep that diffuses into the surrounding area. Thus, the creep accelerates, and finally the thin layer of material begins to melt, producing dynamic slip on the layer, that is, occurrence of an earthquake.

The second hypothesis is the transformational faulting (Kirby 1987; Green and Burnley 1989). Olivine in the mantle of the slab transforms to β -spinel associated with the subduction of the slab. The phase transformation does not occur simultaneously but originates sporadically here and there, forming small lens-shaped spinel phases. The phase transformation proceeds as these spinel lenses expand. The spinel lenses will be formed in a direction perpendicular to the maximum compressive stress axis due to volume reduction occurring in the phase transformation. At the same time, compressive stress will arise at the tip of each spinel lens due to volume reduction as the phase transformation proceeds. This compressive stress promotes the phase transformation. In this way, the spinel lens expands as if it were a crack. Green and Burnley called this spinel lens anticrack. At some critical anticrack density, those anticracks that are

aligned on a plane directed obliquely to the maximum compressive axis at an acute angle are connected with each other and become unified, producing a dynamic slip on the plane, that is, the occurrence of an earthquake.

The last one is the dehydration embrittlement. Although this hypothesis seems to work for the generation of intermediate-depth earthquakes as already explained, some researchers argue that the dehydration reaction continues to occur in the mantle of the slab at greater depths and that dehydration embrittlement is responsible also for deep earthquakes (Omori et al. 2004).

It is not clear which of the three mechanisms is actually working, or if another completely different mechanism is responsible for generating deep earthquakes. More investigations are required for an exact understanding of the mechanism by which deep earthquakes are generated.

Summary

Recent investigations have significantly developed our understanding of generation mechanism for earthquakes in subduction zones. Observed heterogeneous interplate coupling along the megathrust is explained by frictional properties on the fault surface based on laboratory-derived fault constitutive laws. Frictionally unstable patches (asperities) are locked during the interseismic period and finally fail as interplate earthquakes. Surrounding conditionally stable areas typically slide stably, but may slide dynamically if loaded by the seismic slip of an adjacent asperity. Also found are systematically varying rupture properties with depth along the megathrust which are produced by heterogeneous spatial distribution of the frictional properties. Dehydration embrittlement model seems to work as the generation mechanism for intraslab intermediate-depth earthquakes, particularly for earthquakes in the slab crust. Aqueous fluids expelled by the dehydration reaction in the subducted plate migrate upward, finally reaching the arc crust. Recent investigations have shown that the fluids thus supplied originally from the subducting plate play an important role in generating shallow inland intraplate earthquakes. Generation mechanism for deep earthquakes is still an open question. More systematic and intensified studies are expected to resolve it.

Definition

Seismogram interpretation. Identification of various phases appearing on seismograms (measurable changes in frequency and/or amplitude), including the recognition of the waves with respect to possible travel paths through the Earth.

Introduction

A seismogram is the recording of Earth motion (displacement, velocity, or acceleration) as a function of time. Its appearance reflects the combined effects of the source, the propagation path, the characteristics of the recording instrument (see ► “[Seismic Instrumentation](#)”), and the ambient noise due to the specific conditions at the particular recording site. To decipher the often complicated form of seismogram traces requires an extensive knowledge of source physics, structure of the Earth, wave propagation, and earthquake geography. In the early years of observational seismology, say, prior to 1960, the analyst was essentially reading short- and long-period analog seismograms made on smoked, photographic, or heat-sensitive paper or by ink-pen recorders. Approximately, in the middle of the 1980s, the situation changed dramatically. The advent and extensive deployment of broadband digital seismometers with large dynamic ranges complemented with an access to fast, powerful computers opened for seismogram interpreters new possibilities never expected before. Today, the interpreter performs easily a set of operations that significantly improve and accelerate the process of phase identification on digital seismic records. These include, for example, rotation of seismogram components and particle motion techniques. Digital multichannel data serve as input for frequency-wave number analysis and polarization filtering. Synthetic seismograms model observations and phase onsets revealed on seismograms can be associated within narrow time windows with theoretically predicted onset arrival times.

Velocity models for radially stratified Earth have been developed to provide travel times for major seismic waves for the purpose of earthquake location and phase identification. In 1987, IASPEI initiated an effort to update the JB Tables (Jeffreys and Bullen 1940), which have served for 50 years, by constructing new global travel-time tables. With access to an extensive ISC data set (1964–1987), this effort resulted in two velocity models: *iasp91* (Kennett and Engdahl 1991) and *sp6* (Morelli and Dziewonski 1993) deduced from empirical smoothed travel-time curves of the main phases. The two models reveal only small differences in predicted travel times. With respect to the older JB Tables, the most significant differences were found in the upper mantle and core (see ► “[Earth’s Structure, Global](#)”). New, *iasp91*, travel-time tables, which include also the ancillary phases, were calculated from the velocity model (Kennett 1991). For teleseismic *P* waves, the new tables are in average 1.8–1.9 s

faster than the JB Tables. The *iasp91* model was slightly modified in 1995, and a new model *ak135* was proposed (Kennett et al. 1995). The model is suited for predicting the arrival times of a wide variety of seismic phases. It is routinely used by major agencies (ISC, NEIC) in event locations and phase identifications.

At first sight, it seems that there is a contradiction between the duration of the rupture at the source, which takes between a fraction of a second and a few minutes (depending on magnitude), and the length of the observed seismogram, which for large and distant shocks can extend over several hours. The length of the seismogram depends primarily on various wave propagation effects such as reflection, refraction, mode conversion, dispersion, etc. and has little to do with the duration of the quake. A seismogram, especially from a distant earthquake, will often show a number of more or less distinct waves, commonly called phases, distributed in time, which have traveled along different propagation paths and which were subjected to different mode conversions. Numerous manuals for seismogram interpretation have been available since the early 1950s. Some of them have been of local/regional importance, but some have gained worldwide recognition. The latter include works of Neumann (1951), Simon (1968), Willmore (1979), Payo (1986), and Kulhanek (1990). The most recent is the manual edited by Bormann (2012).

Essentially, there are two types of seismic waves, *P* and *S* body waves (see ► “[Body Waves](#)”) and Love (*LQ*) and Rayleigh (*LR*) surface waves (see ► “[Surface Waves](#)”). The most important characteristics of body and surface waves, which are invaluable in any seismogram interpretation, are the following:

- Different waves travel with different velocities. At any epicentral distance, *P* is recorded first, followed by *S*, *LQ*, and *LR*.

- Body waves produce records in the high-frequency range, from 0.1 to 10 Hz, while surface waves occupy low frequencies of about 0.1 Hz and lower. Exceptions will be described later.
- Due to different polarization, *P* waves are usually better displayed on vertical-component seismograms, while *S* waves are often best on horizontal-component records. Fluids do not sustain shear strain, and therefore *S* waves do not travel through liquid parts of Earth’s interior. *LQ*-waves are exhibited only on horizontal-component records, while *LR*-waves are received by both the vertical and horizontal seismometers. For shallow shocks, surface waves usually dominate the seismogram.
- Surface waves exhibit an important property called velocity dispersion (see ► “[Surface Waves](#)”). In practice, this means that the long-period surface waves approach the station first and are recorded ahead of the “slower” shorter waves. Ideally, the seismogram of *LQ*- or *LR*-waves will start with long-period motion, which gradually, as time increases, will turn into shorter and shorter periods.

Some of these features are demonstrated on the seismogram displayed in Fig. 1. There is a sharp *P* onset followed after approximately 4 min by a clear *S*. About 2 min after *S*, we observe the arriving *LR* (vertical-component seismogram). The clearly dispersive character of the recorded *LR* in this case manifests a continental propagation path signature. The large *LR* amplitudes indicate a shallow-focus depth. Except for the first *P* onset, all later arrivals are contaminated by codas of preceding phases so that, on the records, there is virtually no interval of quiescence between individual phases.

In the following description, we introduce several categories of seismic events. The classification is based on the distance between the event and the recording site, that is, on the epicentral distance, which in turn governs propagation paths along which seismic waves travel through the Earth’s

Seismogram Interpretation,

Fig. 1 Long-period, vertical-component, ink-pen seismogram of the Greek earthquake of February 25, 1981 ($M = 6.3$, $h = 33$ km) made at UPP (Uppsala), Sweden, at an epicentral distance of 22° . There is 1 min between successive time marks (small downward offsets)

interior. Events recorded at distances shorter than about 1° will be called local events. Regional earthquakes are shocks recorded at distances between approximately 1° and 10° . For epicentral distances 0 – 10° , seismic waves propagate through the crust and/or along Moho. Accordingly, we call these waves crustal waves. At recording distances 10 – 103° , the waves travel mainly through the mantle. For distances larger than about 103° , seismic waves enter the core or are diffracted along the core-mantle boundary (so-called core waves). Events observed at distances larger than 20° (or 30°) are collectively called teleseisms.

Crustal Waves: Recording Distances 0 – 10°

In a one-layer continental crust, a source located within the crust radiates both P and S waves, which will be recorded along the Earth's surface. These waves are encoded as Pg and Sg . The subscript g refers to granitic layer. In continental earthquakes it has been often observed that Sg has the largest amplitude. The nomenclature of seismic phases used in the present article is that of the IASPEI Standard (Storchak et al. 2003). A reflected wave is also possible from the outer side of the Moho, and the corresponding reflected P and S waves are labeled as PmP and SmS , respectively. At larger distances (beyond the critical distance), we shall record so-called head waves, that is, P and S waves refracted along the Moho discontinuity and labeled Pn and Sn . Head waves propagate with velocities of the uppermost mantle. Note that Pg and Sg exist for all epicentral distances from $\Delta = 0$ and outwards, while Pn and Sn cannot be observed at distances shorter than the critical distance, which for a continental crust is about 100 km. Waves reflected from Moho are rather scarce and difficult to identify. The best chance to discern PmP or SmS on records is at very short epicentral distances where the contamination by Pg and Pn (or Sg and Sn) is not severe.

At epicentral distances shorter than about 10° , records are complicated because of lateral heterogeneities in the crust. In a two-layer crustal model, which includes the Conrad discontinuity, we record new phases. For epicentral distances larger than about 100 km, these are the refracted P and S , traveling along the Conrad discontinuity. An asterisk in the superscript position, P^* and S^* , indicates this phase. An alternative code is Pb and Sb . The subscript b refers to basaltic layer.

Let us assume a continental crust with propagation velocities for Pg , P^* , and Pn of 6.0, 6.6, and 8.0 km/s, respectively. At short distances, less than about 150 km or so, the first seismic wave arriving at the recording station is Pg . For distances larger than critical but less than about 150 km/s, Pg is followed by P^* and Pn , in this order. P^* and Pn travel with velocities significantly higher than Pg . Therefore, at distances larger than approximately 150–200 km, crustal waves change their order of arrival. For distances larger than

about 200 km, the first arriving phase is Pn , next arrives P^* , and then Pg . This is true only for continental travel paths. Seismograms from earthquakes beneath the sea bottom, made at islands or coastal stations, will not show Pg or Sg since there is no granitic layer in the oceanic crust. Similarly, quakes originating in the lower crust, beneath the Conrad discontinuity, do not produce Pg or Sg phases. Hence, first arrivals on records from these events will be Pn or P^* . With a certain time delay following the P phases, proportional to the epicentral distance, the crustal S waves arrive in the same order as P waves. For local events the order of S onsets will be Sg , S^* , and Sn , while for events from distances larger than about 300 km, we observe first Sn followed by S^* and Sg . As an example, a record from a regional earthquake is displayed in Fig. 2. The first discernible phase is Pn , weakly recorded on the vertical and N-S channels. It is followed after about 6 s by strong Pg and after another 39 s by clear Sg , visible on all three components. Sn expected to precede Sg by 9 s cannot be identified on the seismograms.

Short-period S waves, multiply reflected between the free surface and Moho or other crustal velocity discontinuities, interfere with each other and give rise to a wave group labeled Lg . There is no clear distinction between Sg and Lg . Lg waves propagate as guided waves, supercritically incident on the Moho and multiply reflected within the (continental) crust with a velocity of about 3.5 km/s. They may dominate the seismograms made usually at a distance of 5° and larger. Lg are best seen on horizontal-component records. Some rare cases are known where Lg propagated over distances of several thousand kilometers (Kulhanek 1990).

Near-surface local and regional events (earthquakes, industrial explosions, rock bursts, etc.) also generate short-period surface wave of Rayleigh type, labeled Rg . The presence of Rg in the seismogram is a reliable indicator of a very shallow event with focal depth of the order of one or a few kilometers. On the other hand, if Rg waves are absent (epicentral distance of several hundred kilometers or less), we are concerned with a deeper natural event, that is, with a crustal quake at a depth most likely between 5 and 25 km, since all types of man-made events can be excluded. Rg waves travel with a velocity of 3 km/s or slightly higher and are usually well recorded up to distances of about 600 km (Båth 1983). These waves are best, but not exclusively, seen on vertical-component records. An example of a recorded Rg wave is displayed in Fig. 3. The Rg phase is well developed (large amplitudes, clear dispersion) indicating a focal depth of 2 km or less.

Island and coastal seismographic stations frequently record so-called T waves (tertiary waves) arriving after P and S (see ► “[T Waves](#)”). They are characterized by propagation within the oceans as ordinary sound waves emitted by earthquakes near the sea bottom or by submarine volcanic eruptions. The propagation of T waves is very efficient, and

Seismogram Interpretation,

Fig. 2 The Kaliningrad, Russia, earthquake of September 21, 2004 ($M = 5.0$, $h = 15$ km) recorded at broadband station GOT (Gotland), Sweden, at an epicentral distance of 335 km. From top to bottom: vertical, N–S and E–W components. There are 10 s between successive time marks

Seismogram Interpretation, Fig. 3 Weak, near-surface event ($M \sim 2$) in southern Sweden, recorded at broadband station NYN (Nynäshamn) at an epicentral distance of 36 km. From top to bottom: vertical, N–S and E–W components. There are strong onsets of Pg (vertical, N–S) and Sg

(E–W) and a clear Rg phase with distinct dispersion, about 2 s after Sg , best developed on the vertical and N–S components. There is 1 s between successive time marks at the bottom. (Note: epicenter almost due north of NYN)

observations at distances as large as about 80° have been reported. Observations of T phases have proved useful in discriminating between underground nuclear explosions, detonated beneath oceanic islands, and tectonic earthquakes (Adams 1979; Okal 2001). On records, T phases often exhibit rather monochromatic oscillations (periods usually less than 1 s) with a gradual increase and decrease of amplitudes of total duration up to several minutes. There is no sharp onset in the T phase group, which creates difficulties when reading the T arrival times. In general, there is a great variety in the appearance of T phases due to the dependence upon the bottom topography in the vicinity of generation, oceanic stratification, and water-land conversion and transmission.

Appearance of seismograms made at local and/or regional distances varies from place to place mainly due to lateral

variations in crustal structure. It is, therefore, difficult to list generally valid clues for record interpretation. Nevertheless, following principles may guide the analyst to read seismograms and evaluate software solutions of local and regional earthquakes.

- Predominant periods of recorded crustal waves Pg , P^* , Pn , Sg , S^* , Sn , etc. are normally less than 1 s. Rg periods are usually not longer than several seconds.
- Often, Sg has the largest amplitude (when large short-period Rg is missing), best on horizontal-component records. At larger distances, Lg may dominate the records.
- For epicentral distances less than about 200 km (depending upon the crustal structure and focal depth), the first arriving phase is Pg . For larger distances, Pn arrives first.

- Near-surface events, from distances less than about 600 km, often generate short-period Rg with clear dispersion, best seen on vertical channels.
- Local and regional events of low or moderate magnitude are characterized by short total record duration, usually not exceeding several minutes.
- Island and coastal seismographic stations frequently record various types of T phases.

Body Waves Traversing the Mantle: Recording Distances 10–103°

Mantle, in contrast to the overlying crust, may, in the first approximation, be considered as laterally homogeneous. At distances around 10°, Pn and Sn become difficult to identify in the records. Instead, P and S phases show on seismograms. Some workers consider the distance range between 10° and 103° as ideal to record not only the direct P and S waves but also the whole family of reflected and converted waves. Travel paths of these waves are dominated by the mantle, and corresponding seismograms are relatively simple. P is usually stronger on the vertical component, while S is more clearly seen on horizontal components. S often exhibits wave trains with longer periods when compared with corresponding P . Large-amplitude S waves are often observed at distances up to about 100°.

A direct P reflected from the free surface once or twice is called PP or PPP , respectively. In the same way, we have also SS or SSS . For distances larger than about 40°, the free-surface reflected phases become very distinct. At distances around 100° and larger, PP and SS often belong to the largest recorded body waves. Converted waves like PS and SP appear only at distances larger than 40°. Examples of seismograms with free-surface reflections are displayed in Fig. 4.

Core-reflected phases, that is, waves reflected back into the mantle from the outer core-mantle boundary, are labeled PcP and ScS . Including mode-converted waves, we have also PcS and ScP . Because core-reflected phases emerge steeply, ScP is usually stronger on vertical-component records than PcS . Large core-reflected phases are usually recorded at shorter epicentral distances, say at 40° or less. At distances around 39°, ScP and PcS (surface foci) are often contaminated with the arrival of direct S , and the phase separation is difficult. When the ray path of PcP grazes the outer core boundary, the combination of direct P and PcP is called P diffracted and labeled $Pdif$ (older $Pdiff$).

Waves ascending from the focus to the free surface (in continents) or to the sea bottom (under oceans), where they are reflected back into the mantle, are commonly called depth phases. We can list the four possibilities of reflections near the epicenter, which are pP , sP , pS , and sS . The first case, for example, denotes the wave that traveled upward from the focus as P (short leg) and had been reflected back off the free surface again as P (long leg). Depth phases, primarily pP , are the most important phases routinely used in focal-depth estimations. The deeper the focus, the later is the pP phase in relation to direct P . Thus, accurately measured arrival time differences, $pP-P$, are reliable indicators of the depth of the focus. Most teleseismic shallow events (depth of focus around 33 km) will reveal a pP 9–11 s after P (see, e.g., Herrin et al. 1968). In case of a deeper focus, it is sometimes possible to recognize several different reflections/conversions from the free surface, for example, pPP , sPP , pPS , sPS , pSP , etc. Interpretation of depth phases must be done with utmost care since, for example, pP from a deep event can easily be erroneously interpreted as P when the first arrival (P) is weak. Similar difficulty emerges for multiple shocks. Depending on focal orientation and other factors, sP may be stronger than pP and may be mistaken for it. Depth phases are sometimes

Seismogram Interpretation,

Fig. 4 The Costa Rica earthquake of August 20, 1999, ($M = 6.9$, $h = 40$ km). Exhibited seismograms are long period, E–W (upper trace) and vertical-component (lower trace), records made at KONO (Kongsberg), Norway. The epicentral distance is 84°. There are 100 s between two successive time marks at the bottom of the figure. For this distance range, SKS arrives ahead of S , but the separation is difficult. Both displayed channels are dominated by a fundamental LR wave, developed along a mainly oceanic propagation path

stronger than the direct P and may be the first readable phase. We usually require several records made at different epicentral distances to make a reliable identification of the depth phase. We can also mention less common phases like pmP and pwP (first identified by Mendiguren 1971), corresponding to Moho underside reflection and to water surface reflection, respectively (Schenk et al. 1989). A thin layer of low-velocity sediments at the sea bottom may have small impedance contrast. Hence, short-period records may show large pwP when compared with pP reflecting at the sea bottom (Engdahl et al. 1998). pwP can easily be misinterpreted as pP leading to an overestimation of the focal depth.

Bolt (1982) introduced symbols like $P400P$ and $P650P$ to indicate seismic waves reflected at the underside of a secondary discontinuity, in the upper mantle, at a depth of 400 and 650 km, respectively. These phases arrive at the recording station ahead of the expected (calculated) arrival time for the main PP phase and are interpreted as reflections from upper mantle discontinuities, that is, as PdP . When the early arrival time cannot be explained in terms of known discontinuities as PdP , we call these onsets early PP or precursors to PP .

Body Waves Traversing the Core: Recording Distances 103° and Beyond

Due to the diffraction around the core-mantle boundary (see ► “Earth’s Structure, Global”), amplitudes of direct P waves decay dramatically at distances larger than 100° . The short-period P reappears consistently on records first at distances of about 140° . The distance range $103^\circ < \Delta < 140^\circ$ is called the shadow zone. On seismograms, $Pdif$ waves usually show small amplitudes, emergent or gradual onsets, and energy shifts to longer periods. Long-period $Pdif$ are sometimes observed out to distances of 160° or more. S waves are affected at the core-mantle boundary in a similar way.

Waves that traveled through the outer core but do not enter the inner core are labeled PKP (also P'), PKS , SKS (also S'), and SKP . The SKP phase is stronger on vertical components than PKS . These phases have a caustic near 130° , and close to this distance are often the only phase recorded on short-period seismograms. At epicentral distances close to 144° , PKP shows a distinct concentration of energy, that is, large amplitudes on records. The phenomenon may be viewed in terms of two PKP travel-time branches denoted $PKPbc$ and $PKPab$ for the first and the second arrival, respectively. At 144° , the waves from the two branches coincide; the waves reinforce one another, which results in energy concentration near that distance.

P waves that traverse the inner core are denoted by I , giving rise to phases $PKIKP$, $PKIKS$, $SKIKS$, and $SKIKP$, although these are often still simply referred to as PKP , PKS , etc. Phases, with an S leg in the inner core, would

include the letter J , such as $PKJKP$, but these have been difficult to identify on records. Cao et al. (2005) made use of high-quality, broadband seismograms from the Gräfenberg array station, Germany, and identified a phase with arrival time and slowness consistent with predictions of $PKJKP$.

If the studied event is weak, then usually no $Pdif$ is observed in the entire distance interval $\Delta > 103^\circ$, and the first arrival seen on the record will be that of PKP . At epicentral distances 105° – 120° , $PKIKP$ usually provides the first onset discernible on the seismogram. In the region of the caustic, that is, around 144° , the wave train of recorded core phases becomes particularly complicated. It is first at distances beyond the caustic point where observed onsets may be separated into individual PKP branches. The energy distribution changes with the increasing distance. $PKPbc$ is the dominant branch just beyond the caustic, up to about 153° . In records of weaker events ($\Delta = 144^\circ$ – 153°), $PKPbc$ is often the first visible onset since $PKIKP$ (*alt.* $PKPdf$), theoretically preceding $PKPbc$, is too weak to be observed. As the distance increases, $PKPbc$ becomes weaker and vanishes from records at distances of about 160° and larger. For distances beyond, say, 157° , $PKPab$ usually dominates the seismogram. $PKIKP$ in the distance range from about 125° to the caustic is often preceded by early arrivals or precursors, which can arrive many seconds ahead of the main phase. These are often explained by scattering phenomena at or near the core-mantle boundary. Subscripts *ab*, *bc*, and *df* are used in agreement with travel-time charts of Jeffreys and Bullen (1940). Recorded core phases made at a suite of seismographic stations at a distance range from 134° to 173° are shown in Fig. 5.

We may form new symbols for the whole family of waves propagating through the outer core. For example, $PKKP$ is a P wave reflected from the inside of the core-mantle boundary, often very pronounced on records made at distances between 60° and 80° . However, the striking onset may easily be misinterpreted as a first P arrival of another event. P waves trapped inside the Earth’s liquid core and with multiple K legs are called $PNKP$, where $N - 1$ is the number of reflections. Multiple reflections within Earth’s outer core were first observed by Engdahl (1968). He used records from two deep earthquakes and an event in Novaya Zemlya ($h = 0$) and identified recorded seismic waves reflected as many as four times (i.e., $P5KP$) within the Earth’s outer core. Cases like $P4KP$ and $P7KP$ have been reported by Bolt (1982). Waves that traverse the Earth’s interior and are reflected at the outside or inside of the inner core are labeled $PKiKP$ or $PKIIKP$, respectively.

The best chance to observe $PKPPKP$, or for short $P'P'$, is around distances $2 \times 144^\circ = 288^\circ$ or 72° if we take the shortest distance from source to station. $P'P'$ is often well recorded, arriving about 30 min after P , when most of the coda amplitudes of preceding phases have already become faint.

Seismogram Interpretation,

Fig. 5 Seismograms from a Mid-Indian-Rise earthquake of May 16, 1985 ($M = 6.0$, $h = 10$ km), made at a suite of seismographic stations that sample the epicentral distance between 134.3° and 173.2° . Short-period (*left*) and long-period (*right*), vertical-component records are exhibited. Station codes, epicentral distances, and amplitude scaling are given to the left of each trace (G. Choy, personal communication; reproduced from Kulhanek 1990, with permission from Elsevier, Science)

$P'P'$ may in some cases be wrongly interpreted as a new P or PKP . 72° is also equivalent to $3 \times 144^\circ = 432^\circ$, so the phase $P'P'P'$ is also strong at this distance and may be observed, for strong earthquakes, about another 20 min after $P'P'$. In 1969, first observations of precursors to $P'P'$, sometimes called early $P'P'$, were made (Engdahl and Flinn 1969). These were interpreted as $P'dP'$ analogous to PdP , that is, as reflections of PKP at secondary velocity discontinuities within Earth's upper mantle. For example, $P'650P'$ passes through the core twice and on seismograms precedes $P'P'$ by about 2 min.

Similar to PKP and $PNKP$, there are SKS and $SNKS$ waves, respectively. First SKS waves are observed at distances between 60° and 70° , and the range of observations extends to distances of 180° or so. SKS exhibits a caustic point at a distance of about 80° so that the best region to study SKS waves is that between 70° and 90° . The phase identification has to be made with utmost care since SKS recorded at this distance range are often contaminated with direct S . To mistake S for SKS and vice versa will adversely affect the epicentral location. At about 82° (depending upon details in the structural model), SKS begins to arrive ahead of S (Fig. 4). For distances shorter than about 95° , SKS is usually smaller than S ; however, at distances beyond 95° , SKS amplitudes are quite large. S and SKS are best recorded on long-period horizontal-component seismograms. The period of SKS phases may

reach several tens of seconds. Occasionally, these body waves are also seen on short-period records, although the onset time of the later of the two phases is usually very emergent due to the contamination by the coda of the earlier phase.

Body Waves from Intermediate-Focus and Deep-Focus Earthquakes

Later studies confirmed conclusions from Wadati's pioneering work (Wadati 1927) that intermediate-focus and deep-focus shocks produce simpler seismograms with exceptionally well-recorded impulsive body waves while surface-wave amplitudes decrease as the quake becomes deeper. Strong depth phases, such as pP and sS , are also frequently very distinct on records from deep events. However, the duplication of principle phases by surface reflection (e.g., confusion between pP and PP) often complicates the seismogram interpretation. Weak precursors, pmP , (Moho underside reflections) to surface reflections, pP , are discussed in Schenk et al. (1989). They are best observed in long-period records and in continents often produce clear arrivals. In a more retrospective-type interpretation, the absence of aftershocks (see ► "Earthquake, Aftershocks") will support the classification of the shock as a deep-focus or intermediate-

focus event. Fig. 6 shows seismograms from an intermediate-focus earthquake made at an epicentral distance of 41° . Note the impulsive character of the P , pP , PcP , S , and ScS phases; virtually no surface waves have been recorded from this event.

Surface Waves

With exception of very short epicentral distances, long-period surface waves, LQ and LR dominate the seismograms of shallow events. Deep events of the same magnitude will generate abnormally small (insignificant) surface waves. This feature provides the interpreter with a viable tool to discriminate, at first glance, between shallow- and deep-focus earthquakes. (Note a paradox: underground nuclear explosions, being very shallow events, generate only small, sometimes invisible, surface waves.) The analyst has several clues to identify surface waves on the record and to distinguish LQ from LR . While Love waves are best displayed on horizontal-component seismograms, Rayleigh waves are best seen on vertical-component records. Both LQ and LR propagate slower than P or S , but since LQ propagate faster than LR , they are recorded ahead of LR . Due to dispersion, long-period surface waves advance on records toward the beginning of the wave train as it travels through the medium. An experienced analyst will distinguish between recorded surface waves that have traveled along pure oceanic or continental path. Dispersion of oceanic routes gives rise to long wave trains with rather slow and sometimes hardly visible period change over relatively long (10–20 min) record segments (see Fig. 4). In contrast, continental paths generate surface waves with characteristic fast period decrease with time, which is often easily recognized on records (see Fig. 1). Surface waves can also travel by different modes (overtones), which are often seen on records as high-frequency components superimposed on the surface-wave train. We talk then about

fundamental-mode and higher-mode surface waves (see ► “Surface Waves”). Higher modes are most frequently observed for waves traversing purely continental paths. Nevertheless, higher modes have in some cases been associated with oceanic paths. Surface-wave higher modes disappear when the waves cross the transition between continental and oceanic structures. Higher modes propagate faster than the fundamental mode and are, therefore, recorded ahead of LQ and LR .

Dispersion curves (see ► “Surface Waves”) show a rather complicated pattern with several local minima and maxima. Surface waves traveling with these minima or maxima group velocities are called Airy phases. On seismograms, an Airy phase is characterized by a constant-frequency compact wave train, often with a remarkable amplitude buildup of dispersed surface waves traveling by fundamental-mode propagation. In the period range from approximately 50–200 s, the group velocity of LR (both the oceanic and continental paths) monotonically decreases with increasing period. Physically this means that in this period range, long-period RL waves follow the law of inverse dispersion. Observations of this phenomenon are rather scarce. An example is exhibited in Kulhanek (1990).

Extremely long-period surface waves called mantle waves, with periods from somewhat less than 1 min to several minutes, have been observed from large distant shocks. They can be of either Love or Rayleigh wave type. The former propagates with nearly constant speed of 4.4 km/s and shows an impulsive shape on the seismogram. The latter travels with velocity between 3.6 and 4.1 km/s. Wavelengths of mantle waves vary from several hundreds to more than 1,000 km, so that a large part of Earth’s mantle is affected by these waves. An interesting feature of mantle waves is their repeated appearance on records, which is due to their multiple travel around the Earth. The LQ mantle wave was given the label G (after B. Gutenberg) and the LR -type mantle wave the label R . The older nomenclature sometimes uses W instead for

Seismogram Interpretation,

Fig. 6 Seismograms from an intermediate-focus earthquake ($M = 6$, $h = 199$ km) in the Hindu-Kush region on September 4, 1993, made at UPP, Sweden, at an epicentral distance of 41° . The traces show long-period channels from top to bottom: vertical, E–W and N–S components

R (from German *Wiederkehrewellen*, meaning repeated waves). *G* waves that propagate the direct and anticenter routes are labeled *G1* and *G2*, respectively. Waves that have in addition traveled once around the Earth are denoted *G3* and *G4* and so on. Similarly, we have *R1*, *R2*, *R3*, *R4*, etc. As an exceptional case, we can mention records of the 1960 Chile earthquake, $M = 9.5$. Seismograms made at Uppsala, Sweden, reveal mantle waves *G20* and *R20* that have traveled a total distance equal to that from the Earth to the Moon (Båth 1979).

Volcanic Earthquakes and Unusual Seismic Sources

During eruptive episodes, volcanoes can produce up to thousands of small earthquakes per day, recorded only at short distances, say, less than 50 km, from the volcanoes (see ► [“Earthquakes, Volcanogenic”](#)). Different categorization of volcanic earthquakes may be found in the literature. For example, Minakami (1961) classifies volcanic earthquakes into three groups, in accordance with different generation mechanisms and signal characteristics: (1) A-type earthquakes with focal depth between 1 and 10 km near the volcanic magma system, corresponding records show clear high-frequency *P* and *S* phases; (2) B-type earthquakes with foci at depth of 1 km or less, records reveal low-frequency coda, emergent onsets, and usually no distinct *S*; and (3) explosion-type earthquakes taking place at the very surface of the Earth. Close to active volcanoes, we also frequently detect so-called volcanic tremors, which are due to long-duration, more or less continuous, volcanic vibration.

Implosion earthquakes, impact earthquakes (e.g., the Tunguska, Siberia, impact in 1908), frost actions, low-magnitude icequakes generated by temperature changes in glaciers, earthquakes related to large-scale landslides, etc. are some of the types of events that, together with tectonic earthquakes, volcanic earthquakes, and oceanic microseisms, belong to the category of natural seismic sources. There is also a variety of man-made seismic sources such as industrial and military explosions, cultural noise (traffic, industry work), mining activity, high dams (seismicity, triggered/induced), fluid injections, etc. The source identification, for earthquakes other than tectonic or volcanic, is usually a task in itself. A classical example of source identification is the well-known problem of discriminating underground nuclear explosions from earthquakes (see ► [“Seismic Monitoring of Nuclear Explosions”](#)).

Conclusions

Seismogram interpretation, described in this article, is essentially devoted to the art of identification of various seismic

“arrivals” or wave types visible on seismograms. It is usually followed by seismogram analysis, which may include determination of basic source parameters (origin time, hypocenter location, size) but may also cover more advanced studies, such as waveform modeling, determination of velocity distribution, etc. Obviously, a large part of seismogram analysis is a domain of research. Nevertheless, phase identification is a doorway, and without correct seismogram interpretation, hardly any analysis would be possible. Repeated observations of peculiar phases on seismic records often led to new discoveries of details in Earth’s structure and/or dynamics. Sometimes, theories were developed in advance, to be later confirmed by observations (e.g., free oscillations of the Earth). Seismogram interpretation is a fundamental and, in our view, also fascinating and rewarding part of modern seismology.

Seismological Networks. Networks of seismographic stations for the recording of ground motions produced by seismic waves propagating from natural and anthropogenic sources.

Introduction

Seismology has its roots in observations of earthquakes and earthquake-generated ground motion. Seismological networks as envisioned by the pioneers in seismology are now a reality, a reality that is frequently upgraded and expanded as technology improves. A global system of broadband seismographs with high dynamic range is now in place. This is supplemented by many national, regional, and local networks capable of high-resolution monitoring of the frequent smaller earthquakes in seismically active places. Parametric data derived from these networks make a major contribution to national and international information services. Because of page limitations, we can only hope to provide the reader with a glimpse of all there is to know about seismographic networks.

Global Seismic Networks

Seismological recordings have been made on Earth for hundreds of years in some form or another. However, global monitoring of earthquakes only began in the 1890s when John Milne created 40 seismic observatories to measure the waves from these events (see Fig. 1). Shortly after the International Geophysical Year (1957–1958), a concerted effort was made to establish and maintain a more modern standardized seismic network on a global scale.

Worldwide Standardized Seismograph Network

In the early 1960s, the World-Wide Standardized Seismograph Network (WWSSN) was established. Between 1961 and 1966, 120 WWSSN stations with identical seismic instruments were deployed in more than 60 countries and islands throughout the world. The WWSSN program included the collection, review, and copying of the recorded seismograms and the distribution of copies to researchers throughout the world. Considered one of the most important advances ever in observational seismology, the WWSSN produced the data needed to support unprecedented progress in earthquake, explosion, and tectonic research. In the years that followed the deployment of the WWSSN, many of the stations were modernized and expanded into regions not initially covered. Eighty of the original WWSSN stations are still in operation and still supported.

International Federation of Digital Seismograph Networks

In the 1980s, the international seismological community recognized the new opportunities within its field for improved understanding of the internal structure and dynamical properties of the Earth provided by recent developments in

seismograph network technology. It also recognized that rapid access to seismic data from networks of modern broadband digital instruments wherever they might be was now possible. The developments included greatly improved broadband seismographic systems that capture the entire seismic wave field with high fidelity (see Fig. 2), efficient and economical data communications and storage, and widely available, powerful computing facilities.

In view of the above and to take advantage of existing developing global and regional networks, the International Federation of Digital Seismograph Networks (FDSN, <http://www.fdsn.org/>) was formed in 1986 to provide a forum for developing common minimum standards in seismographs (e.g., bandwidth) and recording characteristics (e.g., resolution and dynamic range); developing standards for quality control and procedures for archiving and exchange of data among component networks; and coordinating the siting of additional stations in locations that will provide optimum global coverage.

The FDSN was formed as a global organization, open to all national and international programs committed to the deployment of broadband seismographs and willing to contribute to the establishment of an optimum global system with timely

data exchange. Its membership is comprised of groups responsible for the installation and maintenance of seismographs either within their geographic borders or globally (Fig. 3). Membership in the FDSN is open to all organizations that operate more than one broadband station. However, among the most important contributors are the Global Seismographic Network (GSN) of the Incorporated Research Institutions for Seismology (IRIS) and the French GEOSCOPE and German GEOFON global networks. It is important to note that many stations in the FDSN were formerly part of the WWSSN program, some of them having been upgraded to digital recording (DWWSSN). Members agree to coordinate station siting and provide free and open access to their data. This cooperation helps scientists all over the world to further the advancement of earth science and particularly the study of global seismic activity.

The FDSN goals related to station siting and instrumentation are to provide stations with good geographic distribution, recording data with 24 bits of resolution in continuous time series with at least a 20-sample per second sampling rate. The FDSN was also instrumental in development of a universal standard (SEED) for distribution of broadband waveform data and related parametric information. The FDSN system of

global network observatories includes contributions from many international partners forming a large backbone of permanent seismological observatories. Currently more than 4000 permanent and temporary stations send waveforms in real time to IRIS data center (Fig. 4). Developments in communications and other technological advances have expanded the role of the FDSN in rapid earthquake analysis, tsunami warning, and nuclear test monitoring. With such long-term observations, scientists are now getting a glimpse of Earth structure changes on human time scales, such as the rotation of the inner core. Continued observations for the next 50 years will enhance our image of the Earth and its processes.

International Monitoring System

Under the Comprehensive Nuclear-Test-Ban Treaty (CTBT, <http://www.ctbto.org/>), it is a requirement that there will be an International Monitoring System (IMS) to detect any clandestine nuclear weapon detonation in any environment – underground, underwater, or above ground. The aim of the IMS is detection, identification, and location of any such test, and the technologies involved will be seismological, hydroacoustic, infrasound, and atmospheric radionuclide monitoring. In support of these technologies, there will be appropriate means of global communication and an International Data Centre (IDC) to which monitoring data will be transmitted.

Seismological monitoring is considered the cornerstone of the IMS because of the likelihood that tests would be

conducted underground and out of sight. The seismological technology required for the detection of earthquakes is well known, but the problem for the IMS is to distinguish between signals from weapons detonations, earthquakes, and nonnuclear explosions in quarrying or mining. There are so many earthquakes (>200,000 per year) and mining events worldwide, of similar magnitude to a small nuclear explosion, that data analysis becomes a key problem. The seismological verification program therefore includes intensive study of seismicity and mining operations in order to develop regional backgrounds.

A global network of 50 “primary” stations in 34 countries is planned, with 2 basic equipment packages: “three-component” (3-C) broadband seismometers, which act as single detection systems monitoring ground movement in 3 directions – vertically and horizontally east-west and north-south – or “arrays” which include 3-C systems plus a cluster of narrowly spaced vertical-component short-period sensors distributed to gain optimum signal-to-noise ratios by waveform correlation. Arrays may contain many detectors located over large areas (up to 200 km²). The advantage of an array station is that it allows approximate event location on a stand-alone basis. Historical developments such as the LASA, NORSAR, and Graefenberg arrays have marked important steps in seismological network development that have facilitated new research fields and services in seismology. As Fig. 5 indicates, approximately half of the proposed stations will be arrays.

Seismological Networks, Fig. 5 Locations of stations in the CTBTO IMS network (Comprehensive Nuclear-Test-Ban Treaty Organization www.ctbto.org). Symbols defined as follows: filled symbols,

operational; open symbols, not yet operational; stars, array stations; triangles, three-component stations; large symbols, primary stations; and small symbols, auxiliary stations

In addition to the primary network, an “auxiliary” network comprising 120 stations distributed among 61 countries is planned (Fig. 5). Stations in this network will mainly consist of existing 3-C stations, which already form part of the host countries’ seismological monitoring operations. The purpose of the auxiliary network is simply to provide additional data to support that from the primary network in order to facilitate signal discrimination and hence event detection and location.

Regional Seismic Networks

National seismographic networks operate within the political boundaries of a country, and their primary mission is to issue rapid alerts to government agencies and the general public for potentially damaging earthquakes. National networks typically exchange data with neighboring countries in order to improve the accuracy of the determination of earthquake parameters in border regions.

Regional networks play an important role in monitoring the seismicity of the Earth within a well-defined region. Regional networks may be part of a national network (e.g., the United States, China, Japan, and Russia) or may be constituted from multinational networks (e.g., Euro-Mediterranean region). The magnitude detection threshold of regional networks is typically lower than that of the global networks, which allows for producing bulletins for a specific region that are more complete than it could be achieved at a global scale.

Local networks focus on a much smaller area than regional networks. Examples of local networks include temporary deployments to capture aftershock sequences of a large earthquake, networks monitoring volcano activities, and dense local networks installed in urban areas with elevated seismic risk.

Euro-Med Region

The Euro-Med region encompasses Europe, North Africa, and the Middle East. The European-Mediterranean Seismological Centre (CSEM/EMSC, <http://www.emsc-csem.org>), an international, nongovernmental organization of more than 70 seismological data centers of more than 50 countries, produced earthquake bulletins in the region from 1998 to July 2012, using parametric data reported by national and local networks in the region. After this date, all contacts and exchange procedures were transferred to the ISC to ensure data will remain collected.

The mission of EMSC is to provide rapid comprehensive seismological information and to disseminate notifications for potentially damaging earthquakes in the region in coordination with national and regional institutions as well as to offer redundancy and backup to national services. The EMSC and the US National Earthquake Information Center (NEIC) routinely exchange data, and NEIC bulletin data for the European-Mediterranean region are incorporated in the EMSC data collection. Earthquake parameters (location, magnitude, phase picks, moment tensors, etc.) provided

by the EMSC and its members are incorporated in the global bulletin prepared by the International Seismological Centre (ISC).

The EMSC developed a multichannel information system (websites, Quakebot on Twitter, and a smartphone app, LastQuake) offering rapid information of felt and damaging earthquakes to eyewitnesses and crowdsourcing observations (felt reports, geo-located pictures, and videos) to contribute to improved situation awareness.

United States

In the United States, the US Geological Survey's National Earthquake Information Center (NEIC, <http://earthquake.usgs.gov/regional/neic>) is the national data center and archive for earthquake information. Its mission is to determine as rapidly and accurately as possible the location and size of all significant earthquakes that occur worldwide. The NEIC operates 24 h a day and issues rapid alerts for earthquakes larger than magnitude 3 in the conterminous states of the United States and for those larger than magnitude 5 globally. The NEIC publishes global earthquake bulletins on a daily, weekly, and monthly basis.

The NEIC serves as the National Operations Center of the Advanced National Seismic System (ANSS), which includes the ANSS backbone network and regional seismic networks across the United States. Figure 6 shows the permanent digital

seismic and strong motion stations in the 48 conterminous states of the United States. The strong motion stations (circles) represent an integral part of the ANSS network as first arriving phases are picked on strong motion records and used in the earthquake location procedures. Figure 7 shows the regional Southern California Seismic Network. As in Fig. 6, the map is colored by the peak ground acceleration, a measure of seismic hazard. The network is much denser in urban areas and regions with high seismic hazard.

China

The China Digital Seismograph Network (CDSN) was established in 1986, with nine digital seismic stations. During the past 20 years, the Chinese seismic network, both at the national and regional levels, went through unprecedented improvements. The China Earthquake Administration (CEA) has completed the analog-to-digital transition of the existing analog stations and deployed a large number of new digital stations (Liu et al. 2008). Figure 8 shows the currently operating national network of 162 broadband seismographic stations. Some of these stations also belong to the FDSN. Dense regional networks further support the national network. Each of the 31 provinces, autonomous regions, and municipalities operates regional digital networks. Figure 9 shows the distribution of the 945 regional seismic stations.

Seismological Networks, Fig. 7 The Southern California Seismic Network: an example for a very dense regional network. (Courtesy of Incorporated Research Institutions for Seismology, <http://ds.iris.edu/gmap>)

China's Earthquake Networks Center (CENC) archives the continuous waveform data from the national and regional networks and performs real-time data processing. The CENC issues rapid earthquake alerts for $M_s > 4.5$ events inside China within 10 min and focal mechanism solutions in no more than 30 min after the earthquake occurred.

Large-Scale Arrays

The USArray (www.usarray.org), one of the three-component Earthscope projects (www.earthscope.org), has opened a new chapter in seismology. The project began in

2007 with some 400 high-quality broadband seismographs deployed with 70 km station spacing in the West Coast and marching across the entire mainland United States, reaching the East Coast in 2013. The mainland USArray project finished in 2017, and now it has moved to Alaska (Fig. 10). USArray provided data on the North American lithosphere in unprecedented detail. The success of USArray has inspired large-scale array deployments worldwide, such as the IberArray (iberarray.ictja.csic.es), AlpArray (alparray.ethz.ch), ChinaArray (chinaarray.org), and, most recently, AusArray and AdriaArray.

Seismological Networks,

Fig. 11 Number of stations reporting to the ISC between 1964 and 2016. (Courtesy of James Harris, International Seismological Centre)

International Registry of Seismograph Stations

Since the humble beginnings of instrumental global seismology in the late nineteenth century, the number of seismographic stations has steadily increased every year. Figure 11 shows the number of stations reporting to the ISC in each year since its operations began. In order to be able to uniquely identify seismographic stations, the ISC and the NEIC, in its capacity as World Data Center A for Seismology, jointly maintain the International Registry of Seismograph Stations (IRSS). The IRSS represents a global catalog of seismic stations (currently with some 27,000 registered stations) and contains information about the station coordinates, instruments, operating networks, and when a station began/stopped operating. To facilitate data exchange between networks and organizations, it is strongly recommended that network operators register their stations and use the international station codes.

Summary

The high-quality data recorded by seismographic networks would be of limited value without international cooperation by all countries worldwide in the acquisition and exchange of seismic measurements and waveforms. This cooperation is essential for the location of earthquakes, for understanding the physics of earthquakes, and for studies of Earth's internal structure, properties, and processes. One of the latest challenges to acquiring, processing, and distributing data from

seismographic networks by data centers globally is the automatic performance of traditional tasks in as close to real time as current technology permits.

Definition

Environmental Seismology	Field using seismic waves for investigating phenomena at the interface of solid and fluid Earth.
Anthropic Seismology	Field using seismic waves for investigating phenomena induced by anthropogenic activity (nuclear explosions, triggered seismic events in industry, mines, oil reservoirs, quarries, traffic, . . .).
Glacial Earthquakes	Earthquakes occurring in glaciers or ice polar caps, often associated with calving of icebergs at glacier terminus or at the discontinuity between bedrock and glaciers (specific class of icequakes with large magnitude).
Hurricanes, typhoon	Violent wind with a circular movement originating in tropical zones.
Landslides	Destabilization of rocks or soils from a sloping area such as a mountain, a cliff, or a volcano.
Microseisms	Small earth tremor whose sources are related to the ocean-wave activity. Primary microseisms are oscillating at the characteristic ocean-wave periods (approximately between 10 and 20 s periods) and result from the interaction of these waves with the shallow sea floor. Secondary microseisms are generated by interactions among ocean waves and have the double of their frequency.
Seismic hum	Continuous excitation of the Earth in the absence of earthquakes (at periods longer than 50 s) created by the interaction of long period ocean waves (infragravity waves) and the sea floor. This signal is weak but nevertheless large enough to excite the earth-free oscillations.
Snow avalanches	Destabilization of a mass of snow from a sloping topography turning into a flow of snow particles or aggregates that stop downslope.

Very long
period noise

For periods larger than 200 s, the noise results from gravitational attraction changes induced by local pressure perturbations.

Introduction

Seismology is usually devoted to the investigation of tectonic earthquakes and imaging of the solid structure of the Earth. But with the improvement of seismometers and the explosion of the continuous recording of the ground motion by broadband seismic networks, other phenomena can be investigated. Since seismometers are sensitive to any kind of ground displacement, small events hidden in the noise can be detected. A large part of these small events is related to the interaction or the coupling of the surface of the solid Earth with its surficial unconsolidated solids, fluid/gas envelopes (ocean and atmosphere). Iceberg calving, glacier dynamics, landslides, snow avalanches, hurricanes, and ocean waves belonging to this kind of environmental events are able to generate observable seismic signals. Microseisms permanently excited by the interaction of gravity waves and swells in oceans, fluvial seismic signals, make it necessary to use statistical approaches for extracting useful information on the source processes in a broad frequency range. In contrast to microseisms, some events are episodic, deterministic; some of them well located in space and time and can be individually investigated. The study of all these natural phenomena giving rise to observable seismic signals constitutes the field of environmental seismology.

Due to the faintness of the associated signals, new methods and techniques have been used. For deterministic events, beamforming methods, time-reversal methods or their less general form, and back-projection technique (see Larmat et al., this issue for all references) have been applied to locate them in space and time. Microseisms were investigated by Wiechert (1904), and physical processes to explain them were proposed many decades ago (Longuet-Higgins 1950; Hasselmann 1963). For a stochastic approach of ambient noise, the cross-correlation methods of signals between two seismic stations are now routinely used and make it possible to retrieve the empirical Green's function (impulse response of the propagating medium) between these two stations (see Campillo et al. this issue). They are particularly well suited for monitoring physical parameters such as variation in the sub-soil temperature, aquifers, and climate and global changes.

Environmental seismology can be distinguished from "anthropic seismology," including the study of seismic signals associated with anthropic activity, such as nuclear, mining explosions, attacks, triggered events, and urban seismology (traffic, footquakes, etc.), even though similar methods can be used to study them.

Broadband Seismic Noise

Seismic noise has several and various origins. It is present in the whole seismic frequency range 50 Hz–1 mHz (or period range 0.02–1000 s). It is classical to divide the frequency (or period) range of seismic noise into four bands:

- Frequency higher than 1 Hz (periods smaller than 1 s), noise is mostly related to local sources, impulsive natural events of various origins, and it also corresponds to the area of expertise of anthropic seismology.
- Frequency band between 1 Hz and 0.05 Hz (period range 1–20 s) corresponds to the classical **microseismic** band.
- Frequency range between 0.05 Hz and 0.01 Hz (period range 20–100 s), sometimes named the noise notch where the noise is minimum.
- Very low frequency range (frequency < 0.01 Hz) or very long-period range (period $T > 100$ s) where the seismic **hum** is the best observed.

The high frequency range ($T < 1$ s), where the anthropic sources are the most visible, is routinely used in urban seismology (Ward and Crawford 1966; Bonnefoy-Claudet et al. 2006; Nakata et al. 2011). It is also the frequency range of fluvial seismology where the seismic noise induced by rivers is well correlated with meteorological and hydrological data (Govi et al. 1993; Burtin et al. 2008; Tsai et al. 2012; Gimbert et al. 2014) and can be used as well to investigate erosion processes and sediment transport dynamics (Roth et al. 2016), avalanches, or rockfall activity (Hibert et al. 2011; Dammeier et al. 2011). This rapidly developing field will not be detailed here. Many natural events (icequakes, landslides) can be investigated in the whole broadband frequency range. At longer periods (smaller frequency), noise is dominated by natural sources. It is the strongest between 4 s and 20 s, and this period range is named the microseismic band, with two prominent peaks at ~7 s (secondary peak) and ~14 s (primary peak) due to the complicated nonlinear interaction between oceanic waves and solid Earth (Longuet-Higgins 1950; Hasselmann 1963; Kedar et al. 2008; Arduin et al. 2011; Stutzmann et al. 2012). At longer period, in the absence of earthquakes, the interaction between the liquid/gas envelopes (ocean, atmosphere) and the solid earth continuously excites the free oscillations (Suda et al. 1998; Kobayashi and Nishida 1998; Arduin et al. 2015). This phenomenon is named seismic hum.

Continuous Monitoring of the Earth Environment

Microseisms have been investigated for many decades and are continuously excited, and it is not possible to treat them as individual events. However, for a homogenous distribution of noise sources, it is possible to derive the empirical Green's function by using stacking contributions of all microseismic

sources to the cross-correlations of seismic records of two stations. Cross-correlation formula CC_{AB} between seismic signals $s_A(t)$, $s_B(t)$ of two stations A and B is given by:

$$CC_{AB}(\tau) = \int s_A(t) s_B(t + \tau) dt$$

and the time derivative of $CC_{AB}(\tau)$ is simply related to the Green's function. Seismic records associated with microseisms and hum are dominated by surface waves, but it is possible to also extract body-wave data from noise data. So far, the application of cross-correlation methods has been the local tomography (Shapiro et al. 2005) or global tomography (Nishida et al. 2009) and the monitoring of seismogenic zones, and volcanic zones (see Campillo et al. this issue and references therein). The multiplicity of sources (microseisms, hum) and their continuous excitation can also be used to investigate environmental challenges (Larose et al. 2015).

Usually considered as noise, microseisms (and more generally environmental events) can also be recognized as a meteorological signal (Gutenberg 1958) as they provide complementary information on ocean activity, for example, and can ultimately provide invaluable information on global warming.

Spatiotemporally Localized Events

It is also possible to extract some specific events from the seismic noise that we can consider as deterministic events. Three examples are presented here: the glacial earthquakes, cyclones, and landslides.

Glacial Earthquakes

Cryoseismology, the field investigating seismic signals associated with the dynamics of glaciers, has exploded during the last two decades, (see the review papers of Podolskiy and Walter 2016, and Aster and Winberry 2017). Glacial earthquakes are specific cases of icequakes but belong to this new class of seismic environmental events of large magnitude which can be as large as ~5. These events have been discovered since the 70s and detected automatically in Greenland on long-period seismograms recorded on the FDSN (Federation of Digital Seismograph Networks) (Ekström et al. 2003).

Most glacial earthquakes occur during the late summer in the northern hemisphere, showing a strong seasonality. Most of them have been detected in Greenland and Alaska. Glacial earthquakes in Antarctica are less well studied, but some of them exhibit several characteristics similar to glacial earthquakes in Greenland. Different mechanisms are in play, and the cumulative stickslip motion of ice stream in West Antarctica is equivalent to an earthquake of moment magnitude ~7 in spite of modest seismic amplitudes owing to the source duration of 20–30 min (Wiens et al. 2008). The origin of large

glacial earthquakes has been first interpreted as resulting from stick-slip motion or sliding at the base of marine terminating glacials (Ekström et al. 2003). However, thanks to mechanical models and more precise visual observations, it has been shown that iceberg calving is the main cause for generating the large glacial earthquakes even though other processes can be invoked for different kinds of icequakes (Tsai et al. 2008; Amundson et al. 2008; Sergeant et al. 2019). Indeed, a strong temporal correlation is observed between the distinct seismic signals of glacial earthquakes and large ice-loss events in which icebergs of cubic-kilometer scale capsize against glacier terminus. Figure 1(left) displays an example of seismogram for a glacial earthquake detected in Alaska. It is characterized by abnormal long-period spectral content compared with a classical tectonic earthquake. Since there are generally no clear identifiable P- or S-wave arrivals, innovative techniques have been used to locate and quantify the glacial earthquakes, such as the cross-correlation technique of Ekström et al. (2006) or the time-reversal method (Larmat et al. 2006, Fig. 1 middle).

The seismogenic process is related to the force exerted by these icebergs on the glacier and the underlying solid earth. Sometimes, a sudden change in glacier speed results from these glacial-earthquake calving events. Figure 1 (right) shows the time variations of the force for a large-scale multiple-iceberg calving episode at the terminus of the Jakobshavn Isbrae on 21 August 2009 (Sergeant-Boy et al. 2016). It was recorded by broadband seismic stations located in Greenland including the seismic records from four permanent stations of the GLISN network (Dahl-Jensen et al. 2010).

The rate of glacial earthquake occurrence varied during the last decades but tends to increase since the beginning of the century (Olsen and Nettles 2017; Sergeant et al. 2019). Seasonal and interannual variations in glacier-terminus position partly account for general characteristics of the temporal variation in earthquake occurrence. By coupling seismological analysis with numerical modeling of iceberg calving, Sergeant et al. (2019) quantified the spatiotemporal evolution of ice loss in Greenland from iceberg calving between 1993 and 2013. They showed that calving was responsible for the loss of 370 gigatonnes of ice, representing 8–21% of the mass lost on glacier termini, the rest attributed to ice melt.

Cyclones (Hurricanes–Typhoons)

Tropical cyclones (hurricanes in the Atlantic Ocean and typhoons in the Pacific ocean) are also sources of seismic signal in the microseismic band. They participate to microseismic source distribution, as particular cases of the atmosphere-ocean system interacting with the solid Earth (Ebeling and Stein 2011). Storms are sensitive to topography and also carry information on the structure of the Earth and on meteorological processes.

Ocean wave-wave interactions are very large in the wake of cyclones. They generate P-waves just below the ocean

surface that propagate in the ocean and reach the ocean bottom where they are reflected, transmitted, and converted, and the resulting body and surface waves propagate in the Earth (Gerstoft and Bromirski 2016). The *P* waves penetrated deep into the earth for the super Typhoon Ioke and have been recorded by the SCSN (Southern California Seismic Network) (Fig. 2a), allowing source localization with array processing. One application is the quantification of cyclones, by using the amplitude of seismic waves (Fig. 2b, Farra et al. 2016). The temporal discernible trends in the increase of the hurricane frequency or energy during the last decade can be monitored by their seismic signature.

Using machine learning algorithms such as blind source separation technique, it is also possible to measure travel times from individual strong sources in the diffuse seismic wavefield (Meschede et al. 2019). This method enables to determine the mantle structure along paths usually not sampled by tectonic earthquakes and has promising application for ocean bottom networks (Fig. 3).

Landslides

Landslides are generally unpredictable and inaccessible processes, but their signature is available in the form of seismic waves (Kanamori and Given 1982; Kawakatsu 1989). The same seismic approach was also followed for avalanches (Lawrence and Williams 1976). Indeed, as landslides travel down the slope, the flowing mass apply a time varying force to the topography that generate waves in a broad frequency range (0.005–50 Hz). These waves are recorded at distances up to 1000 km from the source depending on the landslide volume (m^3 to km^3) and the frequency. Beyond mere detection and localization of landslides, exploitation of this amazing amount of high-accuracy wave data provides unprecedented clues to flow characteristics and dynamics (Hibert et al. 2011; Moretti et al. 2012). This is, however, a highly challenging issue because of the complexity of natural processes and of their subtle and intricate imprint on wave characteristics. The sources of the generated waves are highly sensitive to the dynamic history of landslides, which itself depends on landslide characteristics (volume, topography, fluid content, etc.) and on the physical processes involved (friction of the sliding material, collision of particles with the ground, erosion/deposition, etc.). As a result, detailed information on landslides dynamics can only be obtained by comparing the recorded waves with accurate modeling of the source processes and wave propagation.

The low frequency source of landslide-generated waves ($f < 1$ Hz) results from the mean acceleration/deceleration of the flowing mass (Brodsky et al. 2003), while the high frequencies are related to particle-scale force variations (Farin et al. 2018). Indeed, the huge energy released by a landslide at large scale breaks down into increasingly fragmented mass movements, generating different types of seismic waves. The energy is thus dissipated across a granular medium at

Seismology and Environment, Fig. 1 Left: example of Seismogram from a glacial earthquake in Alaska (4 September 1999, 15:15:20.0) (top two traces) compared to a nearby, tectonic, $M = 4.2$ earthquake (bottom two traces) recorded at comparable distances. For each trace pair, top shows broad-band (BB) (0.00833 to 20 Hz) velocity record, and bottom shows filtered long-period (LP) (0.01 to 0.2 Hz) velocity record. Vertical scale is shown by labeled height of line on right. The seismograms are aligned at the predicted P -wave arrival time (Ekström et al. 2003). Middle: localization of one glacial earthquake in Greenland by time-reversal method from broadband seismic records (Larmat et al. 2008). Right: source time function of glacial earthquake on the three-component derived from broadband seismic network in Greenland (Sergeant-Boy et al. 2016)

Seismology and Environment, Fig. 2 (a) The Super Typhoon Ioke in the Pacific ocean from 22 August to 7 September 2006 has been tracked by the National Hurricane Center (blue line), tracks Ioke-generated P wave sources (red) using the Southern California Seismic Network

(SCSN). Locations of P wave sources (red hexagons) and storm centers (blue circles) are marked every second day (Gerstoft and Bromirski 2016). (b) Observed (red) and modeled (black) amplitude of the P -waves generated by the Super typhoon Ioke (Farra et al. 2016)

Seismology and Environment, Fig. 3 (a) (left) Mt. Meager landslide deposit and (right) numerical simulation of the flowing mass at time 120 s (Moretti et al. 2015). The arrows represent the simulated velocities (in red), the velocity (around 40 m/s) of the center of mass (in white), and the horizontal force that the landslide applied to the ground, simulated and inverted from seismic data (in black and orange respectively). The color scale represents the thickness of the flowing mass, and the Capricorn glacier is shown in violet. (b) Sensitivity of the time evolution of the

force to the friction coefficient used in the model. The red line corresponds to the best inverted force and the pink area is the confidence interval, while the black line corresponds to the best simulated force. (c) Friction coefficient that best fits observed deposits (symbols) of landslides on Earth and other planets and that best reproduces seismic data (rectangles with dimensions corresponding to the estimated error on this friction coefficient) (Lucas et al. 2014)

intermediate scales down to the grain scale. Even if, during a landslide, the energy transmitted into seismic waves E_s is much smaller than the loss of potential energy of the granular mass ΔE_p ($E_s \approx (10^{-3}-10^{-6}) \Delta E_p$), it is high enough to be measured by seismometers (Deparis et al. 2008; Levy et al. 2015).

Extensive research has been carried out to extract detailed information on landslide characteristics from low frequency

seismic waves because their inversion makes it possible to calculate the time history of the force exerted by the landslides to the ground (Kanamori and Given 1982). This is however not possible with high frequency seismic waves because of their high sensitivity to topography and Earth properties variations during their travel from the source to the station. However, empirical relations relating landslide characteristics (volume, friction coefficient, velocity, etc.) to high frequency

seismic signals have been proposed (Hibert et al. 2011; Dammeier et al. 2011). Laboratory experiments on granular flows and generated waves have recently provided insight into the physical origin of these relations (Farin et al. 2019).

Unique strategies for landslide detection, quantification, and monitoring can be designed from seismic data analysis (Chao et al. 2017), making it possible to investigate the link between landslide activity and meteorological, climatic, seismic, or volcanic activity. As an example, based on these seismic approaches, Durand et al. (2018) showed the stability of volcanic craters can be inferred from rockfall activity and that rockfall characteristics may be an indicator of the location of future volcanic eruptions.

New Challenges

The new field of environmental seismology makes it possible to provide some key elements on the global change: For example, the increasing number of glacial earthquakes enables us the quantification of ice loss. The continuous monitoring of physical parameters of landslides and the analysis of tropical cyclone through microseisms can provide new insight in temperature, hydrology, and in processes of shallow subsurface and critical zone (thin outer layer of the Earth's surface). As these seismic signals are recorded continuously, their analysis in terms of physical processes involved, makes it possible to relate natural events' characteristics to external forcing such as meteorological (Stopa et al. 2019), climatic, volcanic, or seismic activity (e. g., Durand et al. 2018). This is particularly important nowadays as climate change strongly increases the risks associated with landslides, and glacier ice mass loss in mountainous, polar, and coastal regions (IPCC).

The distinction between anthropic seismology and environmental seismology is minor, since they are both rapidly growing fields addressing similar issues on the spatial and temporal evolution of our environment and using seismic signals previously considered as noise. Particularly challenging is the joint quantitative interpretation of high frequency and low frequency data. New efforts are made to develop methods making it possible to recover quantitative physical processes from the generated seismic waves. A key element of these efforts relies on the improvement of fluid and solid mechanical models used to interpret seismic data, providing unique opportunities to discriminate the intricate physical processes involved at the source of the waves.

Definition

- | | |
|----------------|---|
| Exposure | Elements at risk; an inventory of those people or artifacts (and their characteristics) that is exposed to a hazard. |
| Seismic hazard | A potentially damaging physical event, a phenomenon induced by an earthquake that may cause loss of life or injury, property damage, social and economic disruption, or environmental degradation. Seismic hazards can be single, sequential, or combined in their origin and effects. Each hazard is |

Vulnerability	characterized by its location, intensity, frequency, and probability (https://www.unisdr.org/we/inform/terminology). The conditions determined by physical, social, economic, and environmental factors or processes, which increase the susceptibility of an individual, a community, assets, or systems to the impacts of hazards (https://www.unisdr.org/we/inform/terminology).
Seismic risk	The probability of harmful consequences, or loss of life or injury, property damage, social and economic disruption, or environmental degradation, resulting from interactions between seismic hazards and vulnerable conditions.

Introduction

The assessment and subsequent mitigation of earthquake risks is among the ultimate goals of both seismology and earthquake engineering. During the last two decades, these goals have never been more important and relevant due to rapid urban development and the rise of megacities in earthquake-prone areas which have considerably increased the seismic risk worldwide (Fig. 1).

Seismic risk models are needed for accurate assessment of risks by scientists, engineers, and practitioners, in order to promote risk reduction and mitigating actions, such as

improvement of building codes and construction practices, sustainable land use, emergency response, and protection of critical infrastructures. Risk models are also essential for input to risk financing mechanisms, including catastrophe risk insurance and bonds which are needed to expedite disaster response and recovery efforts and to complement risk reduction and mitigation activities.

The GEM Initiative

In response to this challenge, the Global Earthquake Model (GEM) was put forward in 2006 during the 11th OECD Global Science Forum in Germany. Scientists and engineers realized that such an initiative was needed in order to establish an independent, uniform, and openly accessible standard to calculate and communicate seismic risk worldwide and to develop much-needed tools and software as well as databases for reliable and transparent seismic risk assessment globally. At that time, seismic risk models did not exist for most of the world, and where they did exist, they were not widely or openly accessible.

The GEM Foundation

To ensure that the scientific ambitions and the global seismic risk reduction goals of the GEM initiative are realized, an international community of scientists and professionals bonded together to form the GEM Foundation in 2009 as a nonprofit organization in Pavia, Italy, supported by a public-private sponsorship with a vision to create a world that is resilient to earthquakes.

Seismology, Global Earthquake Model, Fig. 1 Global hazard map with top 15 countries in terms of average normalized annual economic losses (AAL), 2018

In Working Program 1 (2009–2013), GEM focused: (1) on the development of a set of global databases and guidelines to support earthquake hazard and risk assessment; (2) on developing an international collaboration network of scientists and engineers across public, private, and academic sectors; and (3) on developing open earthquake hazard and risk assessment software and tools, and disseminating them globally.

In Working Program 2 (2014–2018), GEM focused on developing major application products, including a global compilation of earthquake hazard and risk models. The OpenQuake suite, launched in Jan 2015, provides free, public access to GEM's open-source earthquake hazard and risk analysis software (OpenQuake Engine) (<https://www.globalquakemodel.org/oq-get-started>), GEM's collection of national and regional-scale open-source earthquake hazard and risk models, and tools for use in building the models. In December 2018, GEM released global earthquake hazard and risk maps, which are based on a mosaic of national and regional models developed and/or implemented using the OpenQuake Engine.

In the third Working Program (2019 onwards), GEM is focused on: continuous improvement and release of the mosaic of national and regional models, including for public and commercial applications; on leveraging its expertise in earthquakes to multi-hazard risk analysis of natural hazards; on extending risk assessment information into decision-making tools for risk reduction and mitigation at national to local scale; and on capacity building assistance with emphasis on developing countries.

Scientific Framework

The GEM scientific framework serves as the underlying basis for constructing hazard and risk models, and consists of interdependent components (Fig. 2: Scientific Framework): seismic hazard; exposure; physical vulnerability;

physical seismic risk; and socioeconomic vulnerability and resilience (SVR).

Physical seismic risk is defined as a product of the following: seismic hazard (the probability of levels of ground shaking, resulting from earthquakes, within a given time span); exposure (the elements at risk – mainly buildings, critical infrastructure, and humans); and seismic vulnerability (the probability of loss given a level of ground shaking).

Earthquakes, however, have an impact that goes beyond physical damage or casualties. Earthquakes can severely damage the economy and influence society and social well-being. The addition of the SVR component aims to analyze and understand the various socioeconomic factors that may exacerbate the impact of an earthquake, including the ability of communities to fully recover.

The understanding of physical seismic risk combined with socioeconomic vulnerability and resilience is what GEM calls integrated seismic risk – a holistic understanding of the effects of earthquakes that can directly support decision making on short-term needs after an event (relief, shelter); medium-term needs (recovery and reconstruction); and long-term needs related to policies on risk mitigation.

Institutional Framework

The formation of the GEM Foundation and the global collaboration network to develop the Global Earthquake Model has been a cooperative public-private initiative, composed of national governments, private organizations, research institutions, international organizations and global risk initiatives, NGOs, and individuals.

The partnership includes a number of authoritative global institutions, such as the Organisation for Economic Co-operation and Development (OECD), the International Association of Seismology and Physics of the Earth's Interior (IASPEI), the United Nations Educational, Scientific and

Seismology, Global Earthquake Model,
Fig. 2 GEM scientific framework

Cultural Organization (UNESCO), and the United Nations Office for Disaster Risk Reduction (UNDRR). It includes organizations or ministries representing many national governments, such as Australia, Canada, Great Britain, Colombia, Germany, Japan, Nepal, New Zealand, Singapore, Switzerland, and the United States, and a number of prominent private corporations from the financial, engineering, energy and risk consulting/modelling sectors, as well as academic institutions worldwide (Fig. 3).

Moreover, there are hundreds of institutions, organizations, and individuals involved in GEM that contribute expertise, data, or software, participate in regional programs, and take part in reviews and public assessments. Participation of individuals and institutions worldwide ensures that the earthquake models, information, and tools are owned and trusted by all relevant sectors, as well as global to local communities, and reflects their needs and knowledge (Fig. 4). For example, IASPEI has endorsed the GEM collaboration network and scientific products through formal resolutions in 2009 (<http://www.iaspei.org/documents/resolutions-statements>) and 2015 (<http://www.iaspei.org/documents/resolutions-statements>).

Milestones and Scientific Products

The Global Earthquake Model

The objective of developing the Global Earthquake Hazard and Risk Model was a key priority for GEM under its 2014–2018 work program. The objective is to collaboratively develop a complete set of earthquake data and models, and to deliver a comprehensive global assessment of earthquake risk. GEM released the first version of the model on December 5, 2018. The OpenQuake Engine was used to calculate all of the risk and hazard values for the global maps.

Global Earthquake Hazard

The Global Seismic Hazard Map (<https://www.globalquake-model.org/gem>) (version 2018.1) depicts the geographic distribution of the peak ground acceleration (PGA) with a 10% probability of being exceeded in 50 years, computed for reference rock conditions (shear wave velocity on the top 30 m, V_{30} , of 760–800 m/s).

The map was created by collating maps computed using national and regional probabilistic seismic hazard models

Seismology, Global Earthquake Model, Fig. 3 GEM collaboration network, 2018

Seismology, Global Earthquake Model, Fig. 4 OpenQuake Platform users, 2018

Seismology, Global Earthquake Model, Fig. 5 Global earthquake hazard map, 2018

developed by various institutions and projects, and by GEM Foundation scientists (Fig. 5).

Global Earthquake Risk

The Global Seismic Risk Map (<https://www.globalquake-model.org/gem>) (v2018.1) is comprised of four global maps: global seismic hazard (PGA 10% exceedance in 50 years), global exposure, global average annual loss, and global

fatalities. The main map presents the geographic distribution of average annual loss (USD) normalized by the average construction costs of the respective country (USD/m²) due to ground shaking in the residential, commercial, and industrial building stock, considering contents and structural and nonstructural components (Fig. 6).

The seismic hazard, exposure, and vulnerability models employed in these calculations were provided by national

Seismology, Global Earthquake Model, Fig. 6 Global Earthquake Risk Map, 2018

institutions, or developed within the scope of regional programs or bilateral collaborations. These global maps and the underlying databases are based on best available and publicly accessible datasets and models.

The GEM global hazard and risk maps are dynamic products that will be updated when new datasets and models become available. Releases of updated versions of these maps are anticipated approximately every 2 years.

Technical details on the compilation of the hazard and risk maps and the underlying models are available at <http://globalquakemodel.org/gem>.

Global Social Vulnerability and Integrated Risk Map

GEM will release a global map of social vulnerability and resilience indicators in May 2020, which will complement the current hazard and risk maps. GEM continues to work in an interdisciplinary manner to integrate social, economic, and physical factors into a comprehensive risk measurement framework that takes into account quantitative, top-down, and stakeholder-based bottom-up approaches.

Software and Analysis Tools

At the core of the Global Earthquake Model is the development of state-of-the-art modeling capabilities and a suite of software tools that can be utilized worldwide for the assessment and communication of earthquake hazard and risk. Most of the tools are already embedded in the engine and the platform, but others are released as stand-alone applications.

OpenQuake Engine and Built-In Toolkits

The OpenQuake Engine (<https://github.com/gem/oq-engine#installation>) is GEM's state-of-the-art software for seismic

hazard and risk assessment at varying scales of resolution, from global to local. It can be used on a computer cluster, in the cloud or on a laptop. It is open-source, fully transparent, and can be used with GEM's or user-developed models to carry out scenario-based and probabilistic calculations and produce a great variety of outputs.

The Engine comes with the following built-in toolkits essential for model development:

- Hazard Modeller's Toolkit (<http://docs.openquake.org/oq-hazardlib/stable/openquake.hmtk.html>) – A suite of tools used to create PSHA input models, mostly developed by GEM scientists.
- Risk Input Preparation Toolkit (<https://platform.openquake.org/ipt/>) – Tools used to create exposure, fragility, and vulnerability risk input models.
- GMPE Strong Motion Modeller's Toolkit (<https://github.com/GEMScienceTools/gmpe-smtk>) – Python and OpenQuake-based toolkit for analysis of strong motions and interpretation of GMPEs.
- The Risk Modeller's Toolkit (RMtk) (<https://github.com/GEMScienceTools/rmtk>) is a library of Python scripts and IPython notebooks that provide engineers with tools to create exposure, fragility, and vulnerability input models required for running seismic risk calculations using the OpenQuake engine.

Interactive Global Earthquake Map Viewer Tool

The interactive map viewer (<https://maps.openquake.org/>) is an online tool that consists of three global maps: seismic hazard, seismic risk, and exposure. The global maps can be used to assess different levels of seismic hazard exposure

by country and territory. Users can click on a country to display the annual cost for residential, industrial, or commercial buildings and can download the full profile for any country.

OpenQuake Platform

The Platform (<https://platform.openquake.org>) is a website that allows the community to explore, manipulate, and visualize the datasets and models from the OpenQuake Engine and to use tools that GEM produces. The platform also allows users to contribute, share, and discuss new findings and results with the GEM community.

The Platform also hosts hundreds of vulnerability and fragility functions, and the Building Classification Survey site.

Integrated Risk Modeling Toolkit (IRMT)

The IRMT (<http://plugins.qgis.org/plugins/svir/version/3.7.2/>) is a QGIS plugin that was developed by GEM and co-designed by the Center for Disaster Management and Risk Reduction Technology (CEDIM). The plugin allows users to form an integrated workflow for the construction of metrics used to assess characteristics within societies that affect earthquake risk. It provides a GIS-based platform for the construction of indicators that foster comparative assessments.

Building Taxonomy

The Building Taxonomy is an online glossary that explains around 400 terms contained in the GEM Building Taxonomy (<https://www.globalquakemodel.org/publications>) v 2.0 with nearly 700 images. Users can contribute in the form of photographs or images, illustrating glossary terms.

The purpose of the GEM Building Taxonomy is to describe and classify buildings in a uniform manner as a key step toward assessing their seismic risk.

Building Classification Survey

The Building Classification Survey (<https://platform.openquake.org/building-class/>) is an online tool that allows users to share information regarding the building stock of a given region. The purpose of the tool is to create a detailed inventory of the most frequent building typologies in the world. The site is hosted by the OpenQuake Platform.

Inventory Data Capture Tools (IDCT)

IDCT is a Building Data Capture application for Android phone or tablet and is available for installation via Google Play (<https://play.google.com/store/apps/details?id=org.globalquakemodel.org.idctdo>).

Global Databases

Since 2009, GEM has compiled several global databases on seismic hazard and risk in collaboration with national, regional, and international partners.

Global Instrumental Earthquake Catalogue (1900–2009)

The GEM-ISC catalogue (<https://platform.openquake.org/maps/79>) was developed under the leadership of the International Seismological Centre (ISC). The catalogue is composed of earthquakes with homogeneous locations and magnitude estimates, determined using the same tools and techniques to the extent possible. The magnitude determination and location procedures applied represent a synthesis of state-of-the-art methods. The catalogue is maintained by the ISC (<http://www.isc.ac.uk/>).

Global Historical Earthquake Catalogue and Archive (1000–1903)

The catalogue (<https://platform.openquake.org/maps/80>) and archive provide a global starting point for continuous improvement of historical seismicity both for science and concrete disaster risk reduction (DRR) applications, especially in regional contexts.

Updated Active Fault Database

The GEM Global Active Faults (<https://blogs.openquake.org/hazard/global-active-fault-viewer/>) project is a global dataset of active faults (<https://github.com/GEMScienceTools/gem-global-active-faults>) for seismic hazard assessment as well as research, education, and general interest. This work is ongoing, and a significant portion of the world has already been covered.

Updated Vulnerability Database

The Global Vulnerability Database (<https://platform.openquake.org/vulnerability/list>) is a collection of vulnerability and fragility models for the most common building classes at a global scale. The creation of the database was supported by the United States Agency for International Development (USAID) and other GEM partners from across the globe.

The completion of over 300 functions has addressed the lack of reliable fragility and vulnerability models for many regions of the globe, which are fundamental for seismic risk assessment at various scales.

Global Exposure Database (GED4GEM and GED4ALL)

GED4ALL (<https://www.globalquakemodel.org/publications>) is an open exposure database schema for multi-hazard risk assessment. The database is capable of storing different assets (building stock, lifelines, infrastructure, crops, forestry, livestock, and socioeconomic data), while considering relevant attributes for six natural hazards: earthquakes, floods, volcanoes, strong winds, tsunamis, and drought. The GED4ALL schema is based on the level 2 schema present in GED4GEM (<https://www.globalquakemodel.org/publications>) with extensions and modifications to improve support for multiple perils.

Current Status

GEM is currently working to make GEM tools, products, and scientific knowledge developed over the last 10 years useful for a wide range of disaster risk reduction (DRR) stakeholders, i.e., governments, insurance companies, risk management agencies, NGOs, emergency responders, etc.. GEM collaborates closely with UNDRR to develop the Global Risk Assessment Framework (GRAF) as part of its commitment to develop a global, multi-hazard framework for risk assessment, including the implementation of the Sendai Framework for Disaster Risk Reduction. GEM also provides risk modeling support to the Insurance Development Forum (IDF), which seeks to build resilience and provide insurance protection to governments, institutions, and people most vulnerable to disasters.

GEM strives to deliver lasting effects on the ground in the form of reduced earthquake risk and improved earthquake risk management at local and national levels.

To date, governments from more than 30 countries are using the OpenQuake Engine and GEM products to develop or revise national hazard maps, e.g., Australia, New Zealand, Indonesia, Colombia, Italy, India, etc.. In fact, many of the models contained in the Global Earthquake Model mosaic are already used at national level to update building codes and compute risk at national level.

From the private sector, insurance and reinsurance companies are now using the OpenQuake engine, GEM resources, and technical services to enhance in-house capabilities in seismic risk assessment and model development.

Since 2015, more than 750 risk professionals from more than 90 countries have been trained in seismic hazard and risk analysis using the OpenQuake engine with its built-in toolkits.

GEM's training and capacity development program combined with multi-scale risk assessment projects have enhanced global understanding of earthquake risk; standardized and made information more accessible for disaster management; improved information for insurance pricing; and improved skills in scientific seismic risk assessment.

Future Program

GEM will continue to focus on the development of models and tools for earthquake risk assessment, and on their application at global, regional, national, and local levels. Key activities will include improving the OpenQuake engine with its built-in toolkits and databases, and strengthening our capacity building and user support program.

GEM will also extend its activities to address more complex risk issues, and will collaborate more extensively with other communities to make OpenQuake tools and models useful for multi-hazard risk assessment.

More information can be found at www.globalquake.org.

Seismology, Monitoring of CTBT

Scientific and Technical Advances in Seismology and Their Relevance to CTBT

Zhongliang Wu¹ and Paul G. Richards²

¹Institute of Earthquake Forecasting, China Earthquake Administration, Beijing, China

²Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, USA

Definition

Monitoring of the *Comprehensive Nuclear-Test-Ban Treaty* (CTBT) entails the detection, identification, and characterization of atmospheric, underwater, and specifically underground nuclear tests, and the discrimination of nuclear explosions from other artificial and/or natural events such as quarry blasts and earthquakes (CTBTO PrepComm. 2009a).

Introduction

Matching the needs of the monitoring of CTBT deals with seismic, infrasound, and hydro-acoustic, as well as radionuclide monitoring systems. At present the CTBT verification system specified by the treaty has three major components: the International Monitoring System (IMS) with a global network of 297 certified facilities up to the time of writing/revision (CTBTO PrepComm. 2019a); the International Data Centre (IDC) for the processing of observational data; and an On-Site Inspection (OSI) regime that utilizes a series of high-resolution technologies and has many similarities to the emergency on-site observation of disaster areas such as the meizo-seismal regions of large earthquakes. In this verification system, seismic monitoring has been the leading subject, due to three aspects: (1) Since 1980 up to this time of writing/updating (2019), all nuclear tests have been conducted underground, and seismic monitoring is the most efficient way to monitor tests in that environment. (2) Development of seismic monitoring played the leading role in the development of IMS. Compared to other monitoring techniques, seismic monitoring data, characterized by the real-time transmission of broadband/high-frequency continuous waveforms, aided by the automatic/intelligent algorithms for data processing, plays a major role in the whole monitoring system. (3) Important concepts in CTBT monitoring, including evasion scenarios such as decoupling and mine-masking which are most directly a challenge to seismic monitoring, were directly or indirectly developed from seismic monitoring practice.

Entry *seismic monitoring of nuclear explosions* describes in detail the basic properties of explosion and earthquake signals and seismological technologies for the detection and identification of explosions. The main tools for such a monitoring purpose, local, regional, and global seismographic networks, are introduced in the entry *seismological networks*. Sections following focus on recent scientific and technical advances in seismology and their relevance to CTBT monitoring.

Evaluation and Design of the Seismic Monitoring System: A Systems Engineering Perspective

Monitoring and verification require an international observational system composed of the following components: observational stations, communication links from the stations to data center/s, and tools for the analysis of signals recorded for verification purposes. The evaluation and design of the seismic monitoring system from the perspective of systems engineering is one of the significant advances in recent years. It is useful not only for the functioning and sustainability of the CTBT monitoring system but also for the operation of modern seismological networks,

which not only record earthquakes but also have missions such as the fast seismological information service and the managing of huge amount of observational data. In 2009 the Project “International Scientific Studies of the Implementation of the CTBT Verification System” (ISS) was organized by the Preparatory Commission of CTBT Organization (CTBTO PrepComm. 2009b), in which *system performance evaluation* provided useful tools for the evaluation and design of the seismic monitoring system. In the following biennial Science and Technology Conference series since 2011 (CTBTO PrepComm. 2019b), *system performance evaluation* kept being one of the important themes under discussion.

Evaluation is to assess the readiness and capability of the monitoring and verification system, while design is to plan the road-map to ensure the expected readiness and capability. Design and evaluation of a seismological monitoring system includes four perspectives: (1) *physical perspective*, including primary seismographic stations and arrays, auxiliary stations, national data centers, international data center, network maintenance centers, communication links, system for the automatic data processing and review of analyst, database, and data sharing devices; (2) *functional perspective*, including data transmission, automatic data processing, automatic seismic phase picking and event location, interactive phase picking and location by analysts, array processing for location, magnitude determination, determination of earthquake parameters such as moment tensor and radiated energy, discrimination tools, and tools for routine evaluation of the state-of-health; (3) *operational perspective*, including the design, implementation, management, and upgrading of the whole system; and (4) *scientific perspective*, dealing with Earth structure model, travel time database, algorithm for location and phase picking, attenuation model and site correction for magnitude determination, Green functions or attenuation relations for source parameter determination, azimuth correction database for array detection, and event database for discrimination. It may be unnecessary for a seismologist to directly use the concepts and tools of systems engineering. However, methodologies such as specification of the system and its components as well as the relationships among the components, specification of the functions of the system and decomposition of system functional requirements into component functional requirements, and development of measures of performance at system level and component level, respectively, provide a clear concept for the systematic evaluation and design of the seismic monitoring system. This becomes especially important when dealing with a modern seismological monitoring system with many stations, working continuously in a real-time mode, being a technically complex system.

Advances in Seismology, Potentially Relevant to CTBT Monitoring

Recent decades have witnessed the fast development of seismology (*Seismological Grand Challenges* Writing Group 2008). These advances have apparent relevance to CTBT monitoring. Location of earthquake epicenters using conventional methods has the uncertainty of up to 10^1 to 10^2 km. This uncertainty is significantly reduced by the modern methods of earthquake location using waveform cross-correlation and relative location technique (Richards et al. 2006). Investigation reveals that “repeating earthquakes,” identified by waveform cross-correlation, seem to be much more common than expected in seismic activity (e.g., Schaff and Richards 2004), providing the evaluation of location accuracy with an innovative and efficient tool (e.g., Jiang et al. 2014). Recent studies show that even with a very sparse set of stations, the location precision can be obtained even at the level of tens of meters, for a cluster of events that were closely-spaced (Slinkard et al. 2016; Schaff et al. 2018). Moreover, by waveform comparison and relative location, it becomes possible for seismologists to determine the accurate location of new tests if data from previous nearby tests is available (e.g., Wen and Long 2010). As archives grow, new seismic events that appear problematic often can best be resolved by comparison of their signals with those of previously recorded events from the same region.

In the evaluation of location accuracy, one of the key concepts is the *ground truth* (GT) *events* (International Seismological Centre 2019), a database of reference earthquakes and/or explosions for which the epicenter information is known with high confidence (to ± 5 km or better) with seismic signals recorded at regional and/or teleseismic distances. GT events are used as “calibrating information” to assess the location accuracy of the monitoring system. Furthermore, a GT database is useful to facilitate better visualization of Earth structure, better modeling of velocities of seismic waves, and more accurate travel time determinations, which are all essential to the enhancement of monitoring capability. Using and developing the GT event database is thus endorsed by international seismological organizations such as the International Association of Seismology and Physics of the Earth’s Interior (IASPEI 2009).

Seismology is a practice-oriented branch of observational science, in which the automated processing of multiple seismic signals to detect and localize seismic events is a central tool. Recent development of seismology has been manifested by its fast enhancement of the capability of observation and data processing, partly due to the advances in information technology. In this field, great progresses have been made, among which, directly related to CTBT monitoring, is the NET-VISA approach to generating a bulletin of seismicity (Arora et al. 2013). It took about 10 years

(2009–2019) to bring the concept to the point of implementation. The up-to-date results showed that it not only does just about as well as is possible for a bulletin-generating process based upon use of phase picks, but also appears to perform even better than a trained analyst (CTBTO PrepComm. 2019b). Related to this field, in recent years, seismographic networks in different regions developed their own algorithms for automatic phase picking, location, magnitude determination, and moment tensor inversion, respectively. Meanwhile, machine learning (ML) has been playing an increasing role in the data-driven studies in geosciences (Bergen et al. 2019), potentially reshaping the technical skyline of seismograph networks and data centers.

Recent developments of seismology kept changing some of the conventional ideas well accepted in the CTBT monitoring practice. At present, there are several complementary methods for the identification of an explosion from an earthquake, such as the difference between m_b and M_s , and the ratio of high-frequency (>2 Hz) P to S energy (Richards and Zavales 1990; Bowers and Selby 2009). One of the important measures is the minimum size of earthquakes and/or explosions for the discrimination, called the *magnitude threshold*, below which the discrimination tool fails to work. Conventionally the *magnitude threshold* for discrimination is regarded as different from, often 0.5 magnitude unit larger than, the *magnitude threshold* for detection (Hannon 1985). However, new results (CTBTO PrepComm. 2009b) showed that these thresholds appear to be very similar if regional data, adequate for measurement of spectral ratios, is available. For purposes of estimating the location and yield of underground explosions, it is always important to have accurate information on the inhomogeneous structure of the Earth within which seismic waves propagate. New approaches to this problem using seismic noise (e.g., Shapiro et al. 2005) provide an innovative tool for imaging the Earth structure. Increasing of seismic stations and development of inversion techniques kept improving the Earth structure model (*Seismological Grand Challenges* Writing Group 2008). Accordingly, traditionally problematic earthquake parameters such as focal depth and “modern” earthquake parameters such as moment tensor and radiated energy potentially can contribute more to CTBT monitoring, along with improved 3D Earth models, and accurate account of wave propagation in complex 3D media.

With the development of digital seismic waveform analysis techniques, it has also become possible for seismologists to capture the time lapse behavior of Earth medium with considerable accuracy (e.g., Grêt and Snieder 2005). Combining with the recent advances in active source technology, this development in turn has direct impact on the OSI technology. Combination of seismic data with remote sensing images shows potential in revealing more details of the explosion source, such as decoupling (Sykes et al. 1993).

This combination, enabled by modern information technology such as “Digital Earth” (Wu and Chen 2000; International Society for Digital Earth 2019), or more practically Google Earth®, provides an alternative approach that supplements the traditional concepts of OSI and even verification.

The advancement of seismic monitoring has been tested by several cases of underground nuclear tests, such as the series of announced tests from 2006 to 2017 carried out by the Democratic People’s Republic of Korea (DPRK). Recent results from the DPRK tests show that high precision relative location methods using geodetic constraints allow the determination of nuclear test epicenters (latitude and longitude) with precision of the order of 100 m (Xie and Zhao 2018; Walter and Wen 2018); with a precise epicenter known and coupled with satellite imagery, the burial depth, an essential event parameter for yield estimate of a nuclear test, can be accurately determined. Additionally, secondary sources accompanying a test (such as a cavity collapse, and explosion-induced aftershocks) can be characterized (Han et al. 2017).

“Forensic Seismology”: Evidences and Judgments

Seismology is a branch of observational science based on the analysis of signals from different sources, penetrating through the Earth, and at last recorded by seismic networks. The field related to seismological observatory practice (Bormann 2002) and the operation of seismic networks is sometimes called *seismological observation and interpretation* (IASPEI 2019). When seismology is applied to the monitoring of CTBT, more considerations are needed beyond the recording and analysis of seismic signals. Key concepts related to the practical functioning of the seismic monitoring system are *monitoring* and *verification*. The term *monitoring* refers to technical activities and analyses associated with objective data from observational systems that acquire signals from different sources, either explosions or earthquakes, in a continuous and, in some cases, real-time, regime. The term *verification* refers to evaluations that include non-seismologists, to enable authorities and the public to judge whether some detected phenomena had its origin in a nuclear explosion. To this end, *verification* is regarded as a branch of *forensic seismology* (Bowers and Selby 2009), in which the word “forensic” means answering questions of interest to (international) legal system/s.

In concept, *monitoring* is different from *verification* in that *monitoring* basically provides objective observational evidences, while *verification* has to have some subjective decision-making processes based on the objective (but in some cases limited) evidences provided by monitoring. Examples of this distinction arise from the six nuclear tests (from 2006 to 2017) conducted and announced by the DPRK.

Seismic signals can be used to distinguish between earthquakes and underground nuclear test explosions, but not between underground nuclear and chemical explosions if, unusually, all the chemical energy is released at essentially the same time and place. For the DPRK's announced tests, all of them clearly recorded by seismic networks, direct (radionuclide) evidence was lacking for some tests, so whether they were chemical or nuclear events remains a question. Another example is the series of nuclear tests in May 1998 carried out by India and Pakistan, for which seismic monitoring data could not provide persuasive evidence that *all* the tests were conducted as successfully as announced. In fact, however, the monitoring system works well for the clarification of special events, such as the earthquake near Lop Nor of China on March 13, 2003 (Bowers and Selby 2009). In practice, an important task of the seismic monitoring system is to *screen* events of interest, to identify events that are definitely not nuclear tests. Note that in the context of forensic science, to verify that a nuclear test has been conducted somewhere and to verify that no nuclear test has been conducted in a certain place for a specific time duration, even when using the same monitoring system, need different sets of evidence from that system.

Concluding Remarks: Interaction Between Science and CTBT Monitoring

The concept of seismic monitoring of nuclear tests can be traced back to the earliest underground nuclear explosions (Bolt 1976; Richards and Kim 2009). In September, 1957, during the General Assembly of the International Union of Geodesy and Geophysics (IUGG), Toronto, K. E. Bullen gave the address "Seismology in our Atomic Age." Needs of nuclear test monitoring played an important role in the development of global seismic networks in the 1960s (Richards 2002). In the meantime, effective techniques have been developed for processing the data from an array of seismometers spread over a few kilometers (Husebye and Mykkeltveit 1981; Richards 2002), enabling the work of monitoring for explosions significantly smaller than those that can be monitored by conventional stations (Douglas 2002).

In recent years, the international CTBT monitoring system, which includes the use of multiple seismometer arrays, has been in operation as a "big science device" that is similar in scale to accelerators in high-energy physics and satellites in space science. It provides not only experiences and lessons in the practice of monitoring, but also unique datasets that are used for basic research and the science and technology for sustainability. Advances in science and technology also promote the implementation and development of CTBT monitoring practice, and assessments of the overall capability. In the above sections, these relevant

advances are introduced via three components: *engineering*, *science and technology*, and *decision-making*. Not discussed above but importantly for future, new studies of the application of fiber-optic cables (Marra et al. 2018; Jousset et al. 2018) have provided seismological monitoring with a brand new type of sensor and an expanded system of observation. The impact of the innovative technologies on CTBT monitoring is hard to predict but noticeable.

It is worth mentioning that, as indicated by a series of important events, especially the Conference "CTBT: Synergies with Science, 1996–2006 and Beyond" (CTBTO PrepComm. 2006), the ISS Project (CTBTO PrepComm. 2009b), and the Science and Technology Conference series followed (CTBTO PrepComm. 2019b), a new era of cooperation between CTBT monitoring communities and scientific research communities has started, which will in turn contribute both to the CTBT monitoring practice and to the development of geophysical science. Starting from the ISS Project, *science and technology foresight*, a professional practice that emerged in recent years, aiming at identifying today's research and innovation priorities on the basis of scenarios of future developments in science and technology, society, and economy, has been introduced to the scientific assessment of CTBT monitoring, which indicates that the interaction between science and CTBT monitoring has started to be systematic and comprehensive, through a professionally planned road-map.

Seismology, Rotational

William H. K. Lee

U.S. Geological Survey, Menlo Park, CA, USA

Definition

Rotational seismology is an emerging study of all aspects of rotational motions induced by earthquakes, explosions, and ambient vibrations. The subject is of interest to several disciplines, including seismology, earthquake engineering, geodesy, and Earth-based detection of Einstein’s gravitation waves.

Introduction

Rotational effects of earthquake waves together with rotations caused by soil-structure interaction have been observed for centuries (e.g., rotated chimneys, monuments, and tombstones relative to their supports). A summary of historical examples of observations on earthquake rotational effects is provided by Kozák (2009), including reproduction of the relevant sections from Mallet (1862) and Reid (1910). Figure 1a shows the rotation of the monument to George Inglis (erected in 1850 at Chatak, India) as observed by Oldham (1899) after the 1897 Great Shillong earthquake. This monument had the form of an obelisk rising over 60 ft. high from a base 12 ft. on each side. During the earthquake, the topmost six-foot section was broken off and fell to the south and the next nine-foot section was thrown to the east. The remnant is about 20 ft. in height and is rotated about 15° relative to the base.

A few early authors proposed rotational waves or at least some “vortical” motions. Many different terms were used for

Seismology, Rotational,

Fig. 1 (a) Rotation of the monument to George Inglis (erected in 1850 at Chatak, India) as observed by Oldham (1899) after the 1897 Great Shillong earthquake. (b) Coordinate system for translational velocity. (c) Coordinate system for body-fixed or instantaneous rotational rate

the rotational motion components at this early stage of the field's development. For example, "rocking" is rotation around a horizontal axis, sometimes also referred to as "tilt." Mallet (1862) proposed that rotations of a body on the Earth's surface are due to a sequence of different seismic phases emerging at different angles. Reid (1910) studied this phenomenon, which was observed in the 1906 San Francisco earthquake, and pointed out that the observed rotations are too large to be produced by waves of elastic distortion. Such waves "produce very small rotations, whose maximum amount, . . . is given by the expression $2\pi A = \lambda$, where A is the amplitude and λ the wavelength; with a wave as short as 10,000 feet (3 km) and an amplitude as large as 0.2 of a foot (6 cm), the maximum rotation would only be about 0.25 of a minute of arc [0.0042 degrees, or 7.3 micro-radians (μrad)], a quantity far too small to be noticeable" (Reid 1910, p. 44). A modern analysis of such rotational effects is presented in Todorovska and Trifunac (1990).

Observational seismology is based mainly on measuring *translational* motions because of a widespread belief that *rotational* motions are insignificant. For example, Richter (1958, footnote on p. 213) states that "Theory indicates, and observation confirms, that such rotations are negligible." Richter provided no references, and there were no instruments at that time sensitive enough to either confirm or refute this claim. Recent advances in rotational seismology become possible because sensitive rotational sensors have been developed in aeronautical and astronomical instrumentation. In this article we provide some background information and selected highlights of recent advances in rotational seismology. An extensive list of references to original papers is given because few "synthesis" articles exist.

Early Attempts in Studying Rotational Motions

Ferrari (2006) summarized two models of an electrical seismograph with sliding smoked paper, developed by P. Filippo Cecchi in 1876 to record three-component *translation* motions and also the *torsion* movements from earthquakes. Although these instruments operated for several years, no rotational motion could be recorded because of low transducer sensitivity. Pioneers in several countries attempted to measure rotational motions induced by earthquakes. Nearly a century ago, Galitzin (1912) suggested using two identical pendulums installed on different sides of the same axis of rotation for separate measurement of rotational and translational motion. This was later implemented, for example, by Kharin and Simonov (1969) in an instrument designed to record strong ground motion. Using an azimuthal array of seismographs, Droste and Teisseyre (1976) derived rotational seismograms for rock bursts in a nearby mine. Inspired by Walter Munk, Farrell (1969) constructed a gyroscopic seismometer, and obtained a static displacement of <1 cm and a tilt of <0.5 μrad at La Jolla, California, during the Borrego Mountain earthquake of April 9, 1968 (magnitude 6.5), at an epicentral distance of 115 km.

Early efforts also included studies of explosions. For example, Graizer (1991) recorded tilts and translational motions in the near field of two nuclear explosions using seismological observatory sensors to measure point rotations directly. Nigbor (1994) measured rotational and translational point ground motions directly with a commercial rotational MEMS sensor and found significant near-field rotational motions (660 μrad at 1 km distance) from a one-kiloton explosion.

Rotations and strains of the ground and of response of structures have been deduced indirectly from accelerometer

arrays using methods valid for seismic waves having wavelengths that are long compared to the distances between sensors (e.g., Trifunac 1979, 1982; Oliveira and Bolt 1989; Spudich et al. 1995; Bodin et al. 1997; Huang 2003; Suryanto et al. 2006; Wassermann et al. 2009). The rotational components of ground motion have also been estimated theoretically, using kinematic source models (Bouchon and Aki 1982; Wang et al. 2009) and linear elastodynamic theory of wave propagation in elastic solids (Lee and Trifunac 1985, 1987).

Measuring Rotational Motions

The general motion of the particles or a small volume in a solid body can be divided into three parts: translation (along the X-, Y-, and Z-axes), rotation (about the X-, Y-, and Z-axes), and strain (six components). Figure 1b shows the axes in a Cartesian coordinate system for *translational velocity* measured by the usual seismometers in seismology, and Fig. 1c shows the corresponding axes of *rotation rate* measured by rotational sensors (Evans 2009). These are “body attached” coordinates, those that a seismic instrument would measure at a given instant as the sensors move and rotate through space. Converting an extended record of these body-fixed motions to recover motions in an Earth-fixed, quasi-inertial coordinate system has been performed for decades in “strapped down” inertial navigation systems such as those attached to a moving airplane. Lin et al. (2010) introduce these equations into seismology and earthquake engineering for recovering inertial-frame ground and structure motions.

Rotational ground motions can be measured directly by gyroscopic sensors or inferred indirectly from an array of translational sensors. According to Cochard et al. (2006), in a linear elastic medium the displacement $\mathbf{u}$ of a point $\mathbf{x}$ is related to a neighboring point $\mathbf{x} + \delta\mathbf{x}$ by

$$\mathbf{u}(\mathbf{x} + \delta\mathbf{x}) = \mathbf{u}(\mathbf{x}) + \boldsymbol{\varepsilon} \delta\mathbf{x} + \boldsymbol{\omega} \times \delta\mathbf{x} \quad (1)$$

where $\boldsymbol{\varepsilon}$ is the strain tensor and

$$\boldsymbol{\omega} = 1/2 \nabla \times \mathbf{u}(\mathbf{x}) \quad (2)$$

is a pseudo-vector representing the infinitesimal angle of rigid rotation generated by the disturbance. The three components of rotation about the X-axis, Y-axis, and Z-axis are given by the following equations for such infinitesimal motions:

$$\begin{aligned} \omega_x &= 1/2 (\partial u_z / \partial y - \partial u_y / \partial z), \\ \omega_y &= 1/2 (\partial u_x / \partial z - \partial u_z / \partial x), \\ \omega_z &= 1/2 (\partial u_y / \partial x - \partial u_x / \partial y) \end{aligned} \quad (3)$$

Therefore, rigid rotations can be observed by: (1) an array of translational seismometers indirectly for “cord” rotations

associated with long wave lengths by assuming that contamination of translational signals by rotational motions is small, and that the linear elasticity theory is valid (e.g., Spudich and Fletcher 2008), or (2) rotational sensors directly for “point” body-fixed rotations (e.g., Lee et al. 2009b; Lin et al. 2010).

In the past decade, rotational motions from small local earthquakes to large teleseisms were successfully recorded by sensitive rotational sensors in several countries (e.g., Takeo 1998; McLeod et al. 1998; Igel et al. 2005, 2007; Suryanto et al. 2006; Cochard et al. 2006). In particular, the application of Sagnac interferometry in large ring laser gyros provided greatly improved sensitivity to rotations at teleseismic distances and showed that they are a good match to those estimated from linear elastic wave theory. Such motions provide additional observations that – combined with translations – lead to new approaches to the seismic inverse problem (Bernauer et al. 2009; Fichtner and Igel 2009). Recently Kurrle et al. (2010b) reported the first observations of Earth’s free oscillations using ring laser recordings, and opened up potential applications of rotational seismology at long periods.

In contrast, strong-motion observations near the source in both Japan and Taiwan showed that the amplitudes of these rotations can be one to two orders of magnitude greater than that expected from linear elasticity theory (e.g., Takeo 1998; Lee et al. 2009b). Theoretical work suggests that in shallow granular or cracked continua (e.g., weathered rock at or near Earth’s surface), asymmetries of the stress and strain fields can create rotations separate from and larger than those predicted by classical elastodynamic theory (e.g., Teisseyre et al. 2006, 2008). Unlike the traditional fault-slip model, Knopoff and Chen (2009) consider the case for faulting that takes place on a fault of finite thickness. They show that there is an additional single-couple term in the body-force equivalence and additional terms in the far-field displacement. They also show that the single-couple equivalent does not violate the principles of Newtonian mechanics because the torque imbalance in the single-couple is counterbalanced by rotations within the fault zone, with torque waves being radiated.

Large Ring Laser Gyros

An unexpected advance in studying rotational ground motions came from a different field of geophysics. Recent developments of highly sensitive ring laser gyroscopes to monitor the Earth’s rotation also yield valuable data on rotational motions from large teleseismic events. The most important property that makes such rotation sensors useful for seismology is its very low noise floor and high sensitivity to rotational motions and its insensitivity to translational and cross-rotational motions. The rotation rates expected and

observed in seismology range from the order of 10^{-1} rad/s (e.g., Nigbor 1994; Trifunac 2009) near seismic sources down to order 10^{-11} rad/s for large earthquakes at teleseismic distances (e.g., Igel et al. 2005, 2007). This range spans at least 10 orders of magnitude, 200 dB, much as for translational motions, and it is unlikely that one instrument or one instrumental technology will be capable of providing accurate measurements over such a large range of amplitudes. Ring laser technology is currently the most promising approach to recording the small rotational motions induced by teleseisms, but the primary drawback is its very high cost.

Ring lasers detect the Sagnac beat frequency of two counter-propagating laser beams (Stedman 1997; and Fig. 2c). These active interferometers generally form triangular or square closed loops several meters across and are evacuated. If this instrument is rotating on a platform with respect to inertial space, the effective cavity length between co-rotating and counter-rotating laser cavity differs and one observes frequency splitting resulting in a beat frequency. This beat frequency δf is directly proportional to the rotation rate Ω around the surface normal $\mathbf{n}$ of the ring laser system, as given by the Sagnac equation:

$$\delta f = \frac{4A}{\lambda P} \mathbf{n} \cdot \Omega, \quad (4)$$

where P is the perimeter of the instrument, A its area, and λ the laser wavelength. This equation has three contributions that influence the beat frequency δf : (1) variations in the scale factor ($4A/\lambda P$) have to be avoided by making the instrument mechanically as rigid and stable as possible, (2) changes in orientation $\mathbf{n}$ (tilting relative to Earth's rotation axis) enter the beat frequency via the inner product, and (3) variations in Ω (e.g., changes in Earth's rotation rate and seismically induced rotations). Thankfully, the dominant contribution to δf is Ω . Note that translations do not contribute to the Sagnac frequency unless they affect P or A in some indirect manner.

Ring lasers are sensitive to rotations only, assuming stable ring geometry and lasing. However, for co-seismic observations at the Earth's surface the horizontal components of rotation (i.e., tilts) will contribute to the vertical component of rotation rate. As shown by Pham et al. (2009), the tilt-coupling effect is several orders of magnitude below the level of the earthquake-induced rotational signal unless one is very close to the source (where sensitive ring lasers would not be the appropriate technology).

At present, there are ring laser gyros capable of measuring rotation (induced by small local earthquakes or distant large teleseisms) at four sites: (1) Cashmere cavern, Christchurch, New Zealand (McLeod et al. 1998); (2) Wettzell, Germany (Schreiber et al. 2005); (3) Conway, Arkansas (Dunn et al. 2009); and (4) Piñon Flat, California (Schreiber et al. 2009a).

G Ring Laser and Recording Teleseisms

Since 2001, the “G Ring” laser (capable of measuring rotation rate of about 10^{-10} rad/s) has been operating at the primary geodetic station (Fundamentalstation) at Wettzell, in Bavaria, (<http://www.fs.wettzell.de/>). A cross-sectional view of the site of the G Ring laser is shown in Fig. 2a. The instrument is resting on a polished granite table (Fig. 2b) embedded in a 90-t concrete monument. As shown in Fig. 2a, the monument is attached to a massive 2.7-m diameter concrete pillar and this is founded on crystalline bedrock 10 m below. A system of concrete rings and isolation material shields the monument and pillar from adjacent weathered rock to eliminate its deformation and heat-flow contributions. The G Ring laser is protected against external influences by a subsurface installation with passive thermal stability provided by a 2-m layer alternating between Styrofoam and wet clay, this beneath a 4-m soil mound. A lateral entrance tunnel with five isolating doors and a separate control room minimize thermal perturbations during maintenance. After 2 years of thermal adaptation, the average temperature reached 12.2 °C with seasonal variations of less than 0.6 °C. Figure 2c shows the schematic drawing of instrument, and Fig. 2d is a photo of the G Ring laser with its designer, Ulli Schreiber.

Figure 3 is a comparison of direct point measurements of ground rotations around a vertical axis (red lines) to transverse accelerations (black lines, converted to rotation rate for each time window) for the M8.1 Tokachi-oki earthquake, September 25, 2003 (Igel et al. 2005). Figure 3a is a schematic view of the great-circle-path through the epicenter in Hokkaido, Japan, and the observatory in Wettzell, Germany. 3b–e show the superposition of the rotation rate derived from transverse translations (black) and measured directly (red) for various time windows: Fig. 3b the complete signal, Fig. 3c the latter part of the surface wave train, Fig. 3d the direct *S*-wave arrival, and Fig. 3e for the initial part of the surface wave train. These results confirm the expectation from linear elasticity that the waveforms of transverse acceleration and rotation rate (around the vertical axis) should be identical assuming plane harmonic waves. Information on subsurface structure is contained in the ratio between the corresponding motion amplitudes.

Strong-Motion Inertial Angular Sensors

In aerospace, automotive, and mechanical engineering, smaller rotational-motion sensors are common and generically known as gyroscopic or inertial angular sensors. Nigbor (1994) used a MEMS-based Coriolis rotation-rate sensor to measure the rotational components of strong ground motions close to a large chemical explosion. Similar sensors were used by Takeo (1998) to measure rotational motions from an earthquake swarm ~3 km away. However, such sensors do not have

Seismology, Rotational, Fig. 2 G Ring laser gyro at the Wettzell Superstation, Germany. (a) Cross-sectional view of the instrument site. (b) Instrument resting on a granite table. (c) Schematic drawing. (d) Photo of G Ring laser gyro with its designer, Ulli Schreiber

the sensitivity to record rotations from small local earthquakes (magnitude ~ 4) at distances of tens of kilometers.

The eentecTM model R-1TM rotational seismometer is the first modestly priced sensor capable of recording small earthquakes at distances up to several tens of kilometers. It

uses electrochemical technology in which the motion of an electrolytic fluid inside a torus is sensed electronically, yielding a voltage signal proportional to rotational velocity. Nigbor et al. (2009) carried out extensive tests of commercial rotational sensors and concluded that the R-1 sensor

Seismology, Rotational, Fig. 3 Comparison of direct measurements of ground rotational motions around a vertical axis (red lines) with transverse accelerations (black lines, converted to rotation rate for each time window) for the M8.1 Tokachi-oki earthquake, September 25, 2003

generally meets the specifications given by the manufacturer but that clip level and frequency response vary from those specifications and between individual channels enough that more detailed calibrations are warranted for each unit. A typical transfer function for the R-1 can be found at the manufacturer's website (<http://www.eentec.com/>). The instrument response is roughly "flat" from 0.1 to 20 Hz, and its self noise (rms) is $<10 \mu\text{rad/s}$ over the same frequency band.

The R-1 rotational seismometers successfully recorded several hundred local earthquakes and two explosions in Taiwan (Lee et al. 2009b). Figure 4a shows the instruments deployed at station HGSD in eastern Taiwan (Liu et al. 2009). The top frame is a schematic drawing of the various seismic, geodetic, and strain instruments there. The bottom frame shows the subset of the instruments deployed in the shallow vault at the left hand side of the upper drawing; these include a datalogger (Quanterra Q330), an accelerometer (Kinematics Episensor), a six-channel digital accelerograph (Kinematics K2 with an external rotational seismometer, R-1 by eentec), and a short-period seismometer (Mark Products L-4A). The

K2 + R-1 instrument is at the left hand side, and the yellow-color box is the R-1 rotational seismometer.

The largest peak rotational rate recorded at the HGSD station (to early 2008) is from a M_w 5.1 earthquake at a hypocentral distance of 51 km at 13:40 UTC, 23 July 2007. Figure 4c shows the amplitudes and spectra of translational accelerations recorded by the K2's accelerometer. The peak ground acceleration was 0.47 m/s^2 , and the two horizontal components have much higher amplitude than the vertical. Figure 4d shows the amplitudes and spectra for rotational rates recorded from its external R-1 seismometer. The peak rotational rate was $0.63 \times 10^{-3} \text{ rad/s}$ for the vertical component, much more than that for the horizontal components. The spectra in Fig. 4c show that the dominant frequency band in ground acceleration is about 2–5 Hz (horizontal components) while those in Fig. 4d show that the dominant frequency band in ground rotation rate is about 2.5–5.5 Hz for the vertical component. Other studies report observations with the R-1 sensor and compare their point measurements of rotation to array-derived area rotations (e.g., Wassermann et al. 2009).

seismometer. (c) Recorded translational accelerations (top) and their spectra (bottom) from an M_w 5.1 earthquake 51 km from this site. (d) Recorded rotational rates (top) and their spectra (bottom) from the same earthquake

Discussions

Many authors have emphasized the benefits of studying rotational motions (e.g., Twiss et al. 1993; Spudich et al. 1995; Takeo and Ito 1997; Teisseyre et al. 2006; Trifunac 2006, 2009; Igel et al. 2007; and Fichtner and Igel 2009). We discuss some basic issues briefly.

Linear and Nonlinear Elasticity

Real materials of the Earth are heterogeneous, anisotropic, and nonlinear, especially in the damage zone surrounding faults and in poorly consolidated sediments, soil, and weathered, fractured rock just beneath seismic instruments, particularly typically installed strong-motion instruments. In the presence of significant nonlinearity we are forced to consider

the mechanics of chaos (Trifunac 2009) and to interpret such complexities must record both the rotational and translational components of strong motion.

Seismology is primarily based on the linear elasticity theory, which is applicable to simple homogeneous materials under infinitesimal strain. “Cord” rotation is defined as the curl of the displacement field in Eq. 2, and in the classical elasticity theory, the rotational components of motion are contained in the S waves. Meanwhile, continuum mechanics has advanced far beyond the classical theory. In particular, the elasticity theory of the Cosserat brothers (Cosserat and Cosserat 1909) incorporates (1) a local rotation of continuum particles as well as the translational motion assumed in classical theory, and (2) a couple stress (a torque per unit area) as well as the force stress (force per unit area). In the constitutive

equation of classical elasticity theory there are two independent elastic constants while in Cosserat elastic theory there are six or more elastic constants. Pujol (2009) provides a tutorial on rotations in the theories of finite deformation and micropolar (Cosserat) elasticity. Twiss (2009) derives an objective asymmetric micropolar moment tensor from a discrete-block model for a deforming granular material. He also investigates seismogenic deformation associated with volumes of distributed seismicity in three different geographic areas, and finds support in the micropolar model for the effects of a granular substructure on the characteristics of seismic focal mechanisms.

Near-Field Seismology

Although the observed rotational motions agree well with the classical elasticity theory for teleseisms, it is not the case for local earthquakes. As first noted by Takeo (1998) and confirmed by Lee et al. (2009b), observed rotational rates from local earthquakes are much larger than those predicted from the classical elasticity theory. For example, Bouchon and Aki (1982) obtained theoretically a maximum rotational rate of 1.5×10^{-3} rad/s magnitude 6.5 earthquake, whereas a maximum rotational rate of $>1 \times 10^{-3}$ rad/s for several magnitude 4.5–5.5 earthquakes had been observed in Japan and Taiwan. Takeo (1998) reported the largest rotational rate was 2.6×10^{-2} rad/s around the north-south axis from the second largest earthquake (magnitude 5.2) during the 1997 swarm (at 14:09 UTC, 3 March), east of Cape Kawana, offshore Ito, Japan (about 3 km away). As of the end of 2009, the largest rotational rate recorded at the HWLB station (Hualien, Taiwan) was 2.58×10^{-3} rad/s around the east-west axis from a M_w 6.4 earthquake offshore (at UTC 13:02, 19 December 2009) at a hypocentral distance of about 49 km. The peak rotational rate is 1.57×10^{-3} rad/s around the north-south axis, and 0.68×10^{-3} rad/s around the vertical axis. The corresponding peak ground acceleration is 1.16, 1.85, and 0.50 m/s^2 for the east-west, north-south, and vertical component, respectively.

Figure 5 shows the vertical peak rotational rate versus horizontal peak ground acceleration for the earthquake data set from Takeo (2009) (top frame), and for the earthquake data set (22 August, 2008 to 25 December, 2009) recorded at the HWLB station, Taiwan (bottom frame), where N = number of data points. As noted by Takeo (1998, 2009), there is a reasonable linear relationship in such plots. The data scatter is larger in the Taiwan data than the Takeo (2009) data. This may due to the fact that the earthquake sources for the Takeo (2009) data were from a nearby offshore swarm, whereas the Taiwan data were recorded from many different earthquake sources. Several authors noted similar linear relationships before (see e.g., Spudich and Fletcher 2008; Stupazzini et al. 2009; Takeo 2009; and Wang et al. 2009). In particular,

Takeo (2009) showed “a linear correlation between the maximum rotational displacements around vertical axis and the maximum [ground] velocities.” The two plots in Fig. 5 are equivalent to Takeo’s linear relationship, without performing the integration for the measured rotational rate and ground acceleration to obtain rotational displacements and ground velocities. The linear slope in Fig. 5 has the dimension unit of s/km, or unit for slowness. Spudich and Fletcher (2008) interpreted this “slowness” as the inverse of an “apparent velocity,” characterizing the seismic wavefield beneath the recording station.

Spudich and Fletcher (2008) computed peak values of ground strain, torsions, and tilts for the 2004 Parkfield earthquake (M_w 6.0) and four aftershocks (M_w 4.7–5.1) using the

Seismology, Rotational, Fig. 5 Vertical peak rotational rate (PRR) versus horizontal peak ground acceleration (PGA) for the earthquake data set from Takeo (2009) (top frame), and for the earthquake data set (22 August, 2008 to 25 December, 2009) recorded at the HWLB station, Taiwan (bottom frame). N number of data points

data recorded by an array of accelerators. Takeo (2009) noted that his observations of peak rotation values are about 100 times larger for earthquakes with similar magnitudes and distances, and proposed the following explanations: the different spatial scale of rotational motion by a single-point gyro measurement and by an array observation, the effect of topography, and the difference of the degree of maturation between the San Andreas fault and the swarm volume of offshore Ito. Two arrays of both rotational and translational sensors have been deployed by Wu et al. (2009) in Taiwan to study this discrepancy problem, and hopeful a resolution may be found after recording sufficient numbers of earthquakes.

Using Explosions to Study Rotational Motions

Since a large earthquake occurring near a station is rare, explosions have been used to study rotational motions by several pioneers (e.g., Graizer 1991; Nigbor 1994). Lin et al. (2009) deployed an array of 8 triaxial rotational sensors, 13 triaxial accelerometers, and 12 six-channel, 24-bit dataloggers with GPS time receivers to record two explosions in northeastern Taiwan. These instruments were installed at about 250 m (1 station), 500 m (11 stations), and 600 m (1 station) from the explosions. The 11 stations form a “Center Array” with station spacing of about 5 m. The code name for the first shot with 3000 kg explosives is “N3P,” and that for the second shot with 750 kg explosives is “N3.” Although the N3P shot used four times larger amounts of explosives than that used for the N3 shot, the peak ground translational acceleration and rotational velocity at the 13 station sites from the N3P shot are only about 1.5 times larger than that for the N3 shot. Large variations (by tens of %) of translational accelerations and rotational velocities were observed at the very small Center Array. The largest peak rotational rate was observed for the horizontal transverse component: 2.74×10^{-3} and 1.75×10^{-3} rad/s at a distance of 254 m from the N3P and N3 shots, respectively.

The acceleration data from these two explosions were used by Langston et al. (2009) to compute acceleration spatial gradients, horizontal strains and horizontal rotation, and to perform a gradiometric analysis of the strong ground motion wave train. The analysis yields a complex, frequency-dependent view of the nature of seismic wave propagation over short propagation distances that imply significant lateral velocity changes in the near-surface crustal structure. Areal strain and rotation about the vertical have equal amplitudes and suggest significant wave scattering within the confines of the river valley where the experiment was performed and/or significant departure from an axisymmetric explosion source. Gradiometry shows that the P wave arrives at the array 35° off-azimuth clockwise from

the straight-line path and appears to have been refracted from the northern side of the valley. Chi et al. (2011) successfully recovered the first order features of vertical rotational rate ground motions from the translational velocity waveforms in the 0.5–20 Hz bandwidth using the software of Spudich and Fletcher (2009), and strain as large as 10^{-4} was deduced. To fulfill the uniform rotation assumption in the linear elasticity theory, it is necessary to use a small-aperture array. However, inverting data from an array of small spatial dimension requires accurate waveforms of high signal to noise ratio and high sampling rates; since waveforms from adjacent stations are very similar, small noises have strong influence on displacement gradients due to the small station spacing. The Lin et al. (2009) recordings were limited to 200 samples per second, and much higher sampling rate will be necessary to record explosions in the near field.

Processing Collocated Measurements of Translations and Rotations

Processing collocated observations of rotation and translation is routinely performed in the inertial navigation units of aircraft and other vehicles. A similar analysis is possible for various combinations of strain components, rotations, and translations. With the exception of velocity–strain combinations (e.g., Gomberg and Agnew 1996) this terrain was largely unexplored until the work of Lin et al. (2010), who have demonstrated an appropriate set of these equations for earthquake engineering and seismology to recover inertial-frame displacements and rotations. Further, it is already apparent that rotational motions provide useful additional analysis opportunities, simply put, that more data at a site yield more results.

Phase Velocities and propagation directions. A simple calculation for non-dispersive linear-elastic plane waves with transverse polarization shows that the ratio of transverse acceleration to vertical-axis rotation rate is proportional to local phase velocity. This result implies that information on subsurface velocity structure (otherwise only accessible through seismic array measurements and combined analyses) is contained in any single-point measurement that includes rotational sensors. It has been shown that such ratio-derived phase velocities agree with velocities predicted by theory (Igel et al. 2005; Kurrle et al. 2010a). In a recent theoretical study based on full ray theory for Love waves (normal mode summation), Ferreira and Igel (2009) demonstrated that the Love wave dispersion relation also can be obtained by taking the spectral ratio of transverse acceleration to vertical-axis rotation rate. This result implies that seismic shear wave tomography is possible without requiring sub-arrays to determine local mean phase velocities. Information on the direction of propagation also is contained in the azimuth-

dependent phase fit between rotations and translations; this fit is optimal in the direction of propagation, from which back azimuths can be estimated to within a few degrees (Igel et al. 2007). Linking observational translations, strains, and rotations together also is advocated by Langston (2007) to yield a snapshot of the wavefield including wave direction, slownesses, and radial/azimuthal amplitude gradients independently at each such station.

Toward a new kind of tomography. The possibility of deriving local dispersion relations from single-station records leads to the question of what subsurface volume one resolves and to what depth velocity perturbations can be recovered. The method of choice to answer this type of question is the adjoint method (Fichtner and Igel 2009), with which sensitivity kernels (first Fresnel zones) can be calculated to indicate the volume in which the observable (typically travel times) is sensitive to structural perturbations. Fichtner and Igel (2009) introduced a new observable quantity – apparent shear wave velocity – which is a time-windowed ratio of the moduli of translational velocity and rotation angle. It turns out that the sensitivity near the source vanishes, leading to a new type of kernel that shows high sensitivity only in the vicinity of the receiver and in a somewhat smaller portion of that volume than the kernels of translational motions alone. This result implies that a tomographic inversion for near-receiver structures based on rotations and translations is possible and further highlights the potential of rotation measurements. Synthetic tomographic inversions are given in Bernauer et al. (2009).

Scattering properties of the crust: Partitioning of P and S waves. The partitioning of P and S energy and stabilizing the ratio between the two is an important constraint on the scattering properties of a medium. Igel et al. (2007) discovered surprisingly great rotational energy in a time window prior to teleseismic S , containing the P -coda. Detailed analysis of the signals and modeling of wave propagation through three-dimensional random media demonstrate that these signals can be explained with P - SH scattering in the crust with scatterers of very roughly 5-km correlation length and rms perturbation amplitude of 5% (better constrained). This result further illustrates the efficacy of rotation measurements in their own right, for example, as a filter for SH type motion, as noted by Takeo and Ito (1997).

Similar processing steps will be possible for the horizontal components of rotation and the corresponding components of translation, both to reduce the effects of tilt on the horizontal translational sensors and to extract new information. It is conceivable that the combination of these various components might lead to tight constraints on near-receiver structure, results otherwise only available from array measurements.

Conclusion

Seismology has been very successful in the *far field* because large (magnitude >6) earthquakes occur every week somewhere on Earth, and because classical elasticity theory works very well for interpreting the recorded *translational* motions at large distances. Because of this success and limited instrumentation options, most funding for earthquake monitoring historically has gone into global and regional seismic networks using only translational seismometers. However, to improve our understandings of damaging earthquakes we must also deploy rotational and translational instruments in the *near field* of active faults where potentially damaging earthquakes (magnitude >6.5) occur *infrequently*. For strong-motion seismology and engineering, this is a risky business because a damaging earthquake on any given fault may not take place for hundreds of years. Recording ground motions in the near field would require extensive seismic instrumentation along some well-chosen active faults and luck.

Ring laser observations at Wettzell, Germany, and at Piñon Flat, California, demonstrated consistent measurements of rotational ground motions in the *far field*. So far this success can only be demonstrated with one component of rotation. The high cost of present high-precision ring laser gyros makes widespread deployment unlikely. Less expensive and/or less sensitive alternatives are now being pursued by five academic groups (Cowsik et al. 2009; Dunn et al. 2009; Jedlička et al. 2009; Schreiber et al. 2009b; Takamori et al. 2009). As of the end of 2009, only Taiwan has a modest program (Lee et al. 2009b) to monitor both translational and rotational ground motions from local and regional earthquakes at several permanent seismic stations, as well as by two arrays in a building and a nearby free-field site. These two arrays are designed to “capture” a repeat of the 1906 Meishan earthquake (magnitude 7.1) in the *near field* with both translational and rotational instruments (Wu et al. 2009).

Based on the developments described in the BSSA Special Issue on rotational seismology and engineering (Lee et al. 2009a), observation, analysis, and interpretations of both rotational and translational ground motions will soon play a significant role in seismology and earthquake engineering. An international working group on rotational seismology (IWGoRS) was organized in 2006 to promote investigations of rotational motions and their implications, and for sharing experience, data, software, and results in an open Web-based environment (Todorovska et al. 2008). Anyone can join IWGoRS at <http://www.rotational-seismology.org>, subscribe to the mailing list, and contribute to the content (publications, data, links, etc.). Rotational

seismology is also of interest to physicists using Earth-based observatories for detecting Einstein's gravitational waves (e.g., Lantz et al. 2009) because they must correct for the underlying Earth motion.

Sentinel Satellites Initiate New Era in Earth Observatories

The European Space Agency's Josef Aschbacher Talks with Eos About the Sentinel Fleet of Earth Observing Satellites

Randy Showstack

American Geophysical Union, Washington, DC, USA

Independent Journalist, Washington, DC, USA

With the European Space Agency's (ESA) Sentinel-1A satellite entering into its operational phase in the summer of 2014, it ushered in a new series of Earth observation satellites. The first generation of the fleet of satellites, which will total 20 when all are launched, will comprise "the most comprehensive Earth observation system worldwide," according to Josef Aschbacher, head of program planning and coordination for ESA's Earth Observation Programs directorate. The satellites are a key part of Copernicus, the European Earth Observation Program that from 1998 to 2012 was called the Global Monitoring for Environment and Security (GMES) program.

Aschbacher spoke with *Eos* about Copernicus, which is a joint initiative of the European Commission and ESA; the Sentinel fleet of satellites; free and open data access; and the relationship between the Sentinels and some other Earth-observing satellites.

He told *Eos* that because of the resolution scale and the way the Sentinels are built, they will be used mostly for environmental applications. "Literally, it is for the benefit of mankind," he said of the Sentinel fleet. "The biggest hope is to have an everlasting observation system based on Earth observation data that provides all these observations, ad infinitum, eternally, in order to serve many disciplines on our planet, from agriculture to marine science to climate change to forestry to security to disaster management and so on."

The Copernicus program includes space, services, and in-situ components, with the space component comprising about 80% of the budget, he explained. Within the space, component are the Sentinels and the use of other data from contributing missions available on the market for free or on a commercial basis.

The Sentinel Satellites

Sentinel-1A, which was launched on 3 April 2014, is a polar-orbiting radar mission with a 5-m ground range resolution and a 12-day orbit repeat cycle at the equator. Its applications

comprise land and ocean monitoring, including sea ice detection, oil spill monitoring, ship detection and tracking, and flood mapping. Even with the satellite still in its commissioning phase, it already was useful for some important monitoring, including providing data that helped map floods in Bosnia and Herzegovina in May. With its twin, Sentinel-1B, the pair has a 6-day repeat cycle.

The Sentinel-1 family helps ensure continuity with ESA's Envisat satellite, which had a 35-day repeat cycle and stopped working in April 2012. Envisat's failure at the end of 10 years – twice its nominal life – "was a bit of a shock for us. It certainly put urgency on the Sentinel development," in particular Sentinel-1 with its critical radar capability, Aschbacher said.

Other members of the fleet, some already launched, include Sentinel-2A and -2B, a high-resolution optical mission for land monitoring; Sentinel-3A and -3B, a medium-resolution imaging and altimetry mission for marine observation; Sentinel-4A and -4B, a geostationary atmospheric chemistry mission; Sentinel-5A, -5B, and -5C, a low Earth orbit atmospheric chemistry mission; and Sentinel-6A and -6B, an altimetry mission. Also, Sentinel-5p is a low Earth orbit atmospheric chemistry precursor mission. In addition, several Sentinels will have recurrent units.

"This really is a suite of sensors in one programmatic context – Copernicus – which doesn't exist anywhere else in that magnitude covering the major domains in terms of instruments and sensors," Aschbacher said. "We are starting to develop a long-term operational program with satellites that are providing measurements for decades from now, up to 2030."

Sentinels and Landsat

Aschbacher discussed the Copernicus program and the Sentinels in the context of other Earth observation systems. He said the program has "extremely good cooperation" with US federal agencies involved with distributing Landsat data. "The plan is that we have both science groups and technical groups to work on the complementarity of Landsat and Sentinel-2 data, for example – because Sentinel-2 and Landsat are quite similar in terms of sensors, resolutions, and purpose."

Aschbacher said that with Landsat and the Sentinel-2 pair working together, global coverage would be more frequent. Landsat along with Sentinel-2 "is a great combination for a number of applications, including for natural resources, agriculture, and forestry," he said.

ESA and US federal agencies involved with Landsat have cooperated for a number of years already, and "we are

working now more intensely on how this can be better exploited, because this would be fantastic to better use Landsat together with Sentinel-2,” Aschbacher said.

The United States is interested in access to data from other Sentinel satellites as well, he added, noting that there are discussions regarding how to better exchange data and allow ESA and US federal agencies involved with Landsat each to have access to the other’s respective data.

“We are very open and very constructive in finding the best ways of giving the best access to [Sentinel] data,” Aschbacher said. “Europe has been the beneficiary of using Landsat. I would hope that in the future, also, America can be a beneficiary of using our Sentinels.”

Free and Open Access to Data

A policy of free and open access to environmental data – with some security and other exceptions – from the Copernicus program, including from Sentinel satellites, in some ways follows on the Landsat open data policy, Aschbacher said. The Landsat policy “was one of our main influences or inspirations for the data policy,” he stated.

With the Sentinel-1 calibration validation completed, “we expect to widely open distribution to everyone,” he said. “I expect that the free and open data will be a big change for the community, and this is not only the specialized Earth observation community, but really the IT [information technology] community at large [that] is combining different sources of information.”

A European Commission regulation on free and open Sentinel data, which came into force in December 2013, noted that the data could help users “to capitalize on the social benefits arising from an increased use” of the data.

Aschbacher said that the adoption of the data policy “was quite a debate.” The debate “was mostly between some commercial data suppliers who are in the domain which is complementary to the Sentinels but maybe close enough in terms of resolution so that they feared that free data from the Sentinels would impact on their market,” he said.

Widening the Market and the Access to Data

“I think what convinced them, at the end, that a free and open data policy may, first of all, not hinder their market but maybe even be supportive to their market is, first of all, with free data – free Sentinel-2 data, for example – you really promote the use of Earth observation at large to many users [who] don’t exist today and which they may not even have access to. It’s also a campaign to widen the market and widen the access to these data,” Aschbacher said.

“Secondly, if they could offer their commercial data in combination with free data from the Sentinels, they have a product which is unique and which may be a good market entry from many segments,” he noted.

Although some companies have expressed concern about the data policy, Aschbacher stressed that commercial and Sentinel systems can work complementarily. He said that commercial systems often have a resolution of a half meter or 1 meter – much better than the Sentinel satellites – that can focus on details for city planning, security, or other applications. Sentinel and commercial systems could, he said, be used “in combination: one for the large overview and the other one really to focus on a certain area [to] zoom in and get information on the particular area of interest that you need and a much better geographic resolution.”

The European Association of Remote Sensing Companies has supported the adoption of a free and open data policy for the Sentinel data as the “most effective way to develop the downstream market (and generate pull on the upstream),” among other reasons, association secretary general Geoff Sawyer noted in a March 2014 presentation about industry’s perspective on Copernicus and big data.

These satellites are providing an enormous amount of data: Whereas Envisat provided 0.3 terabyte (TB) per day, each Sentinel-1 provide 1.8 TB/day, with Sentinel-2 s providing 1.6 TB and Sentinel-3 s providing 0.6 TB, Aschbacher said. Access to the large volume of Sentinel data “will be a bit of a hurdle at this point in time, but with the advancement of technology, this will be figured out,” he said, acknowledging an initial potential bottleneck.

Aschbacher compared the availability and amount of satellite data today with what he worked with as a doctoral student. He used data from NASA’s Nimbus satellite, launched in 1978. Accessing that data on huge magnetic tapes – for which he received special access through his professor and for which he remains grateful to NASA – was cumbersome, he said, adding, “Data were really handled like gold in my age as a student. There, you could only dream of getting free and open access to data.”

Financial Challenges

Another challenge that needed to be overcome was finances for the Copernicus program. The program currently is fully funded through 2020, he said.

Aschbacher said financial discussions were complicated by the number of parties involved, including member states of ESA and the European Union, ESA itself, the European Commission, and the European Organization for the Exploitation of Meteorological Satellites (EUMETSAT), the latter of

which is a partner for Sentinel-3, -4, and -5 operations. He added, “To get the financing organized in times of financial crisis [was] not an easy thing.” However, he said that Copernicus’s usefulness to society and cost-benefit analyses that indicated the program’s economic value helped convince parties to fund the program.

With various hurdles to the program overcome, Aschbacher admitted that “when Sentinel-1A was launched, I had an emotional moment. I thought, goodness me, 16 years ago” – since the 1998 Baveno Manifesto that marked the start of GMES – “when we [began] putting this together, and working hard over all these years to make it happen, and despite arguments against, and despite resistance of people [who] needed to be convinced, now it flies. Of course, one has to see it through [to] the end and the whole thing has to fly as a constellation, but yes, I think it is pretty much an achievement.”

Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting

Stuart Crampin
British Geological Survey, Murchison House, Edinburgh, UK

Synonyms

Birefringence; Double refraction

Definition

Observations of shear-wave splitting in the Earth lead to a new understanding of fluid-rock deformation: a New Geophysics, where earthquakes can be stress-forecast.

Shear-wave splitting	Seismic shear-waves propagating through effectively anisotropic solids, such as aligned crystals or aligned microcracks, split into two phases with different velocities and approximately orthogonal polarizations.
New Geophysics	A new understanding of fluid-rock deformation in distributions of stress-aligned fluid-saturated microcracks where microcracks in the crust are so closely spaced that they verge on fracturing and hence are critical-systems (also known as complex-systems). Critical-systems impose fundamentally new properties on conventional

Earthquake stress-forecasting

subcritical geophysics and hence are a New Geophysics.

Shear-wave splitting above swarms of small earthquakes can be used as stress-measuring stations to monitor stress-accumulation and stress-relaxation (crack-coalescence) before earthquakes, and hence *stress-forecast* the time, magnitude, and, in some cases, fault-break of impending large earthquakes.

Introduction

Transversely polarized seismic shear-waves propagating through in situ rocks with some form of elastic anisotropy, such as aligned microcracks, split into two orthogonal polarizations which propagate with different velocities, and hence lead to shear-wave splitting. The polarizations are strictly orthogonal for phase-velocity propagation, and approximately orthogonal for group-velocity propagation. Figure 1 is a schematic illustration of shear-wave splitting in the parallel vertical stress-aligned microcracks characteristic of most rocks in the Earth’s crust, once below near-surface weathering and stress-release anomalies. Originally referred to as birefringence or double refraction, shear-wave splitting was known to exist from the properties of anisotropic elastic solids (Love 1927; Nye 1957).

Double refraction has been observed experimentally as two orthogonally polarized shear-waves with different velocities in a stressed rock sample (Nur and Simmons 1969). The

Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting, Fig. 1 Schematic illustration of stress-aligned shear-wave splitting through parallel vertical microcracks (after Crampin 1994). σ_v , σ_H , and σ_h are principal axes of vertical stress, and maximum and minimum horizontal stress, respectively

phenomenon of shear-wave splitting was first recognized (and named) in synthetic seismograms in an anisotropic crystalline Earth model (Keith and Crampin 1977) and in distributions of parallel vertical microcracks (Crampin 1978). Shear-wave splitting was first positively identified in the field (above swarms of small earthquakes) by Crampin et al. (1980) and in seismic reflection surveys in hydrocarbon reservoirs by Alford (1986). An earlier attempt by Gupta (1973) to demonstrate double refraction in shear-waves some 100 km from small earthquakes failed because of misunderstanding the behavior of shear-wave splitting and the shear-wave window (Crampin et al. 1981).

Although variation of velocity with direction is certainly characteristic of seismic propagation in anisotropic media, shear-wave splitting (or the generalized three-dimensional coupling of surface-wave motion), easily identifiable in particle-motion diagrams (hodograms), is highly diagnostic of some form of effective anisotropy. One of the major difficulties is that observations of shear-wave splitting are path-integration phenomena that give no indication of where the anisotropy is located along the ray path, nor its extent or strength. The only exception is in sedimentary basins where the processing seismic surveys in exploration seismology may locate the anisotropy more accurately (for example, in Angerer et al. 2002).

Note that shear-wave splitting, as in Fig. 1, seems quite simple in concept which may tempt authors, such as Gupta (1973), to make unfounded assumptions which lead to incorrect and misleading conclusions. Shear-wave splitting is comparatively straightforward, but requires a jump in comprehension from previous isotropic experience. Two early comprehensive reviews (Crampin 1977, 1981) outlined seismic-wave propagation in anisotropic and cracked elastic media. Crampin and Peacock (2008) recently reviewed the current understanding of shear-wave splitting and identified 17 commonly assumed fallacies in understanding shear-wave splitting that can lead to unjustified conclusions.

It is suggested that the behaviour of shear-wave splitting is now comparatively well-understood. The major new advance is that observations of shear-wave splitting indicate that the stress-aligned fluid-saturated microcracks in almost all rocks are so closely spaced that they verge on failure by fracturing (and earthquakes). Such verging on failure indicates that the distributions of microcracks are critical-systems. Critical systems are a *New Physics* (Davies 1989), hence a *New Geophysics* that imposes a range of fundamentally new properties on the previous subcritical geophysics. This is a major advance in understanding fluid-rock deformation that has applications to many branches of solid-earth geophysics (Crampin and Peacock 2005, 2008; Crampin 2006).

This entry will not discuss the theory of seismic anisotropy and shear-wave splitting which is adequately outlined in

Crampin (1977, 1981), Helbig (1994), Maupin and Park (2007), and elsewhere. Here, we merely outline the behaviour of shear-wave splitting in the crust that leads to the New Geophysics and stress-forecasting earthquakes.

Terminology: references to terminology in the text will be indicated by (qv).

APE: anisotropic poro-elasticity is a model for deformation/evolution of critical-systems of distributions of stress-aligned fluid-saturated microcracks under changing conditions (Zatsepin and Crampin 1997; Crampin and Zatsepin 1997).

Aspect-ratio: Crack thickness over crack diameter.

Band-1 directions: Band-1 ray-path directions are the solid angle between 15° and 45° either side of the crack planes in a distribution of vertical parallel microcracks (Crampin 1999). APE shows that the effect of increasing (or decreasing) stress is to increase (or decrease) the average time-delays in Band-1 directions.

Band-2 directions: Band-2 ray-path directions are in the solid angle $\pm 15^\circ$ to the crack planes (Crampin 1999). Band-2 directions are sensitive to crack density, but APE shows that crack density does not vary consistently for small changes of stress.

Complex-systems: see critical-systems.

Crack density: Dimensionless crack density, CD , is specified by $CD = N a^3$ where N is number of cracks of radius a per unit cube.

Critical-systems: Critical-systems (also known as complex-systems, Davies 1989) are complex heterogeneous interactive systems which verge on fracture-criticality and failure. Extremely common in a huge range of different phenomena, critical-systems impose fundamentally new properties on the previously subcritical physics and subcritical solid-earth geophysics, and hence are a New Geophysics (Crampin 2006).

Earthquake prediction: The prediction of time, magnitude, and location of earthquakes by conventional sub-critical techniques, but not using shear-wave splitting which implies critical techniques.

Earthquake stress-forecasting: Using shear-wave splitting to monitor stress-accumulation and stress-relaxation in the surrounding rock mass that allows the time and magnitude of earthquakes to be stress-forecast, where other precursory phenomena may indicate the fault-break.

EDA: Extensive-Dilatancy Anisotropy is the name given to the distributions of fluid-saturated microcracks pervading most rocks in the crust (Crampin et al. 1984). EDA-cracks, in ostensibly unfractured rocks, are observed to have crack densities between ~ 0.015 and ~ 0.045 : that is shear-wave velocity anisotropy of $\sim 1.5 - 4.5\%$ (Crampin 1994). This comparatively small percentage of velocity anisotropy has massive implications for a huge range of phenomena and leads to the New Geophysics.

Fracture-criticality: The value of crack density, ~ 0.055 , at which stress-aligned microcracks are so closely spaced they verge on fracturing, and hence are critical-systems (qv) (Crampin 1994, 1999; Crampin and Zatsepin 1997).

New Geophysics: Shear-wave splitting indicates that microcracks in the crust are so closely spaced they verge on fracture-criticality and fracturing, and hence are critical-systems. Critical-systems are a *New Physics* (Davies 1989), hence a *New Geophysics*, that imposes a range of fundamentally new properties on conventional subcritical geophysics (Crampin 2006). Most of these properties have been observed in the field (Crampin and Peacock 2005, 2008).

PTL-anisotropy: Distributions of horizontal Periodic Thin Layers lead to a form of anisotropy (hexagonal symmetry, commonly known as transverse isotropy, with a vertical axis of symmetry) that is common in sedimentary basins, including many hydrocarbon reservoirs (Wild and Crampin 1991). Shear-wave velocity anisotropy in PTL-anisotropy may exceed 30% and would be likely to generate cusps in shear-wave velocity sheets. Such cusps have been observed (and modeled) in hydrocarbon reservoirs in the field (Slater et al. 1993).

Seismic anisotropy: Seismic anisotropy describes an elastic solid; these properties vary with direction as in aligned crystals or solids pervaded by aligned microcracks.

Seismic isotropy: Isotropy describes an elastic solid which has the same elastic properties in all directions.

Stress-forecasting earthquakes: see Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting.

TIH- (or HTI-) anisotropy: Transverse isotropy with a horizontal axis of cylindrical symmetry: the typical symmetry of EDA-cracks. Note that although transverse isotropy is specified by five elastic constants, distributions of vertical parallel EDA-cracks are specified by only three: crack density, crack aspect-ratio, and crack strike.

TIV- (or VTI-) anisotropy: Transverse isotropy with a vertical axis of cylindrical symmetry: the typical symmetry of PTL-anisotropy. In TIV-anisotropy, propagation in the horizontal plane is isotropic with no variation with azimuth.

Time-delay: The time-delay between the arrivals of the two split shear-wave phases in seismic anisotropy. Time-delays above earthquakes are frequently normalized by path length to ms/km.

Transverse isotropy: Transverse isotropy (strictly hexagonal symmetry) is the anisotropic symmetry system with five elastic constants, and is isotropic in directions perpendicular to an axis of cylindrical rotational symmetry.

90°-flips in shear-wave polarisations: Abrupt 90° changes in shear-wave polarisations (90°-flips) have been observed and modeled along shear-wave ray paths passing near to point-singularities (see below) (Bush and Crampin 1991; Crampin 1991). 90°-flips can also be caused by critically high pore-fluid pressures locally re-orienting stress-aligned

fluid-saturated EDA-cracks, both in fluid-injection in critically pressurized hydrocarbon reservoirs (Angerer et al. 2002) and adjacent to seismically-active (critically-pressurized) faults (Crampin et al. 2002).

Fundamental Features of Shear-Wave Splitting in the Crust

Observations of shear-wave splitting at a horizontal free surface typically display stress-aligned parallel polarisations. Since only transverse isotropy with a horizontal axis of symmetry (TIH-anisotropy) has such parallelism, and only parallel vertical cracks have such symmetry, the splitting is necessarily caused by stress-aligned EDA-microcracks. Microcracks is conformed as temporal changes in time-delays are observed, in fluid-injections (Angerer et al. 2002) and before earthquakes (Crampin and Peacock 2008). Only microcracks have sufficient compliance to allow such changes.

Observations of azimuthally varying stress-aligned shear-wave splitting, in almost all igneous, metamorphic, and sedimentary rocks in the crust, indicate a minimum of $\sim 1.5\%$ shear-wave velocity anisotropy and a maximum in ostensibly unfractured rock of $\sim 4.5\%$ (Crampin 1994, 1999; Crampin and Peacock 2008). Since crack density can be written as a dimensionless quantity $CD = Na^3$, where N is the number of cracks of radius a per unit cube and if Poisson's ratio is 0.25, $CD \approx 1/100$ of the percentage of shear-wave velocity anisotropy, observed shear-wave splitting can be imaged as uniform distributions of parallel vertical dimensionless cracks in Fig. 2 (Crampin 1994; Crampin and Peacock 2008).

The evolution of an initially random distribution of stress-aligned fluid-saturated microcracks under changing conditions can be modeled by the equations of anisotropic poroelasticity, APE, (Crampin and Zatsepin 1997). Figure 3 gives a schematic illustration of APE-deformation. The effect of increasing (or decreasing) stress is to increase (or decrease) the average aspect-ratio for cracks parallel to the increasing stress. APE-deformation is almost without parameters and yet matches a huge range of phenomena in exploration and earthquake seismology (Crampin and Peacock 2008), where the general applicability is because microcracks are so closely spaced that they are critical-systems and lead to the New Geophysics. Note that APE-modeling, because of the universality of critical-systems, is almost without parameters, and yet is widely applicable.

Classes of Anisotropic Symmetry and Shear-Wave Splitting

Shear-wave splitting has characteristic patterns of polarizations and velocities in three-dimensional propagation

Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting, Fig. 2 Schematic illustration of dimensionless three-dimensional crack distributions in situ rocks for a range of percentages

shear-wave velocity anisotropy, where ε is crack density and a is normalized crack radius (after Crampin 1994). Fracture-criticality is at $\sim 5.5\%$ shear-wave velocity anisotropy (Crampin and Zatsepin 1997)

Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting, Fig. 3 Schematic illustration of anisotropic poroelastic (APE) modelling of the effects of increasing stress on aspect-ratios of (6% porosity) microcracks, where aspect-ratios are given below (Crampin and Zatsepin 1995; Crampin 2006)

depending on the class of anisotropic symmetry (Nye 1957; Crampin 1977; Crampin and Kirkwood 1981). Elastic constants allow eight classes of anisotropic symmetry (including isotropic symmetry which describes a material with two elastic constants, usually written λ and μ , and has identical elastic properties in all directions of propagation). It is the characteristic 3D patterns of planes of mirror symmetry which define

the classes of anisotropic symmetry. Four types of anisotropic symmetry are commonly found in the Earth (where the horizontal plane is typically a plane of mirror symmetry):

1. *Orthorhombic symmetry* with nine independent elastic constants has three mutually-orthogonal planes of mirror symmetry. Crystalline olivine, a possible upper mantle constituent has orthorhombic symmetry, where shear-waves split in 3D patterns of polarizations. In addition, simple combinations of EDA- and PTL-anisotropy also have orthorhombic symmetry (Wild and Crampin 1991). The effects of combinations of EDA- and PTL-anisotropies have been observed in hydrocarbon reservoirs (Bush and Crampin 1991).
2. *Transverse isotropy with a vertical axis of cylindrical symmetry* commonly referred to as TIV-anisotropy. In TIV, shear-waves split strictly into phases oscillating in the vertical plane (*SV* waves) and phases oscillating horizontally (*SH* waves). There is no azimuthal variation. TIV is the effective anisotropic symmetry of finely divided horizontal layers found in many hydrocarbon reservoirs. It is also the symmetry of small horizontal platelets in shales. Thomsen (1986) derived three highly important approximations (the Thomsen parameters) for the behaviour of seismic waves in TIV media which are directly analogous to parameters measured in reflection surveys. Thomsen parameters are widely used and highly effective in interpreting exploration surveys. Thomsen parameters cannot be used to describe *azimuthally varying* anisotropy, except in isolated directions of sagittal symmetry.
3. *Transverse isotropy with a horizontal axis of cylindrical symmetry* commonly referred to as TIH-anisotropy. TIH is commonly observed above small earthquakes where the faster split shear-wave is polarized parallel to the direction of maximum horizontal stress. Only TIH-anisotropy can produce such parallelism. Only fluid-saturated microcracks are common to the huge variety of geological materials where TIH is observed, and since temporal changes before earthquakes are observed in the field, only fluid-saturated

microcracks have sufficient compliance to display temporal changes for small changes in parameters. Consequently, the observed parallelism of fast polarizations directly confirms stress-aligned microcracks throughout almost all rocks in the crust (Crampin and Peacock 2008).

4. *Monoclinic symmetry* has 13 elastic constants and is the symmetry of two (or more) sets of intersecting non-orthogonal vertical parallel EDA-cracks. Shear-wave splitting in such monoclinic symmetry has been observed and modeled in the field (Liu et al. 1993a). If two intersecting sets of vertical EDA-cracks are orthogonal, the symmetry is orthorhombic. Liu et al. (1993b) display the theoretical effects of intersecting sets of parallel vertical EDA-cracks for a range of parameters and a range of angles of intersection.

Cusps

In strong shear-wave velocity anisotropy, the direction of group-velocity (energy) propagation of the faster of the two split shear-wave may deviate so strongly that they overlap themselves and cause large amplitude cusps. Cusps have been observed and modeled in hydrocarbon reservoirs (Slater et al. 1993). However, the commonest form of cusps that occur in all anisotropic symmetry systems are the cuspidal lids, fins, and ridges associated with point- and line-singularities in group-velocity shear-wave surfaces (Crampin 1991; Wild and Crampin 1991).

Shear-Wave Window

Shear-waves with *SV* orientations incident on the free surface of an isotropic medium are identical to the incoming shear-wave (but double the amplitude) *only within* the shear-wave window. Outside the window, *S*-wave energy is lost to *SV*-to-*P* conversions so that *SV* waves are heavily distorted and even the arrival of the direct *S* wave may be unreadable. The edge of the shear-wave window is outlined by the critical angle of incidence, $i_c = \sin^{-1}(V_s/V_p)$, where V_p and V_s are the isotropic *P*-wave and *S*-wave velocities, and i_c is the critical angle for *S*-to-*P* conversions (Evans 1984; Booth and Crampin 1985). The conical solid angle of the shear-wave window may be considered as *above* small earthquakes or *below* surface recorders.

Other features of the shear-wave window:

1. The critical angle of incidence i_c is $\sim 35^\circ$ for a uniform isotropic medium with a Poisson's ratio of 0.25, where Lamé parameters $\lambda = \mu$.
2. Because of near-surface low-velocity layers, ray paths tend to curve upwards as they approach the free surface, so that the effective shear-wave window is often out to straight-line source-to-receiver incidence of 45° or greater.
3. Topographic irregularities may seriously distort the shear-wave window and may cause *S*-to-*P* conversions (the Local *SP*-waves) both inside and outside the theoretical

shear-wave window. Local *SP*-waves are frequently observed in the field as large single-sided pulses on the *SV*-component, and may be mistakenly interpreted as anomalous shear-wave splitting (Crampin 1990).

4. The shear-wave window only refers to *SV*-propagation. No energy is lost by *SH* waves at any angle of incidence on a plane horizontal free surface. Consequently, only the *SV*-component of any incident-split shear-wave is affected by the shear-wave window.
5. In anisotropic propagation, the shear-wave window may severely disturb shear-wave splitting.

These various anomalies mean that shear-wave splitting recorded at a free surface needs to be interpreted with caution (Crampin and Peacock 2008).

Shear-Wave Singularities

The three body waves in anisotropic solids trace out three velocity surfaces for propagation in three-dimensional propagation: a *P* wave; and two orthogonally-polarized shear-wave surfaces. The phase-velocity shear-wave surfaces from a point of propagation necessarily touch and are continuous in a variety of singularities in three-dimensional patterns of direction characteristic of the anisotropic symmetry class (Crampin and Yedlin 1981; Crampin and Kirkwood 1981; Wild and Crampin 1991). The only way for energy of a split shear-wave arrival to pass from one shear-wave surface to the other is along directions passing directly through a singularity.

Fig. 4 shows the three types of singularity in *phase-velocity surfaces*:

1. *Kiss-singularities* where two shear-wave surfaces touch tangentially (Fig. 4a, b). Kiss-singularities occur in directions of principal crystallographic axes and are restricted to cubic, tetragonal anisotropic symmetry, and along the cylindrical symmetry direction of transversely isotropic symmetry. Kiss-singularities can also occur in orthorhombic and monoclinic anisotropic symmetry when two shear-wave surfaces happen to touch serendipitously.
2. *Point-singularities* (sometimes called conical points) where the two shear-wave surfaces touch at the vertices of convex and concave cones (Fig. 4c). Shear-waves in all classes of anisotropic symmetry possess point-singularities except transverse isotropy (hexagonal symmetry), which only has kiss- and line-singularities (Fig. 4a). Point-singularities are particularly numerous in combinations of PTL- and EDA-anisotropy, where thin layers are pervaded by vertical microcracks (Wild and Crampin 1991).
3. *Line- or intersection-singularities* occur only in transverse isotropy where the two shear-wave phase-velocity surfaces intersect each other in circular line-(intersection-) singularities about the symmetry axis (Fig. 4a, d). In even marginally disturbed transverse isotropy, there are

Shear-Wave Splitting: New Geophysics and Earthquake Stress-Forecasting,

Fig. 4 Schematic illustration of the intersection of two shear-wave phase-velocity surfaces showing topography near: (a) line-singularity or intersection-singularity (with kiss-singularity); (b) kiss-singularity; and (c) point-singularity (after Crampin and Yedlin 1981). (d) A segment of a representation of a line-singularity, and (e) a *pull-apart remnant of a line-singularity* when the transverse isotropy symmetry is disturbed (after Wild and Crampin 1991)

dramatic changes. Since both PTL- and EDA-anisotropy have transversely isotropy symmetry with line-singularities, Wild and Crampin (1991) show that the phase-velocity representations of combinations of PTL and EDA have *pull-apart remnants of line-singularities*. The intersections of the inner and outer shear-wave surfaces separate, and 'pinch' together, in varying degrees of tightness, between a string of point-singularities (Fig. 4e).

Singularities in *group-velocity surfaces* have a variety of behaviour:

1. *Kiss-singularities* have simple group-velocity representation, the shear-wave surfaces again touch tangentially.
2. *Point-singularities* in group-velocity surfaces: the faster shear-wave surfaces transform into open almost circular "holes", whereas the slower surfaces transform into flat cuspidal "lids" which exactly fit into the open holes. The effects of such point-singularities have been observed and modeled in a hydrocarbon reservoir the field (Bush and Crampin 1991). Crampin (1991) modeled synthetic seismograms for ray path directions passing close to point-singularities. The effects can be dramatic with possibly great amplification or attenuation of amplitudes and abrupt 90° changes in shear-wave polarisations (90°-flips) either side of point-singularities.
3. *Line- or intersection-singularities*. In undisturbed transverse isotropy, the group-velocity representations of line-singularities merely intersect with each sheet showing no evidence of intersection, as in the phase-velocity

representation in Fig. 4d. However, group-velocity representations of pull-apart remnants of line-singularities in disturbed transverse isotropy typically display thin cuspidal "fins", "ridges", and "lids" of extraordinary complexity (and beauty) (Wild and Crampin 1991).

There are two conclusions. The effects of pull-apart remnants of line-singularities are sensitive to very small differences in direction of propagation or microcrack geometry, say. The subtleties of shear-wave propagation near the extensive pull-apart remnants of line-singularities are likely to be the reason for many of the complications frequently observed in field records of shear-waves in sedimentary basins. If correctly interpreted, such features can provide crucial information particularly about the relative proportions of PTL- and EDA-anisotropy (Bush and Crampin 1991).

Sources of Shear-Wave Splitting

There are three common areas of investigation into shear-wave splitting (and seismic anisotropy).

1. *Shear-wave splitting in the upper mantle*, which is typically assumed to be caused by strain-aligned crystals such as olivine, and is used to demonstrate directions of stress and flow in plate tectonics (reviewed by Savage 1999).
2. *Shear-wave splitting in hydrocarbon reservoirs* in seismic exploration in industrial seismology, where initially "anisotropy is a nuisance" (Helbig 1994) because many

well-established processing procedures assume isotropic propagation and are no longer valid if the rocks are anisotropic. More recently, however, azimuthally varying shear-wave splitting in TIH-anisotropy is being actively used to determine fracture orientations and improve fluid-flow for hydrocarbon recovery (reviewed by Helbig and Thomsen 2005).

3. *Shear-wave splitting above small earthquakes* initially stimulated development of the theory (reviewed by Crampin 1981) and observation (Crampin et al. 1980; Alford 1986), and is now demonstrating the *New Geophysics* of a crack-critical crust (Crampin 2006), where time-delays directly monitor low-level fluid-rock deformation at levels of deformation well-below those at which fracturing takes place (Crampin and Zatsepin 1997).

Remarkably, there has been very little interaction between these three areas of investigation. Each has developed largely independently where papers in one area seldom cite other areas of research. Shear-wave splitting in these three areas of investigation will be discussed separately.

Shear-Wave Splitting in the Upper Mantle

Seismic anisotropy in the mantle was first recognized from the incompatibility of Rayleigh and Love surface-wave inversions (Anderson 1961) and from the velocity anisotropy of horizontally propagating *Pn*-waves in oceanic basins (Hess 1964; Raitt et al. 1969). Another anisotropic surface-wave phenomenon directly analogous to shear-wave splitting of body waves is the coupling of surface-wave motion of Raleigh and Love modes into Generalized modes varying in three-dimensions (Crampin and King 1977). Just as shear-wave splitting is highly diagnostic of some form of seismic anisotropy, coupled surface-wave motion is highly diagnostic of anisotropy in the mantle. The pronounced coupling between Second Mode Rayleigh and Second Mode Love waves across Eurasia could be caused by as little as 4 km of 4% shear-wave velocity anisotropy at the top of the upper mantle (Crampin and King 1977).

Shear-wave splitting of body waves in the mantle only became observable with advances in digital instrumentation. The first reports of such shear-wave splitting were by Ando et al. (1980) who reported time-delays of ~1 s on 2 s-period shear-waves propagating vertically. This was attributed to 2–4% shear-wave velocity anisotropy in propagation through a magma reservoir, 100–200 km in depth beneath a volcanic area in Japan above the subducting Pacific Plate.

Since that time, shear-wave splitting has been observed extensively in the uppermost 200 km of the mantle and in the D region (Silver and Chan 1988, 1991), reviewed by Savage (1999), and Long and Silver (2009) and others. These observations are principally of shear-wave splitting in *SKS*-phases, which are frequently large amplitude, where the *P-S*

conversion on exiting from the core provides a known *SV* orientation at the start the final shear-wave path to the surface. Frequencies are typically 0.5–0.25 Hz leading to 2–4% shear-wave velocity anisotropy, similar to the crack-induced shear-wave velocity anisotropy in the crust.

The cause of the shear-wave splitting in the mantle is not wholly resolved. The most frequently cited cause is referred as lattice-preferred orientation (LPO) of the crystallographic axes of elastically anisotropic crystals, such as olivine (Karato and Wu 1993) or orthopyroxene (Ben-Ismaïl et al. 2001). These crystals are assumed to be aligned by convective flow where the presence of water, induced by bending of subducting slabs (Faccenda et al. 2009), say, could have major effects on crystal orientations and shear-wave splitting (Karato and Jung 1998; Katayama et al. 2005).

However, the similarities in the degree of shear-wave splitting and the polarization to splitting in the crust which is certainly caused by EDA-cracks suggests the alternative source of anisotropy of fluid-saturated stress-aligned cracks. There is water in much of the upper mantle. Water lowers the melting point of rock, and when crystalline rock first begins to melt, it melts along grain boundaries. Thus the anisotropy in the mantle could be caused by aligned cracks of films of liquid melt (Crampin 2003).

Shear-Wave Splitting in Hydrocarbon Reservoirs

The effective TIV-anisotropy of finely stratified rocks was demonstrated by Postma (1955) and others, where double refraction (shear-wave splitting) only has *SV*- and *SH*-polarisations. Shear-wave splitting of TIV-anisotropy was not much investigated at that time since the predominant single-component vertical seismometers only recorded *SV* waves.

Azimuthally varying shear-wave splitting in hydrocarbon reservoirs burst onto the seismic exploration industry in a series of some dozen papers in two sessions at the 1986 SEG symposium in Houston. Alford (1986) rotated (“Alford rotations”) the polarisations of reflection surveys recorded on two-component horizontal geophones from two-component horizontal vibrators, and showed that seismic shear-wave reflection sections displayed coherent behavior only when both source and receivers were rotated into the preferred (anisotropic) polarizations. These papers stimulated great activity in exploring seismics in order to obtain preferred directions of fluid-flow by locating fracture orientations (reviewed by Helbig and Thomsen 2005). This interest in anisotropy still continues today but is frequently investigated by wide-angle and other *P*-wave surveys because of the expense of three-component shear-wave surveys including instrumentation as well as the tripling of the quantity of data to be recorded and processed.

Note that azimuthally varying shear-wave splitting in hydrocarbon reservoirs has been typically interpreted by the

hydrocarbon industry as being caused by *aligned fractures*, where dimensions of the fractures are unspecified but are expected to be large enough to lead to improved hydrocarbon recovery. In contrast, Crampin and Peacock (2008) suggest that the remarkable compliance of shear-wave splitting to low-level deformation necessarily means that the splitting is caused by stress-aligned fluid-saturated *microcracks*. Since in many circumstances microcracks are parallel to macrofractures, the difference in interpretation is often immaterial. However, the recent demonstration, both in theory (Chapman 2003) and observations (Maultzsch et al. 2003), that anisotropy is frequency-dependent and varies with the dimensions of microcracks may change this interpretation.

Shear-Wave Splitting Above Small Earthquakes

Shear-wave splitting was first positively identified in the crust above a swarm of small earthquakes near the North Anatolian Fault in Turkey in the Turkish Dilatancy Project (TDP1) experiment, (Crampin et al. 1980). This experiment was designed to search for the microcrack-induced shear-wave splitting suggested by Crampin (1978). Similar observations have now been observed above earthquakes worldwide (reviewed by Crampin and Peacock 2008). However observations above earthquakes need to be recorded by three-component seismic networks within the shear-wave window of the earthquakes. This is a severe restriction as swarms of small earthquakes are scarce and intermittent, and seldom observed by seismic networks. Nevertheless, such swarms of small earthquakes have been used as ‘stress-measuring stations’ to monitor the effects of stress changes before impending earthquakes (Crampin and Peacock 2008).

Iceland is an optimum location for studying shear-wave splitting. It is an offset of the Mid-Atlantic Ridge where, uniquely, (two) transform faults run onshore. These transform faults have persistent swarm activity monitored by a state-of-the-art seismic network (Stefánsson et al. 1993) available over the Internet (Volti and Crampin 2003).

The APE model of microcrack deformation (Crampin and Zatsepin 1997) shows that increases of stress increase crack aspect-ratios (crack thicknesses), and increases of aspect-ratio can be recognized by increases of average time-delays in Band-1 directions of the shear-wave window (Crampin 1999), and have been used to stress-forecast earthquakes (Crampin et al. 1999, 2008).

The New Geophysics

The shear-wave velocity anisotropy observed in the crust of the Earth indicates that the distributions of stress-aligned fluid-saturated microcracks (EDA-cracks) are so closely spaced they verge on fracturing and hence are critical-systems

(Fig. 2). Such critical microcracks are the most compliant elements of in situ rock, and indicate profound differences from conventional subcritical solid-earth geophysics. Critical systems are a *New Physics* (Davies 1989), hence a *New Geophysics*, which imposes a range of fundamentally new properties on conventional subcritical physics (Crampin and Peacock 2005; Crampin 2006). All complex heterogeneous interactive systems are critical-systems, and they are extremely common: the weather, clustering of traffic on roads, the life-cycle of fruit flies, and a huge range of physical phenomena from stellar radiation to quantum mechanics. Since the Earth is an archetypal complex heterogeneous interactive system, it is necessarily expected to be a critical system.

The new geophysical properties include:

1. *Monitorability* – effects of criticality (on the geometry of EDA-cracks) can be monitored within the interior of the crust by shear-wave splitting (Crampin 1994, 2006).
2. *Calculability* – the evolution of microcrack geometry can be calculated by APE (Crampin and Zatsepin 1997; Crampin 1999; Angerer et al. 2002).
3. *Predictability* – if changing conditions are known, the effects on crack geometry can be predicted (as in Angerer et al. 2002).
4. *Controllability* – if the intended effects of some operation (fluid-injection, say) are desired (the opening of specific fractures for fluid-flow, say), the effects can be calculated by APE, and the effects can be controlled by feedback by analyzing shear-wave splitting. Crack aspect-ratios, as in Angerer et al. (2002) where the effects of fluid-injections were calculated, could be controlled by feedback.
5. *Universality* – the changes in critical-systems are pervasive over all available space where appropriate conditions are maintained. The coincidence of observations of 1.5–4.5% shear-wave velocity anisotropy with similar stress-oriented polarizations in all types of rock regardless of porosity, rock types, or geology (Crampin 1994; Crampin and Peacock 2005, 2008) is an example of universality in the crack-critical Earth, that is difficult to explain in a conventional sub-critical Earth.
6. *Sensitivity* – extreme (butterfly wings) sensitivity to initial conditions. A prime example of such sensitivity is the SMSITES experiment in Iceland where distinctive variations in *P*- and shear-wave travel-time variations were observed at 70 km from swarm activity with an energy equivalent to a $M = 3.5$ earthquake at 70 km distance. A $M = 3.5$ earthquake is small, so these effects are observed at hundreds of times the likely source diameter in a conventional subcritical earth and are a clear demonstration of critical-system sensitivity (Crampin et al. 2003).

Stress-Forecasting Earthquakes

Shear-wave splitting and the New Geophysics lead to a new understanding of tectonic deformation before earthquakes. Initially, tectonic stress accumulates by interactions at plate boundaries leading to deformation of EDA-cracks which can be monitored by shear-wave splitting. Such stress-accumulations are not initially associated with any particular source-zone and may be observable at great distances from any potential source. As the stress-field approaches, fracture-criticality weaknesses are identified and microcracks begin to coalesce onto the potential slip-plane. There is stress-relaxation, and eventually the impending earthquake occurs (Gao and Crampin 2004). Logarithms of the durations of increases (stress-accumulation) and decreases (crack-coalescence) are each separately proportional (self-similar) to impending earthquake magnitudes (Crampin et al. 2008), similar to the linearity of the Gutenberg–Richter relationship. Consequently, shear-waves above swarms of small earthquakes can be used as “stress-measuring stations” to monitor such stress-accumulation and stress-relaxation before impending earthquakes.

Peacock et al. (1988) were the first to recognize such changes in shear-wave time-delays (now identified with stress-accumulation), using seismic station KNW as a stress-measuring station, before a $M = 6$ earthquake near the San Andreas Fault in California. A few other examples were found worldwide (reviewed by Crampin and Peacock 2008), but the significant advances came when persistent seismicity in Iceland became available for analysis online. Volti and Crampin (2003) displayed increases of Band-1 time-delays before five earthquakes in Iceland monitoring stress-accumulation. The time, magnitude, and fault-plane of a fifth earthquake were successfully stress-forecast 3 days before it occurred in a comparatively tight time/magnitude window (Crampin et al. 1999, 2008).

Crack-coalescence (stress-relaxation), before the impending earthquake occurs when the increasing stress-accumulation abruptly begin to decrease, was first recognized by Gao and Crampin (2004). Since then, stress-accumulation has been recognized before 15 earthquakes worldwide, of which nine had sufficient seismicity beneath stress-measuring stations to also display crack-coalescence (Crampin and Peacock 2008).

Unfortunately, swarms of small earthquakes are far too scarce and irregular to be used as stress-measuring stations for reliable routine stress-forecasting. Reliable stress-forecasting requires three 1–1.5 km-deep borehole Stress-Monitoring Sites (SMSs), where a Downhole-Orbital Vibrator source (DOV) (Leary and Walter 2005) radiate shear-waves to borehole geophones in Band-1 directions. A prototype SMS in non-optimal source-to-geophone geometry between existing

boreholes in Iceland recorded exceptional sensitivity to low-level seismicity equivalent to a $M = 3.5$ earthquake at 70 km-distance (Crampin et al. 2003) demonstrating that SMSs have sufficient sensitivity to stress-forecast times and magnitudes of $M = 5$ earthquakes up to 1000 km from impending source zones (Crampin and Gao 2010).

Summary

Shear-wave splitting in the Earth reveals a fundamentally new understanding of fluid-rock deformation, where APE-modeling shows that modifications to shear-wave splitting directly monitor stress-induced modifications to microcrack geometry. Since if the changing conditions can be specified, the deformation can be calculated and predicted by APE; this is a substantial advance, a New Geophysics, on conventional subcritical solid-earth geophysics. Changes in microcrack geometry can be monitored, calculated, predicted, and in some circumstances potentially controlled. There is extreme sensitivity to initial conditions, and universality, so that effects are widely and uniformly distributed.

The New Geophysics allows stress-accumulation and stress-relaxation (crack-coalescence) before earthquakes to be recognized and impending large earthquakes stress-forecast. There are many important implications and applications. In particular, any solid-earth application that cannot accommodate compliant stress-aligned fluid-saturated EDA-microcracks pervading most in situ rocks is in error and may lead to serious misunderstandings. New Geophysics leading to monitorability; calculability; predictability; potential controllability; universality; extreme sensitivity; and earthquake stress-forecasting, is likely to be the most fundamental advance in solid-earth geoscience for many decades.

Single and Multichannel Seismics

Tamás Tóth

Geomega Limited, Budapest, Hungary

Definition

Seismics or Seismic survey	The method of imaging the subsurface with reflected and refracted seismic waves, which are generated by controlled sources and sensed by seismic detectors.
Single-channel seismics	Seismic survey using one detector (channel) for sensing returning seismic waves.
Multichannel seismics	Seismic survey using multiple detectors (channels) at different locations for sensing returning seismic waves generated by each source points.

Introduction

Reflection and refraction seismology has been applied for imaging the subsurface since the 1920s (Karcher 1987; Keppner 1991) and is still one of the most powerful methods of exploration geophysics. Applied technology has evolved considerably over the decades, but the principles have not changed. Imaging is performed by elastic waves generated by controlled sources, such as explosive, vibroseis, air gun, sparker, boomer, or similar sources. Generated waves propagate through the subsurface layers and part of them get reflected or refracted back from layer boundaries. These returning waves are sensed on the surface by seismic detectors, geophones on land, and hydrophones in water.

In case of single-channel seismic recording, elastic waves generated by each shot are recorded by one single detector or a group of detectors. On the other hand, multichannel seismic recording utilizes multiple detectors or groups of detectors located at different positions for recording the wavefield generated by each shot. Multichannel seismics provide several advantages over single-channel seismics; however, simplicity of the recording equipment and high resolution of the recorded seismic profiles make single-channel seismics still a powerful and cost-effective tool for shallow investigations.

Single-Channel Seismics

Simplest possible configuration for a seismic reflection survey is single-channel recording. Reflected energy from each shot is sensed by only one receiver or one group of receivers, normally positioned at a constant distance from the source (see Fig. 1).

The source–receiver pair is moved, and each shot generates one seismic trace for the profile. In case of singlechannel recording, each shot provides information from one subsurface location only, therefore it is critical to have a low cost and high repetition rate source. Shot generation is more labor intensive on land; hence, single-channel recording is hardly used for onshore surveys. Situation is more favorable for offshore surveys, as easy-to-operate sources with high repeatability are available and make single-channel recording an attractive alternative. This is especially true, when relatively shallow “penetration” is sufficient, but *high resolution* is needed.

Penetration, on the one hand, strongly depends on the seismic source used; on the other hand, it is also determined by the physical properties of the subsurface strata. Seismic *resolution* is a function of the frequency content of the source used. It is important to note that penetration and resolution are not independent parameters. Higher frequency sources ensure maximum resolution, but as high.

frequencies attenuate quicker, they provide less penetration. Highest frequency sources are Compressed High Intensity Radar Pulse (*CHIRP*) and boomers, while

Single and Multichannel Seismics, Fig. 1 During singlechannel recording, seismic energy generated by each source point images one subsurface point of each layer boundary, generating one seismic trace

sparkers and small volume air gun sources with their higher energy provide deeper penetration, but generally lower resolution.

Multichannel Seismics

Several advantages are gained by recording the reflected energy of each shot by multiple detectors, which is called multichannel seismic recording (see sketch in Fig. 2 and sample shot gathers in Fig. 3). The most important of these advantages are multifold imaging of the same location, called the common depth point (CDP) and the possibility to estimate seismic velocity from the recorded data itself. Multifold imaging enhances the signal/noise ratio of the final seismic section through stacking. The best possible estimate of velocity field of the subsurface layers is necessary for normal move out (*NMO*) correction and “migration” before and after stacking. This information is derived from the parameters of the hyperbola fitted on the reflections in the CDP gathers, a process called “velocity analysis.”

Single and Multichannel Seismics, Fig. 2 Reflected energy generated by each source point is recorded by multiple detectors. Each detector images a different subsurface point. Reflection at each subsurface point follows Snell’s law. Angles of incidence and reflection (marked α) are equal; hence, distance between the subsurface reflection points is half of the distance between the detectors. Upper part of the Figure shows the theoretical hyperbola of the reflection arrivals and the direct arrival between source point and detectors

Single and Multichannel Seismics, Fig. 3 The figure shows four subsequent shot gathers recorded by a 48-channel recording system. Upper series displays the shot gathers in red-blue color display with wiggle trace overlay, while the lower series shows the same traces in

wiggle trace – varying area (WT/VA) display. Seismic energy was generated by an air gun and the direct arrival, bubble energy and reflections are clearly visible on all of four shot gathers

Commonly Used High-Resolution Single- and Multichannel Seismic Sources

The *CHIRP* systems use sweep signals for generating pressure waves. Electromagnetic sweep signals are commonly used in

commercial and military radar systems, while acoustic sweeps are used in sonar systems for marine applications, and for *vibroseis* on land. *CHIRP* systems (e.g., Schock and LeBlanc 1990; Gutowski et al. 2002) became very popular in marine surveys, while *vibroseis* is the most commonly used

seismic source on land. Marine CHIRP systems typically operate in the 400 Hz–25 kHz frequency range, providing decimeter resolution of the sub-bottom layers down to a few meters or maximum few tens of meters depth in unconsolidated sediments. Advantage of the CHIRP systems is the high repeatability and good S/N (signal-to-noise) ratio. Disadvantage is the loss of phase information of the signal due to the cross-correlation during signal recording. CHIRP sources are used mainly for single-channel seismic recording; however, high-resolution 3D Chirp system has also been developed and used for decimeter-scale object detection (Vardy et al. 2008; Plets et al. 2009).

Boomers are electromagnetically driven sources consisting of a flat coil and a metal plate below the coil (Edgerton and Hayward 1964). Discharge of a high-voltage capacitor bank through the coil generates Eddy-current in the metal plate. The generated Eddy-current violently repels the plate from the coil. Pulling back the plate by strong springs or rubber bands creates a cavitation in the water acting as a sound source. Energy of the source depends on the capacitor bank, which is typically ranging between few 100 and 1,000 J, but several kJ systems have also been used. Boomers generate highly repeatable source signatures in the frequency range of 300 Hz–20 kHz with decimeter resolution and several tens of meters penetration. Innovative system design, such as the IKB-Seistec system utilizing a boomer source and a hydrophone group shielded by a focusing cone (Simpkin and Davis 1993), can further improve S/N ratio of boomer-based systems providing exceptional combination of resolution and penetration, as shown in Fig. 4. Boomers used to

be typical single-channel seismic sources; however, multi-channel systems developed for high-resolution 3D data acquisition are also built around boomer sources (Müller et al. 2009).

In *sparker* sources, similar to the sparking plug of an engine, discharge of a capacitor bank creates a spark between the positive and negative electrodes of the sparker. This spark vaporizes water between the electrodes and generates a pressure impulse. Energy and shape of the sparker wavelet are influenced by the physical design of the sparker, but is mainly controlled by the capacitance and the voltage of the high-voltage capacitor bank, commonly called “shot box.” Typical energy values per shot range between few 100 J and several thousand or even tens of thousands of Joules (Allen 1972). Large energy sparkers are rarely used nowadays as air gun sources mainly replaced them. Small-energy sparkers are still in use for engineering and research applications as they provide an alternative source fitting between boomers and small air guns. Sparkers are cost-effective to run, but shape of the wavelet, directivity, and repeatability are better controlled for other sources. Use of the sparker is also limited by the conductivity of the water. It is normally used in saltwater environment as in fresh water, extra care has to be taken to increase the conductivity of the fluid between the electrodes. This can be achieved, for example, by wrapping the sparker in a plastic bag and adding salt inside.

Air gun is a pneumatic seismic energy source generating pressure waves by the sudden release of high-pressure (70–200 bar) air into the water (Giles 1968). The gun is charged with high-pressure air from a compressor or air

Single and Multichannel Seismics, Fig. 4 Single-channel boomer profile recorded in the Bay of Napoli showing decimeter resolution and more than 30 m penetration. Comparing the left and right inserts, the attenuation of high frequencies and decreasing of seismic resolution with

depth are also visible. High resolution of the seismic combined with gravity coring enabled exceptional dating along the recorded profiles. Details of the research can be found in Sacchi et al. 2009

container and explosively releases the air from its chamber. The release of the high-pressure air produces a shock wave followed by bubble forming and several oscillations resulting from the expansion and collapse of the air bubble. Good example of bubble energy from the first oscillation is shown in Fig. 3.

Energy and frequency content of the air gun are determined by the volume of the gun, the pressure of the air and tow depth of the gun. High-resolution surveys require the smallest volume guns, typically 5–20 in³ (1 in³ = 16.39 cm³); however, gun clusters of 1,000–10,000 in³ are also commonly used during surveys with deeper targets. High-frequency content of small air guns can exceed 1,000 Hz, and large volume guns or gun clusters may provide enough energy for several kilometer deep penetration. Air guns are highly repeatable sources with considerable literature on

measuring and designing their wavelet (Ziolkowski et al. 1982).

Bubble oscillation can be decreased or even completely diminished by the timely injection of a second volume of high-pressure air. Guns operating under this principle are called *Generated Injection Air Guns* or simply *GI guns*. GI guns have two chambers. The primary chamber (generator) produces the actual pressure impulse, while the secondary chamber (injector) is used to inject a second air volume near the maximum expansion of the first bubble in order to prevent its collapse.

Air gun and *GI* sources due to their higher energy and deeper penetration are mainly used for multichannel recording. A good comparison of single-channel boomer profile and a multichannel air gun profile is shown in Fig. 5.

Single and Multichannel

Seismics, Fig. 5 Bottom image shows a multichannel seismic profile recorded on river Danube, Hungary. Middle image is an optical zoom of the area in the red rectangle. Top image shows the corresponding single-channel boomer profile recorded along the same section of the river. Blue color indicates water, green, recent river sediments, while shades of yellow, Pliocene-Pleistocene sediments. Note the order of magnitude difference in resolution but also in penetration between the two profiles

Single and Multichannel Seismics, Fig. 6 Top image shows single-channel boomer data recorded on river Rhine with several decimeter amplitude waves. Wave action has been estimated from the cross-correlation of the seismic traces and the necessary time shift is displayed

in the middle graph. Lower image shows the seismic profile after correction for surface wave action. Note that the velocity pull-up and push-down effects due to the velocity difference between water and sediments are clearly visible along the reflector just below 15 ms in the lower image

Processing Considerations for High-Resolution Single- and Multichannel Seismic Profiles

Static correction is always a key issue for proper imaging of the subsurface with seismic waves. This is especially true for high-resolution surveys. Offshore seismic surveys present a special static problem due to the wave motion. This equally affects single- and multichannel surveys, but the higher the resolution of the seismics, the more severe the problem can be. Coherency of the reflections in a decimeter resolution boomer survey can be severely affected by surface waves. Heave motion detectors offer a compensation via measuring the wave motions together with the seismic profile; however, if no heave motion is available for the survey, the necessary correction can be calculated from the data. Example of this is shown in Fig. 6.

High repeatability of many of the sources (boomer, air guns) offers good opportunity for wavelet determination and

application of deterministic *deconvolution* using the calculated wavelet. This is illustrated in Figs. 7 and 8 showing two seismic profiles before and after deterministic wavelet deconvolution and the calculated wavelets and deconvolution operators.

Migration is also a key processing step not only for the multichannel, but also for the single-channel seismic profiles. In the latter case, estimation of the migration velocity is more complicated, as there is no a priori information available from stacking velocity analysis. Velocity estimates from other measurements or migration velocity analysis can be used for migrating single-channel data. An example of this is shown in Fig. 9.

Multiples generated by the free water surface present a significant problem for single-channel seismic profiles. Several processing algorithms exist for multichannel seismic data in order to suppress multiple energy, but almost all of them fail in case of single-channel seismic profiles. Figure 10

Single and Multichannel Seismics, Fig. 7 Two images on the left show profiles without wavelet deconvolution applied. Note the “ringing” of the wavelet running parallel with the water bottom and intersecting

genuine reflectors below the water bottom. Profiles on the right have been deconvolved using wavelet-based deterministic deconvolution. The ringing of the wavelet is completely eliminated

18 ms TWT. Lateral resolution of the profile is significantly improved by the migration process

shows a single-channel profile recorded in lake Balaton, Hungary with significant multiple energy.

Summary

Seismic surveys provide one of the most detailed image of the subsurface from shallow (few tens of meters) to deep (several kilometers or even tens of kilometers) intervals. Although most of the recent seismic surveys utilize multichannel recording, high-resolution single-channel seismic surveys can also provide a cost-effective solution for offshore surveys. Main advantage of single-channel seismics is high-resolution

imaging and relative simplicity of the survey. Multichannel surveys, on the other hand, can significantly improve the signal-to-noise ratio of the seismic profile by applying multi-fold imaging and at the same time also provide additional information, for example, estimates of the velocity field.

Single and Multichannel Seismics, Fig. 10 Top right image shows the original seismic profile recorded in lake Balaton, Hungary. In the lake, approx. 4 m water and 4 m soft, unconsolidated mud can be found above the older Pliocene strata. This, together with the dipping strata in the Pliocene, presents an ideal condition for multiple generation. Top sketch marks with blue the interfaces considered for multiple generation. These are: water surface, water bottom, mud bottom, and two dipping intra-Pliocene strata. First, the free surface multiples (marked by pink) are calculated for each of these interfaces. This is followed by different peg-leg multiples calculated and marked by brown, yellow, and green lines on the profile. It is very interesting to observe that very many of the reflections recorded on the seismic profile are actually multiple energies generated by the above mentioned surfaces only

Slow Earthquake

Teruyuki Kato

Earthquake Research Institute, The University of Tokyo,
Bunkyo-ku, Tokyo, Japan

Definition

An earthquake is a sudden rupture of a fault embedded in the crust or upper mantle, and radiates elastic waves toward the earth's surface to vibrate the ground. Ground vibration includes wide spectrum of frequencies from tens of hertz to hundredth of seconds or lower. The ground vibration is recorded by a pendulum called a seismograph. Since the pendulum has its own frequency characteristics, components of longer periods becomes less visible and are not recognizable in the longest period.

Some types of fault ruptures have predominant component in long-period seismogram and such earthquakes are called

slow earthquakes. The earthquake that does not radiate enough energy to be recorded on seismogram is called a silent earthquake or slow slip event (SSE). In this definition, observed pre-seismic or post-seismic slip, or creep events may all be categorized in the silent earthquake or SSE.

Early Studies on Slow and Silent Earthquake

Earlier studies of slow earthquake were made by examining difference in magnitude determined by different frequency ranges (e.g., Kanamori 1972; Kanamori and Stewart 1979). Seismic magnitude of large earthquakes estimated from shorter period wave such as body waves are significantly smaller than that determined from longer period seismic waves. Ultimately, magnitude determined by seismic wave analysis is often much smaller than the moment magnitude or that estimated by the geodetic data inversion analysis that includes longest period (or permanent displacement) data. These have been interpreted such that the significant amount of moment release was achieved by the component of fault rupture that is slow enough not radiating much seismic wave. Kanamori and Stewart (1979), for example, showed that a series of such slow events were triggered after the June 6, 1960, Chilean earthquake (Mw 9.5).

One of such difference could be manifested by a type of earthquake called “tsunami earthquake.” The tsunami earthquake is characterized by anomalously high tsunami generation than that expected from body wave or surface wave magnitude. This can be interpreted by source characteristic such that the fault rupture was slow enough not radiating shorter seismic wave but rapid enough to generate tsunami. The 1896 Sanriku, Japan, earthquake (Ms 7.2, Mw 8.0), 1992 Nicaragua earthquake (Ms 7.0, Mw 7.6) are examples (e.g., Kanamori and Kikuchi 1993).

If the rupture is much slower and does not radiate any seismic energy, then it is called a silent earthquake. Beroza and Jordan (1990) tested if such very slow or silent earthquake could be detected using spectra of Earth’s free oscillations. Another trial is the comparison of long-term moment release rate at subduction zones. If all of strain accumulated along plate boundaries is released by seismic energy, then the released moment at the time of earthquake should be equal to the accumulated moment. Kawasaki et al. (2001) examined this hypothesis and found that the total moment released by earthquakes along the plate boundary is far smaller than the totally accumulated moment in an interseismic stage. This means that there are other unknown slow processes that release remaining moment at the plate boundaries.

One of possible mechanisms of slow strain release would be post-seismic transient displacement. Earlier discovery of post-seismic crustal deformation was found due to the 1946 Nankai, Japan, earthquake (Mw 8.1) (e.g., Okada and Nagata

1953). The cause of such a post-seismic crustal deformation was interpreted as a retarded slip after the earthquake (Fitch and Scholz 1971). Kawasaki et al. (1995) asserted that a post-seismic slow rupture was generated after the 1992 Sanriku, Japan, earthquake (Ms 6.9), by examining the strain records observed at the Esashi, Northern Japan, station. However, the question if such post-seismic transients on the records of strain sensors might stem from instrumental drifts after a strong shake was not well resolved.

More direct and convincing finding of slow slip events was brought in 1990s by the advent of the Global Positioning System (GPS). Geographical Survey Institute of Japan (GSI) first deployed nationwide GPS network to monitor crustal deformation of the Japanese Islands starting in 1992. The network was much densified in 1996 with more than 600 permanent GPS sites together with near real-time monitoring facility. The network is called GPS Earth Observation Network System (GEONET). It has been further augmented to more than 1,200 sites all over the Japanese Islands. This nationwide array of continuous GPS observation provided such a powerful tool to discover slow slip events around the Japanese Islands, as described in the following section.

Also, the USA deployed a large array of GPS together with strain and tilt meters along the western coast of the North American continent and is called Plate Boundary Observatory (PBO), which also enabled discoveries of slow slip events.

Rapid developments of GPS arrays all over the world, in particular along the Pacific Rim areas, enabled us to discover that silent earthquakes or slow slip events (SSE) are occurring at various areas around the globe, in particular, along the subducting plate interface. Comprehensive description on where do those slow events are taking place are found in Schwartz and Rokosky (2007) and Schwartz (2009).

Long-Term Slow Slip Events

A variety of slow slip events, including post-seismic slip, whose time durations are months to years have been discovered along the subducting plate boundaries.

The first eminent case of large slow slip events found using GPS network data would be the post-seismic slip due to the 1994 Sanriku-haruka-oki earthquake (Heki et al. 1997). Heki et al. (1997) analyzed the GEONET data and found that the moment released by the post-seismic slow slips is bigger than that released at the time of earthquake (Fig. 1). Then, Hirose et al. (1999) found a slow slip event in the Bungo Channel, western part of Japan, that occurred after the two 1996 Hyuganada earthquakes of Mw 6.6 on October 19 and Mw 6.7 on December 3 that occurred in the south of the region. This slip continued about 1 year in 1997 and was assumed to be due to a slip on the subducting Philippine Sea plate. Their geodetic inversion suggested that the slip occurred on about

Slow Earthquake, Fig. 1 Moment release rate due to the 1994 Sanriku-Haruka-oki, Japan, earthquake. Figure suggests that the moment released in 1 year after the earthquake is bigger than the co-seismic moment release (Heki et al. 1997)

60 × 60 km surface with the maximum fault slip of about 18 cm, which is equivalent to M_w 6.6 earthquake (Fig. 2).

Other examples of slow events found in the Japanese region include (1) east off the Boso Peninsula where slow slip events have repeated in 1996 and in 2002 and they were followed by earthquake swarms (Sagiya 2004; Ozawa et al. 2003) and (2) a post-seismic transient slip after the 2003 Tokachi earthquake (M_w 8.0) (Miyazaki et al. 2004).

Lowry et al. (2001) found a transient movement at a continuous GPS site established at Cayaco, Guerrero region, Mexico in early 1998. The area has been considered as a seismic gap. The event lasted about several months with 2 mm east, 26 mm south, and 16 mm up of displacements. They suggested that the displacement is consistent with a slip along the subduction interface that propagated from east to west. The transient displacement repeated in 2001–2002 for about 6 months. Kostoglodov et al. (2003) and Yoshioka et al. (2004) further investigated the mechanism of the event. Another repeated transient event in Mexico has been found in Oaxaca segment, hundreds of kilometers southeast of Guerrero segment, with more dense GPS array, and was studied by Brudzinski et al. (2007) and Correa-Mora et al. (2008).

Other long-term slow events have been found in Costa Rica (Protti et al. 2004), Alaska-Aleutian (Ohta et al. 2006), and New Zealand (Douglas et al. 2005). SSEs have also been found along the shallower part of the San Andreas fault (e.g., Wesson 1987; Gladwin et al. 1994; Linde et al. 1996), and in Italy (Crescentini et al. 1999; Amoruso et al. 2002). Readers are asked to refer to Schwartz and Rokosky (2007) and Schwartz (2009) for a detailed review.

Slow Earthquake, Fig. 2 Slip distributions on the subducting plate interface shown by equi-depth contours, projected on the earth's surface: (Blue) The slip distribution due to the 1997 slow event at the Bungo Channel, Japan (After Yagi and Kikuchi 2003). (Red) the slip distribution due to the 1968 Hyuganada earthquake, and (Green) area of steady slip. (Courtesy by Y. Yagi.)

Yagi et al. (2001), and Yagi and Kikuchi (2003) used GPS data to examine areal distribution of co-seismic slip, post-seismic slip, and slow slip events for two Hyuganada earthquakes of 1996 (M_w 6.6 and M_w 6.7). They found that these areas complementarily share the areas and postulated that this complementarity may come from different constitutive parameters of slip at respective regions (Fig. 2). A similar complementary region of seismic slip and aseismic slip is found also in the northeastern Japan (Yagi et al. 2003). Correa-Mora et al. (2008) indicated that the repeated transients at the Oaxaca segment occurred at the lower extension of the locked part of the seismogenic zone. These lines of evidence may suggest distinct physical rock properties along the different segments of the subducting plate interface.

The largest and the longest slow slip event, that has ever been found, lasted for about 5 years. It was recorded along the northern margin of the subducting Philippine Sea plate, namely, Tokai district (Fig. 3). The event started in the middle of 2000 and continued until mid-2005. Both Ozawa et al. (2002) and Miyazaki et al. (2006) employed a state-space model to delineate temporal evolution of the slow slip event (Segall and Matthews 1997). The slip amounted to be about several tens of centimeters, which is equivalent to

moment magnitude of about 7.2–7.3 earthquake. Figure 3 shows a sample time series of coordinate change at a GEONET station that is located right above the slowly slipping region.

Slow Earthquake, Fig. 3 (a) A sample GPS time series at the Hamakita site for the Tokai slow slip event. Permanent trend for the period from 1996 to 2000 was removed. Slow slip event was attributed in the period from late 2000 to early 2005. (From webpage of the Geographical Survey Institute) (b) Cumulative slip inferred from the extended Network Inversion Filter. Arrows show the direction and magnitude of slip of the upper plate (Miyazaki et al. 2006)

Low-Frequency Tremor and Short-Term Slow Slip

Obara (2002) discovered so-called deep low-frequency tremor using a nationwide seismic array in Japan, which is named as HiNet (High Sensitivity Seismograph Network) constituting of about 600 sites all over Japan. The deep low-frequency tremor is about 1 h of tremor activity, which is located nearly at the plate interface of 35–40 km in depth (Fig. 4). The tremor has 0.2–2 Hz in predominant frequency. And then, the tremor was found to be accompanied by small silent slips of a few to several days (Obara and Hirose 2006; Hirose and Obara 2006).

Similar nonvolcanic tremor accompanied by short-term slow events were found also in the Northwestern Pacific (Dragart et al. 2001; Rogers and Dragart 2003; Miller et al. 2002). Dragart et al. (2001) indicated that the SSE rather regularly repeats with interval of about 14 months and is associated with seismic swarm activities (Fig. 5). The estimated slip is about 3 cm. Such slow events associated with swarm activities are called episodic tremor and slip (ETS) (Rogers and Dragart 2003).

Hirose and Obara (2005) found that mid-term (about a month) and short-term (1 or 2 weeks) of slow slip events are accompanied by low-frequency tremors. The short term silent slip was too small to be monitored by GPS but can be observed on highly sensitive tiltmeters, which are mostly embedded in HiNet boreholes. The estimated amount of slip was only 1–2 cm. They also found repeated similar short-term slow slip events associated with low-frequency tremors at the Tokai region (Hirose and Obara 2006; Fig. 6). Observed slow events were modeled by a slip at the depth of 25 km and the slip amounted only 1.2 cm.

Several lines of evidence from seismological studies suggest that the occurrence of low-frequency tremors and slow slip events may somehow be related to the existence of fluid flow. Shelly et al. (2006) and Obara and Hirose (2006) suggested that episodic tremors that include low-frequency earthquakes are generated by a slow shear slip on the plate interface. Fluids might play a key role for the generation of such low-frequency earthquakes. Matsubara et al. (2009) and Kato et al. (2010) also indicated that the high-pressure fluids released by dehydration from the subducting oceanic crust generates those tremors and slow slip events.

In addition to the low-frequency tremor that occurs at a deeper extension of the seismogenic zone, low-frequency earthquakes (LFE) of a characteristic period of 10–20 s have also been observed at very shallow areas at the updip extension of the seismogenic zones along the subducting plate. They are found along the Nankai trough (e.g., Ishihara 2003; Obara and Ito 2005) and at the junction between the Japan trench and the Kuril trench (Asano et al. 2008). Considering that the LFEs along the Nankai trough are occurring within the accretionary prism and have higher dip angle

Slow Earthquake, Fig. 4 Distribution of low-frequency tremor shown in dots (Obara 2002)

Slow Earthquake, Fig. 5 Frequently and regularly repeating slow slip events and low-frequency tremors along the Cascadia subduction zones (Dragart et al. 2004)

compared with the subducting plate interface, Ito and Obara (2006a) hypothesized that they may occur in the splay faults (or out-of-sequence thrusts) in the wedge.

Existence of fluid would have a key role for generating such low-frequency events, for both deep and shallow low-frequency earthquakes (e.g., Davis et al. 2006; Ito and Obara 2006b).

Pre-Seismic Slip

A number of possible pre-seismic slips have been reported. Roeloffs (2006), among others, compared ten distinct examples of reported pre-seismic deformation rate changes before large earthquakes. For example, anomalous crustal

Slow Earthquake, Fig. 6 (a) Map of studied area. (b) Observed tilt changes in November and December 2004, due to short-term slow slip events in the Tokai region. Periods of slow events are bounded by dashed

lines. Recorded low-frequency tremors are also shown, (c) Modeled source region and estimated parameters. Observed and predicted tilt changes are shown in vectors (Hirose and Obara 2006)

deformations were observed before the 1944 Tonankai and 1946 Nankai earthquakes in Japan. Linde and Sacks (2002) showed that these deformations are consistent with the assumed aseismic slip of about 2 m in the down dip extension of the seismically slipped interface. Kanamori and Cipar (1974) and Linde and Silver (1989) postulated that a slow event had preceded the 1960 Chile earthquake.

It might be pointed out that the mechanism of precursory slow slip would be physically the same as slow slip event. Only the difference would be that while the precursory slip is an accelerating phase toward the rapid rupture, slow slip event is the slip that is not grown to a rapid rupture. Studies to clarify the mechanism that creates such difference are yet to be conducted in the future.

Scaling Relation

An important question raised is if the discovered slow earthquakes or slow events are just the slow version of “regular” or “normal” earthquakes. If this is the case, those slow events may have the similar scaling relations as the other regular earthquakes. Ide et al. (2007), however, suggested that the slow earthquakes including silent earthquake, slow slip, etc., had different scaling relation and spectral behavior compared with normal earthquakes (Fig. 7). They suggested that the characteristic duration (T sec) and the released moment (M_0 Nm) has linear relationship:

$$M_0 \approx T \times 10^{12-13} \quad (1)$$

Slow Earthquake, Fig. 7 Comparison between seismic moment and the characteristic duration of various slow earthquakes. LFE (red), VLF (orange), SSE (green), and ETS (light blue) are low-frequency earthquake, very low frequency earthquake, slow slip event, and episodic tremor and slip, respectively. See Ide et al. (2007) for more details

While this relation for the regular earthquake is

$$M_0 \approx T^3 \times 10^{15-16} \quad (2)$$

Thus, the characteristics of moment rate spectrum are also different between these events.

This finding may tell us that the slow events are not just a slower extension of seismic slip but rather have a physically different nature. They suggest that such differences would be interpreted by “a constant low-stress drop model or a diffusional constant-slip model” (Ide et al. 2007). Though the idea is yet to be tested, this might bring us a new insight for understanding the mechanism of fault slip or “earthquake” itself.

Mechanism of Slow Earthquake

The mechanism of fault slip has been extensively studied in the field of rock mechanics including theoretical treatments. It is inevitable to clarify the constitutive relations of fault ruptures to understand what mechanism controls the occurrence of slow earthquake (or earthquake itself). Numerous

experimental and theoretical studies have been conducted for this purpose in decades. Among various proposed constitutive laws, the rate- and state-dependent friction law has been widely accepted (Dieterich 1979; Ruina 1983). The law is expressed by the following equations:

$$\mu\left(\frac{\tau}{\sigma}\right) = \mu^- + a \ln\left(\frac{V}{V^*} + \theta\right) \quad (3)$$

$$\frac{d\theta}{dt} = -\left(\frac{V}{L}\right) \left[\theta + b \ln\left(\frac{V}{V^*}\right)\right] \quad (4)$$

Where, μ is friction coefficient, τ is shear stress, σ is normal stress, μ^- is friction coefficient at V^* where V^* is constant, L is characteristic slip distance, and θ is so-called state variable that represents the state along the fault surface. Coefficients a and b are constant. When the state θ does not change with time, it is called steady state and the friction coefficient in such steady state μ^{ss} is shown as

$$\mu^{ss} = \mu_0 + (a - b) \ln\left(\frac{V}{V^*}\right). \quad (5)$$

A simple spring-slider model is often used to model the fault slips (Ruina 1983; Rice and Ruina 1983). The system is characterized by the normal stress, shear stress, and the stiffness (or spring constant) k . Studies suggest that the type of slip, either rapid or slow slip, is controlled by several parameters. From Eq. (5), it is suggested that, if $(a - b)$ is negative, the friction coefficient μ_{ss} becomes smaller when slip velocity V increases, which is called velocity weakening. In case of velocity weakening, system stiffness k controls the slip mode; if k is smaller than a critical value k_c which is given by $(b - a) \sigma/L$ (e.g., Dieterich 1979), then the slip is unstable. Even in case of velocity weakening, the slip becomes slow if $(a - b)$ is close to zero. When $(a - b) > 0$, it is called velocity strengthening and the slip is decelerated.

Marone et al. (1991) used the case of velocity strengthening to interpret the post-seismic transient slow slip along the San Andreas fault and estimated the thickness of surface velocity strengthening layer to be 2–5 km. Yoshida and Kato (2003) used two tethered spring-sliders model to investigate fault interactions and examined what kind of conditions controls the occurrence of slow slip events. They showed that the repeated slow slip events may occur if the stiffness of the first block k is smaller than k_c and the second block is such that k is slightly bigger than k_c (which means that the condition is close to the boundary between stable and unstable slip). They also examined the case that an earthquake triggers the slow slip events in the adjacent region as was observed in the case of 2003 Tokachi-oki earthquake.

Further application of the rate- and state-dependent friction law to the numerical simulation of slip along the fault has been developed by a number of researchers. Tse and Rice (1986), for example, applied the relation to the two-dimensional San Andreas fault and suggested that unstable sliding may be limited to the depth shallower than 5–7 km and the steady slow slips prevails below 13–15 km of depth. Three-dimensional application was, for example, done by Rice (1993) and Stuart and Tullis (1995).

Concluding Remarks

Although the slow earthquake has been studied for decades, its rapid progress was realized since the advent of the Global Positioning System observations in the middle of 1990s. Slow slip events would be one of the most important discoveries in seismology in the recent decades, thanks to GPS. In addition, the discoveries of other low-frequency events by high-sensitivity seismic arrays provided another important progress in understanding the mechanism of earthquake generation.

It may be reminded that the whole earthquake cycle was once categorized into four stages, namely, interseismic, pre-seismic, co-seismic, and post-seismic stages, and they had been studied rather independently. However, these stages are now recognized as cross-sectional views of single continuous series of progress of slips along the fault under the unified governing fault constitutive law.

Synthetic image of earthquake from high frequency that has been recorded by seismometers to very low frequency including transient slow events provided seismologists with opportunities of ultimate understanding of what “earthquake” is. In order, however, to realize this, a lot of more advanced researches are to be conducted and the results should be synthesized; for example, detailed deep sounding of structures of the lower crust and upper mantle where brittle and ductile ruptures are taking place should be conducted to clarify the field of earthquakes. Also, laboratory experiments for developing more conclusive governing laws of rapid and slow ruptures are indispensable. In addition, further findings of slow slip events and slow earthquakes at various fields in the world will provide deeper insights on the mechanism of earthquake generation. Such progresses might lead to a further development toward the most difficult seismological problem of earthquake prediction.

Reston, VA, USA

Synonyms

Fourier expansion on the sphere; Spherical harmonic decomposition; Spherical harmonic expansion; Spherical harmonic transform

Definition

A square integrable function, defined on a surface that has a one-to-one correspondence with the unit sphere, may be represented as a linear combination of *Surface Spherical Harmonic functions*. *Spherical Harmonic Analysis* (SHA) is the process by which the coefficients defining this linear combination are determined. These coefficients constitute the *Surface Spherical Harmonic spectrum* of the function. Functions that satisfy Laplace's partial differential equation are called *harmonic*. These can be decomposed into series of *Solid Spherical Harmonic functions*. Although SHA is *not* restricted to functions that represent potential fields, it plays a special role in the determination of such fields through the solution of *Boundary Value Problems* (BVP).

Introduction: Basic Formulas

A scalar function V , representing a potential field such as the Earth's gravitational or magnetic field, satisfies Laplace's partial differential equation (PDE), in the space outside of the sources generating the field. In geocentric spherical polar coordinates (r, θ, λ) , where r is the radial distance, θ is the geocentric colatitude (defined as 90° minus the geocentric

latitude), and λ is the longitude, Laplace's PDE takes the form (Heiskanen and Moritz 1967, Eq. 1–41):

$$\Delta V \equiv \nabla^2 V = \frac{\partial^2 V}{\partial r^2} + \frac{2}{r} \frac{\partial V}{\partial r} + \frac{1}{r^2} \frac{\partial^2 V}{\partial \theta^2} + \frac{\cot \theta}{r^2} \frac{\partial V}{\partial \theta} + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 V}{\partial \lambda^2} = 0. \quad (1)$$

Equation 1 may be solved using the method of separation of variables. For the space outside a sphere of radius $r = a$, its solution may be written in the form (see Heiskanen and Moritz 1967 for a complete derivation):

$$V(r, \theta, \lambda) = \sum_{n=0}^{\infty} \left(\frac{a}{r}\right)^{n+1} \sum_{m=-n}^n v_{nm} Y_{nm}(\theta, \lambda). \quad (2)$$

The functions $[(a/r)^{n+1} Y_{nm}(\theta, \lambda)]$ are called *Solid Spherical Harmonic functions*. The *Surface Spherical Harmonic functions* $Y_{nm}(\theta, \lambda)$ are defined as:

$$Y_{nm}(\theta, \lambda) = \bar{P}_{n|m|}(\cos \theta) \cdot \begin{cases} \cos m\lambda & \text{if } m \geq 0 \\ \sin |m| \lambda & \text{if } m < 0 \end{cases}. \quad (3)$$

$\bar{P}_{n|m|}(\cos \theta)$ is the fully normalized *Associated Legendre function* of the first kind, of degree n and order $|m|$ (Heiskanen and Moritz 1967, Sects. 1–11 and 1–14). *Fully normalized* Associated Legendre functions are commonly used in geodesy. These are related to their unnormalized counterparts $P_{n|m|}(\cos \theta)$ by:

$$\bar{P}_{n|m|}(\cos \theta) = \sqrt{(2 - \delta_{m|0|})(2n+1) \frac{(n-|m|)!}{(n+|m|)!}} \cdot P_{n|m|}(\cos \theta), \quad (4)$$

where:

$$\delta_{m|0|} = \begin{cases} 1 & \text{if } m = 0 \\ 0 & \text{if } m \neq 0 \end{cases}. \quad (5)$$

For the surface spherical harmonic functions Y_{nm} , this normalization implies that:

$$\frac{1}{4\pi} \iint_{\sigma} Y_{nm}^2(\theta, \lambda) d\sigma = 1, \quad (6)$$

with the integration being performed over the unit sphere σ , whose area element is $d\sigma$ ($d\sigma = \sin \theta d\theta d\lambda$). Note that in geomagnetism, the *Schmidt seminormalized* Associated Legendre functions (Blakely 1995, p. 113) $\tilde{P}_{n|m|}(\cos \theta)$ are used instead. These are defined by:

$$\tilde{P}_{n|m}(\cos \theta) = \sqrt{(2 - \delta_{|m|0}) \frac{(n-|m|)!}{(n+|m|)!}} \cdot P_{n|m}(\cos \theta). \quad (7)$$

Surface spherical harmonics constitute a set of *orthogonal* basis functions on the unit sphere, i.e.:

$$\iint_{\sigma} Y_{nm}(\theta, \lambda) Y_{sr}(\theta, \lambda) d\sigma = 0 \text{ if } n \neq s \text{ or } m \neq r \text{ or both.} \quad (8)$$

This property of *orthogonality* permits the determination of the spherical harmonic coefficients v_{nm} , which appear in Eq. 2, as follows. Assume for the sake of this discussion that the function $V(r; \theta, \lambda)$ is observable everywhere on the surface of the sphere $r = a$. Eq. 2 then takes the form:

$$V(a, \theta, \lambda) = \sum_{n=0}^{\infty} \sum_{m=-n}^n v_{nm} Y_{nm}(\theta, \lambda). \quad (9)$$

In this case, the orthogonality of surface spherical harmonics implies that:

$$v_{nm} = \frac{1}{4\pi} \iint_{\sigma} V(a, \theta, \lambda) Y_{nm}(\theta, \lambda) d\sigma. \quad (10)$$

The coefficients v_{nm} constitute the *surface spherical harmonic spectrum* of the function $V(r; \theta, \lambda)$, pertinent to the surface of the sphere of radius $r = a$. It should be emphasized that *spherical harmonic expansions*, as the one given in Eq. 9, are *not* restricted to functions satisfying Laplace's equation (*harmonic functions*). Any square integrable function $f(\theta, \lambda)$, defined over a surface S that has a one-to-one correspondence with the unit sphere, may be expanded in surface spherical harmonics as:

$$f^S(\theta, \lambda) = \sum_{n=0}^{\infty} \sum_{m=-n}^n f_{nm}^S Y_{nm}(\theta, \lambda), \quad (11)$$

with the coefficients f_{nm}^S given by:

$$f_{nm}^S = \frac{1}{4\pi} \iint_{\sigma} f^S(\theta, \lambda) Y_{nm}(\theta, \lambda) d\sigma. \quad (12)$$

The superscript “S” emphasizes the dependence of the spectrum f_{nm}^S of the function $f(\theta, \lambda)$, on the particular surface S over which its values $f^S(\theta, \lambda)$ are given. Jekeli (1988) carefully distinguishes between the direct Legendre transform (i.e., the spectrum) of an arbitrary square integrable function $f(\theta, \lambda)$, defined on a surface S that has a one-to-one correspondence with the unit sphere, and the special case of the

solution of Laplace's equation when the boundary data reside on the surface of the sphere $r = a$. The former is expressed in Eqs. 11 and 12 above; the latter in Eqs. 9 and 10. Obviously the two quantities take the same form with an appropriate choice of coordinates. Furthermore, note that while rather arbitrary functions can be expanded in surface spherical harmonics, *only* harmonic functions (i.e., functions satisfying Laplace's equation) can be expanded into solid spherical harmonics, within their region of harmonicity.

The total power of the function $f(\theta, \lambda)$, defined over the surface S , is defined to be:

$$M\{[f^S]^2\} = \frac{1}{4\pi} \iint_{\sigma} [f^S(\theta, \lambda)]^2 d\sigma. \quad (13)$$

A generalization of Parseval's theorem permits the computation of $M\{[f^S]^2\}$ from the spectrum f_{nm}^S , by:

$$M\{[f^S]^2\} = \sum_{n=0}^{\infty} f_n^S = \sum_{n=0}^{\infty} \sum_{m=-n}^n [f_{nm}^S]^2. \quad (14)$$

The quantities f_n^S , defined as:

$$f_n^S = \sum_{m=-n}^n [f_{nm}^S]^2, \quad (15)$$

represent the total power (or variance) per spherical harmonic degree. In geodetic literature, they are known as *degree variances*. A direct correspondence exists between spherical harmonic degree and spatial wavelength. Therefore, the degree variances enable the study of the distribution of power within the function $f^S(\theta, \lambda)$, in terms of spatial wavelength. For example, Fig. 1 (Pavlis et al. 2008) shows the degree variances implied by the Earth Gravitational Model 2008 (EGM2008) for the *free-air gravity anomaly* signal.

Spherical harmonic expansions of functions, such as the Earth's topography (heights above and depths below the Mean Sea Level), surface temperature, atmospheric pressure, etc., are very useful since they permit the study of the spectral properties of these functions. Furthermore, the decomposition of these functions into their spectral components permits the efficient application of *convolutions* on the sphere (Driscoll and Healy 1994), and of band-pass filtering of data, with strict control on the filter's spherical harmonic-degree bandwidth. For functions representing potential fields, in addition to these spectral analysis applications, spherical harmonic analysis offers one approach for the solution of the underlying *Boundary Value Problem* that is associated with the specific *functional* of the field that has been observed. We discuss these aspects next.

Spherical Harmonic Analysis Applied to Potential Fields,

Fig. 1 Degree variances (c_n) of the free-air gravity anomaly signal (in mGal^2) implied by the EGM2008 global gravitational model, as a function of spherical harmonic degree n . The degree variances refer to the surface of a sphere of radius $a = 6,378,136.3$ m. The relationship between half-wavelength ($\lambda/2$) resolution and spherical harmonic degree is provided in the *insert*. In SI units, $1 \text{ mGal} = 10^{-5} \text{ ms}^{-2}$

Boundary Value Problems (BVP) of Potential Theory

In general, a BVP consists of a differential equation that is subject to a set of boundary conditions. In potential theory, the unknown (scalar) function to be determined is the potential, V , which satisfies Laplace's PDE, in the space outside of its generating sources. The function V should vanish at infinity as the reciprocal of the distance between the point in question and the generating source element. The boundary conditions, in order to be of practical use, should represent quantities related to V (*field functionals*) that are observable over some surface S . Two general approaches exist for the solution of a BVP:

- (a) Solution using spectral analysis, i.e., spherical harmonics
- (b) Solution using *Greens functions*, i.e., integral formulas

Traditionally, in gravimetric geodesy, the following three BVP of potential theory have been considered:

1. First BVP of potential theory, or *Dirichlet's problem* (Heiskanen and Moritz 1967, Sects. 1–16): given an arbitrary function f on a surface S , determine a function V that is harmonic either inside or outside S and which assumes on S the values of the prescribed function f . If the surface S is a sphere of radius $r = a$, the solution in terms of spherical harmonics, for the region outside S , is given by Eq. 2. The corresponding Greens function solution is given by *Poisson's* integral formula (Heiskanen and Moritz 1967, Eq. 1–89).
2. Second BVP of potential theory, or *Neumann's problem* (Heiskanen and Moritz 1967, Sects. 1–17): here, instead of

the values of the potential V itself, one is given on a surface S the values of its normal derivative $\partial V/\partial n$. The normal derivative is the derivative along the outward-directed surface normal n to S . If the surface S is a sphere of radius $r = a$, the solution in terms of spherical harmonics, for the region outside S , is given by:

$$V(r, \theta, \lambda) = -a \sum_{n=0}^{\infty} \frac{1}{n+1} \left(\frac{a}{r}\right)^{n+1} \sum_{m=-n}^n u_{nm} Y_{nm}(\theta, \lambda), \quad (16)$$

where u_{nm} is the spectrum of the $\partial V/\partial n$ boundary values, given on the sphere $r = a$, i.e.:

$$\begin{aligned} \left(\frac{\partial V}{\partial n}\right)_{r=a} &= \left(\frac{\partial V}{\partial r}\right)_{r=a} \\ &= \sum_{n=0}^{\infty} \sum_{m=-n}^n u_{nm} Y_{nm}(\theta, \lambda). \end{aligned} \quad (17)$$

The values of u_{nm} can be obtained from:

$$u_{nm} = \frac{1}{4\pi} \iint_{\sigma} \left(\frac{\partial V}{\partial r}\right)_{r=a} Y_{nm}(\theta, \lambda) d\sigma. \quad (18)$$

The corresponding Greens function solution to the second BVP is given by *Hotine's* integral formula (Hotine 1969).

3. Third BVP of potential theory (Heiskanen and Moritz 1967, Sects. 1–17): here, a linear combination of V and of its normal derivative $\partial V/\partial n$ is given on the surface S , i.e., $hV + k(\partial V/\partial n)$ is given on S . Again, if the surface S is a

sphere of radius $r = a$, the solution in terms of spherical harmonics, for the region outside S , is given by:

$$V(r, \theta, \lambda) = \sum_{n=0}^{\infty} \frac{1}{h - (k/a)(n+1)} \left(\frac{a}{r}\right)^{n+1} \sum_{m=-n}^n w_{nm} Y_{nm}(\theta, \lambda), \quad (19)$$

where w_{nm} is the spectrum of the $hV + k(\partial V/\partial n)$ boundary values, given on the sphere $r = a$, i.e.:

$$\left(hV + k \frac{\partial V}{\partial n}\right)_{r=a} = \left(hV + k \frac{\partial V}{\partial r}\right)_{r=a} = \sum_{n=0}^{\infty} \sum_{m=-n}^n w_{nm} Y_{nm}(\theta, \lambda). \quad (20)$$

The values of w_{nm} can be obtained from:

$$w_{nm} = \frac{1}{4\pi} \iint_{\sigma} \left(hV + k \frac{\partial V}{\partial r}\right)_{r=a} Y_{nm}(\theta, \lambda) d\sigma. \quad (21)$$

This particular BVP is of great importance to physical geodesy. The determination of the *geoid* given *gravity anomalies* as boundary data – called the BVP of physical geodesy – represents a specific case of this third BVP, where $h = -2/a$ and $k = -1$. With these values for h and k , if the surface S is a sphere of radius $r = a$, the solution in terms of spherical harmonics, for the region outside S , is given by:

$$V(r, \theta, \lambda) = a \sum_{n=0}^{\infty} \frac{1}{n-1} \left(\frac{a}{r}\right)^{n+1} \sum_{m=-n}^n g_{nm} Y_{nm}(\theta, \lambda), \quad (22)$$

where g_{nm} is the spectrum generated from the SHA of the gravity anomaly boundary values that are given on the sphere $r = a$. The corresponding Greens function solution to the BVP of physical geodesy is given by *Stokes'* integral formula (Heiskanen and Moritz 1967, Sects. 2–16).

Other BVP may also be formulated and solved, which correspond to other observable boundary data. For example, one may consider the *tensor* of second-order gradients of the gravitational potential (Moritz 1980, p. 4) (or some subset of the elements of this tensor) as boundary data, which give rise to BVP corresponding to *gravity gradiometry*.

Equations 9, 17, and 20 are all of the same form as Eq. 11. Therefore, provided that the boundary data are given on, or can be reduced to, the surface of a sphere of radius $r = a$, surface SHA may be used to determine the surface spherical harmonic spectrum of the field. This surface spectrum, multiplied by the appropriate radial terms that appear in Eqs. 2, 16, and 19,

provides then a solution in terms of solid spherical harmonics, to the corresponding BVP. The convergence of the series 2, 16, and 19 is guaranteed in the space outside of the sphere $r = a$.

Laplace's PDE can also be expressed in terms of the *ellipsoidal coordinates* (u, δ, λ) , where u is the semi-minor axis of the confocal ellipsoid, δ is the *reduced colatitude* (defined as 90° minus the reduced latitude), and λ is the longitude (Heiskanen and Moritz 1967, Sects. 1–19). The Cartesian coordinates (x, y, z) of a point are related to its spherical (r, θ, λ) and ellipsoidal (u, δ, λ) coordinates as follows:

$$\begin{aligned} x &= r \sin \theta \cos \lambda = (u^2 + E^2)^{1/2} \sin \delta \cos \lambda \\ y &= r \sin \theta \sin \lambda = (u^2 + E^2)^{1/2} \sin \delta \sin \lambda, \\ z &= r \cos \theta = u \cos \delta \end{aligned} \quad (23)$$

where E is the constant linear eccentricity of the family of confocal ellipsoids defining the coordinate system. Expressed in the (u, δ, λ) coordinate system, Laplace's PDE can also be solved using the method of separation of variables. The solution, for the space exterior to a reference ellipsoid with semi-minor axis $u = b$, is given by (Heiskanen and Moritz 1967, Sects. 1–20):

$$V(u, \delta, \lambda) = \sum_{n=0}^{\infty} \sum_{m=-n}^n \frac{Q_{n|m}(i(u/E))}{Q_{n|m}(i(b/E))} z_{nm} Y_{nm}(\delta, \lambda). \quad (24)$$

$Q_{n|m}(i(u/E))$ is the *Associated Legendre function* of the second kind, of degree n and order $|m|$ (Heiskanen and Moritz 1967, Sects. 1–12). i is the imaginary unit ($i = \sqrt{-1}$). On the surface of the reference ellipsoid $u = b$, Eq. 24 becomes:

$$V(b, \delta, \lambda) = \sum_{n=0}^{\infty} \sum_{m=-n}^n z_{nm} Y_{nm}(\delta, \lambda). \quad (25)$$

Equation 25 is of the same general form as Eqs. 9 and 11, with the important distinction that δ now represents the *reduced colatitude*. The surface *ellipsoidal* harmonic spectrum z_{nm} can be determined from:

$$z_{nm} = \frac{1}{4\pi} \iint_{\sigma} V(b, \delta, \lambda) Y_{nm}(\delta, \lambda) d\sigma, \quad (26)$$

in exactly the same fashion as in the case of the surface *spherical* harmonic spectrum in 10 and 12. Note that the integration is again over the unit sphere, whose area element is now defined as $d\sigma = \sin \delta d\delta d\lambda$.

Spherical harmonics are used extensively in geodesy because of their simplicity, and because the Earth, to a first-order approximation, is a sphere. Since, to a second-order approximation, the Earth resembles more an ellipsoid of

revolution, ellipsoidal harmonics are more suitable for the solution of BVP, when the boundary data reside on or near the surface of the Earth. The transformation between ellipsoidal and spherical harmonics can be performed using the exact analytical relationships formulated by Jekeli (1988) and implemented by Gleason (1988). In this fashion, the use of the rather complicated solid ellipsoidal harmonics of Eq. 24 may be avoided altogether.

Spherical Harmonic Analysis (SHA): Numerical Techniques

Let us consider Eqs. 11 and 12. Eq. 11 is representative of Eqs. 9, 17, 20, and 25, while Eq. 12 is representative of Eqs. 10, 18, 21, and 26. Each one of Eqs. 11 and 12 suggests an alternative approach for the estimation of the coefficients f_{nm}^S , as we discuss next.

Least Squares Adjustment. The first approach uses the linear mathematical model of Eq. 11 to set up a system of *observation equations*. With f_{nm}^S representing the observable quantity and $\hat{f}_{obs}^S$ the estimates of the unknown parameters, the observation equations can be written as:

$$v(\theta, \lambda) = \sum_{n=0}^N \sum_{m=-n}^n \hat{f}_{nm}^S Y_{nm}(\theta, \lambda) - f_{obs}^S(\theta, \lambda), \quad (27)$$

where $v(\theta, \lambda)$ is the residual associated with the observation $f_{obs}^S(\theta, \lambda)$. Notice that in Eq. 27 the summation over spherical harmonic degree was truncated to a finite maximum degree N . In vector-matrix notation, Eq. 27 takes the form:

$$\mathbf{v} = \mathbf{A}\hat{\mathbf{x}} - \mathbf{I}. \quad (28)$$

$\mathbf{v}$ is the vector representing the residuals $v(\theta, \lambda)$, $\mathbf{A}$ is the *design matrix* containing the terms that multiply the unknown parameters $\hat{f}_{nm}^S$, $\hat{\mathbf{x}}$ is the vector representing the unknown parameters $\hat{f}_{nm}^S$, and $\mathbf{I}$ is the vector containing the observations $f_{obs}^S(\theta, \lambda)$. In Eq. 28, only the matrix $\mathbf{A}$ and the vector $\mathbf{I}$ are known quantities. The linear system (28) can be solved using the method of *Least Squares Adjustment*. If Σ denotes the variance-covariance matrix of the errors associated with the observations $f_{obs}^S(\theta, \lambda)$, then, minimization of the quadratic form:

$$\phi = \mathbf{v}^T \Sigma^{-1} \mathbf{v}, \quad (29)$$

subject to the condition (28), leads to the *normal equations*:

$$\begin{aligned} \mathbf{N}\hat{\mathbf{x}} &= \mathbf{U}, \text{ where } \mathbf{N} = \mathbf{A}^T \Sigma^{-1} \mathbf{A} \text{ and} \\ \mathbf{U} &= \mathbf{A}^T \Sigma^{-1} \mathbf{I}. \end{aligned} \quad (30)$$

A scaled version of the inverse of the variance-covariance matrix is the weight matrix $\mathbf{P}$. $\mathbf{P} = \sigma_0^2 \Sigma^{-1}$ and σ_0^2 is called the

a priori variance of unit weight. σ_0^2 represents the error variance of an observation whose weight is equal to 1. The solution of the system of normal equations is:

$$\hat{\mathbf{x}} = \mathbf{N}^{-1} \mathbf{U}. \quad (31)$$

The variance-covariance matrix of the errors associated with the estimated values $\hat{\mathbf{x}}$ is given by:

$$\Sigma_{\hat{\mathbf{x}}} = \mathbf{N}^{-1} = \left(\mathbf{A}^T \Sigma^{-1} \mathbf{A} \right)^{-1}. \quad (32)$$

Carl Friedrich Gauss (1777–1855), who is credited with the development of the Least Squares Adjustment technique, used this approach in the analysis of geomagnetic data. Herein, we abbreviate the Least Squares Adjustment technique by LS.

Although in the previous discussion we presented the application of the LS method to a mathematical model that describes a *surface* spherical harmonic expansion, the LS method could be applied equally well to mathematical models describing *solid* spherical harmonic expansions, like those of Eqs. 2, 16, and 19. This means that one may use the LS method to estimate the spectra of potential fields, even when the boundary data are arbitrarily located in the three-dimensional space. In contrast, the *Numerical Quadrature* technique that we discuss next, when used for the determination of potential fields, requires that the boundary data are located over surfaces that are coordinate surfaces in the coordinate system in which Laplace's equation is formulated and solved ($r = \text{const.}$ for spherical harmonics, $u = \text{const.}$ for ellipsoidal harmonics). In theory, these coordinate surfaces must also encompass all the sources generating the field.

Numerical Quadrature. In the above discussion of the LS technique, the distribution, both in terms of location and in terms of number, of the measured values $f_{obs}^S(\theta, \lambda)$ remained unspecified. Consider now an equiangular ($\Delta\theta = \Delta\lambda$) partition of the unit sphere, along meridians ($\lambda = \text{const.}$) and parallels ($\theta = \text{const.}$). Such a partition creates a grid of $L \times 2L$ cells on the unit sphere, where $L = \pi/\Delta\theta$. Let us assume that the function $f(\theta, \lambda)$ was sampled in such a way that, for each one of the $L \times 2L$ cells, a value $f_{obs}^S(\theta, \lambda)$ exists that corresponds, for example, to the center of that cell. Such a sampling suggests a possible *discretization* of the surface integral of Eq. 12, leading to the following *Numerical Quadrature* (NQ) formula (Colombo 1981, Eq. 1.5):

$$\hat{f}_{nm}^S = \frac{1}{4\pi} \sum_{i=0}^{L-1} \sum_{j=0}^{2L-1} f_{obs}^S(\theta_i, \lambda_j) Y_{nm}(\theta_i, \lambda_j) \Delta\sigma_i, \quad (33)$$

where the area element $\Delta\sigma_i$ of the cells residing on the i th “row” is given by:

$$\Delta\sigma_i = \Delta\lambda \int_{\theta_i}^{\theta_{i+1}} \sin \theta d\theta = \Delta\lambda \cdot (\cos \theta_i - \cos \theta_{i+1}). \quad (34)$$

Equation 33 is a simple NQ formula, applicable to data $f_{obs}^S(\theta, \lambda)$ that represent point values.

In general, the estimate of the spectrum obtained either by using LS or by using NQ, will be different from the “true” spectrum f_{nm} of the function $f(\theta, \lambda)$. Furthermore, even when the two techniques are applied to the same data $f_{obs}^S(\theta, \lambda)$, their estimates will be, in general, different, i.e.:

$$\hat{f}_{nm}^S \neq \tilde{f}_{nm}^S. \quad (35)$$

It is therefore appropriate to consider the specific errors that affect $\hat{f}_{nm}^S$ and $\tilde{f}_{nm}^S$, compare the LS and NQ techniques, and determine if it is possible to design and formulate any other SHA technique(s) that would satisfy some desirable optimality criterion. This study was essentially carried out by Colombo (1981), in his treatise of the subject, entitled *Numerical Methods for Harmonic Analysis on the Sphere*. We summarize in the following Colombo’s developments and provide some examples of practical application of his formulations. Before this, however, we need to define and discuss briefly the error sources that affect any estimate of the spectrum of a function that is obtained on the basis of observed data, regardless of the technique that is used to obtain this spectrum.

- **Error Sources.** Two types of errors affect any estimate of the spectrum that is obtained from observations of a function: (a) Sampling error, and, (b) Propagated noise. The sampling error arises due to the fact that in reality, observations can only be made at a finite number of discrete points, while Eqs. 11 and 12 require the function $f(\theta, \lambda)$ to be known at every point on the surface S . Propagated noise, on the other hand, arises due to the fact that observations can never be error-free. Therefore, errors in the observations (both random and systematic) will generally propagate into the spectrum that is estimated from them.

Optimal Estimation. The particular way that sampling errors and propagated noise affect the estimated spectrum depends on the particular technique used to estimate the spectrum. Colombo (1981) designed and formulated a linear estimator of the spectrum, which is optimal in the sense that it minimizes the sum of the squares of the sampling error and the propagated noise. His *Optimal Estimation* (OE) technique is a form of Numerical Quadrature, where the *optimal* quadrature weights are defined using the formalism of *Least Squares Collocation* (LSC) (Moritz 1980). By exploiting the geometry of regular grids (i.e., grids where at least the longitude increment is constant) of data located over surfaces that

have rotational symmetry (such as a sphere or a rotational ellipsoid), and by imposing certain conditions on the *covariance functions* of the signal and the data noise, Colombo (1981) demonstrated that the variance–covariance matrix of such data sets consists of *Toeplitz-circulant* blocks. These matrix blocks can be formed and inverted very efficiently, even when the size of the data set is very large. Colombo’s OE technique was used in the gravitational field expansion developed by Hajela (1984), and in the OSU86C/D global gravitational models developed by Rapp and Cruz (1986a). Additional discussion about the estimation of gravitational spectra using LSC can be found in Tscherning (2001).

Colombo (1981, p. 76) also investigated the use of a semiempirical set of numerical quadrature weights, which depend only on the spherical harmonic degree, and can be evaluated very easily as a function of Pellinen’s smoothing factors (Colombo 1981, p. 85). Although suboptimal, these numerical quadrature weights proved to be quite adequate and were used in several gravitational modeling studies. The OSU86E/F (Rapp and Cruz 1986b) and the OSU89A/B (Rapp and Pavlis 1990) global gravitational models were developed using these semiempirical numerical quadrature weights.

Practical Aspects

Several factors complicate the application of SHA techniques when analyzing real data. These are related on the one hand to the inherent properties of the alternative SHA techniques, and on the other to the properties of the data to be analyzed. The former have to do with the computational capabilities and requirements (i.e., the flexibility and efficiency) of the different SHA techniques. The latter include issues related to the distribution and type (point or area-mean values) of the available data, the geometry of the grid to which the original data are reduced, the spectral properties of the function $f(\theta, \lambda)$ that is being approximated, and the spectral properties of the errors that may affect the observed values $f_{obs}^S(\theta, \lambda)$. We discuss briefly these factors in the following paragraphs.

- **Computational Issues.** An inspection of Equations such as (11) indicates that a spherical harmonic expansion complete to degree and order N contains $(N + 1)^2$ harmonic coefficients f_{nm}^S in total. Therefore, the normal matrix $\mathbf{N}$ of Eq. 30 has dimensions $(N + 1)^2 \times (N + 1)^2$. The structure and characteristics of the matrix $\mathbf{N}$ depends on the geometry of the available data distribution and on the characteristics of the variance–covariance matrix $\mathbf{\Sigma}$ of the data errors. If the data to be analyzed are arbitrarily located in latitude and longitude, as is the case with most raw geophysical data collected in the field (e.g., gravimetric or magnetometric data), then, apart from symmetry, the matrix $\mathbf{N}$ would be fully occupied. The same is true

(in general) if the error variance–covariance matrix Σ is arbitrary. The size of the normal matrix N is already formidable for expansions complete to degree and order 200 or so. Normal matrices for expansions to degree and order 2160, as the one corresponding to the EGM2008 model (Pavlis et al. 2008), are well beyond current computational capabilities. Nevertheless, provided that the size of the normal matrix can be handled computationally, LS adjustment and LSC are the *only* techniques that can handle arbitrarily located data, with arbitrary error variance-covariance matrices. NQ and OE require the data to be input in the form of a grid, and impose restrictions on the stochastic properties of the noise, represented within the matrix Σ . In the following, we assume that the raw data have been preprocessed in some fashion, so that the input data to the various estimators are available in gridded form.

As we mentioned previously, unlike estimators based on orthogonality relations, LS permits also the use of *solid* spherical harmonics in the formation of observation equations. Assume for the sake of this example, that a grid of potential values V is available over the physical surface of the Earth (the topography). One may then form observation equations on the basis of the mathematical model given in Eq. 2. In such a case, even if the V values are given over a regular latitude-longitude grid, these values would still be located arbitrarily in the radial direction. This would then require the formation and inversion of a fully occupied normal matrix, as it is described by Pavlis (1988), who performed such estimations to degree 36, 50, and 70, using equiangular grids of free-air gravity anomalies defined on the surface of the Earth's topography.

- *Data Organization, Types, and Distribution.* In most geodetic and geophysical SHA applications, the data are organized in geographic grids. Equiangular grids are most often used, although grids with cells of equal area are also possible, and have been used in some cases. There is therefore a need to transition from the arbitrarily located point measurements, to “artificial” measurements referring to the nodes of some specified grid. In geodetic practice, this transition is accomplished by predicting what the “artificial” grid measurements would have been, given the available arbitrarily scattered data. The prediction is done using the LSC formalism, which requires some knowledge of the signal and noise covariance functions of the data (Moritz 1980). One usually applies LSC to predict area-mean values for the grid cells, rather than point values. SHA can be applied equally well using either point or area-mean gridded data. In the case of area-mean values, the mathematical models have to be modified

appropriately, so that they accurately represent the area-mean character of the data. This is done by integrating the surface spherical harmonic functions over the specific latitudinal and longitudinal limits of each grid cell. From Eq. 3 one has:

$$\begin{aligned} & \int_{\theta_i}^{\theta_{i+1}} \int_{\lambda_j}^{\lambda_{j+1}} Y_{nm}(\theta, \lambda) \sin \theta d\theta d\lambda \\ &= \int_{\theta_i}^{\theta_{i+1}} \bar{P}_{n|m|}(\cos \theta) \sin \theta d\theta \\ & \int_{\lambda_j}^{\lambda_{j+1}} \begin{cases} \cos m\lambda & \text{if } m \geq 0 \\ \sin |m| \lambda & \text{if } m < 0 \end{cases} d\lambda \end{aligned} \quad (36)$$

Efficient recurrence relationships for evaluating the integrals of the Associated Legendre functions have been derived by Paul (1978). The numerical treatment of the evaluation of Associated Legendre functions of very high degree (e.g., $n > 1,400$ or so) requires special care since some of the values of these functions become exceedingly small, which could cause numerical problems.

Even after the gridding of geophysical data collected on or near the Earth's surface, the radial location of these data, corresponding to the Earth's topography, remains arbitrary. Solutions of BVP that are based on orthogonality relations, formulated in either spherical or ellipsoidal harmonics, require these data to be located over a sphere or an ellipsoid, respectively. This artificial (approximately radial) “movement” of the data can be accomplished using *analytical continuation*. Wang (1987, 1988) discusses some techniques that can be applied to analytically continue gravity anomaly data.

In many geophysical problems where SHA techniques are applied, the available data do not suffice to cover completely the Earth. Data gaps can produce undesirable *leakage* effects in the spectral estimates, which by definition are of global character, and require global coverage. These undesirable effects are different depending on the particular technique used to estimate the spectrum. In LS, the spectral estimator “interprets” a data gap as an undefined data value with infinite error, i.e., zero weight (see Pavlis 1988 for details). In NQ techniques, the estimator “interprets” a data gap as a data value that is equal to zero. In either case, the estimated spectrum would produce undesirable results when evaluated over the region of the data gap. It is therefore preferable to “fill in” data gaps with some reasonable values of the quantity under consideration. These “fill-in” values may be obtained on the basis of other data and/or models. For example, in

gravity modeling, topographic elevations and models of the *isostatic compensation* may be used to “fill in” areas void of actual gravity measurements (cf. Pavlis and Rapp 1990).

- *LS versus NQ techniques.* It is of interest to compare the LS and the NQ techniques from an analytical as well as a numerical perspective. Such studies have been reported by Rapp (1969, 1986), Colombo (1981), and Pavlis (1988). Sneeuw (1994) discussed the two techniques from a historical perspective. A brief review of the conclusions reached by these investigations follows. Detailed derivations and analyses supporting these conclusions can be found in the cited references. NQ is used here to identify the simple numerical quadratures formula with the semi-empirical set of suboptimal quadrature weights proposed by Colombo (1981, p. 76).

1. NQ determines each harmonic coefficient independently of all others. In contrast, LS estimates a correlated set of coefficients; thus, solutions to different maximum degrees will yield different values for the common harmonic coefficients. This will occur even if the input data are uncorrelated, and arises from the loss of orthogonality between the discrete (point or integrated) samples of the Associated Legendre functions (Pavlis 1988, Sect. 4.2.1). Unlike the Legendre functions, discrete (point, as well as integrated) samples of $\cos m\lambda$ and $\sin m\lambda$ preserve their orthogonality in the interval $[0, 2\pi)$, as long as the sampling interval $\Delta\lambda$ is constant. It is this orthogonality property of sines and cosines, along with the equatorial symmetry and the parity properties of Legendre functions, which produce the sparsity patterns of the *Block-Diagonal (BD) Least Squares* technique that we discuss next.
2. NQ cannot account for varying accuracies of the input data, while the LS estimator is capable of accounting for any (positive-definite) error variance–covariance matrix Σ associated with the input data.
3. If $L(= \pi/\Delta\theta)$ denotes the *Nyquist degree* implied by the data sampling interval, then the normal equations formed based on observation equations like (27) become singular if $N \geq L$ (Colombo 1981), where N is the maximum solved-for degree.
4. LS estimation (and LSC) can recover *exactly* a set of coefficients from “synthetic” noiseless data, provided that the data are band-limited and their frequency content does not exceed the Nyquist degree. This property offers also one verification test that any software developed to perform SHA using the LS technique should pass (Pavlis 1988, Sect. 4.2.2). The simple NQ technique is incapable of recovering the original “true” coefficients from which

the “synthetic” data were computed, as Rapp’s (1986) numerical experiments have also demonstrated.

5. Unlike the LS technique, the simple NQ does not involve any matrix formation or inversion. In this regard, the simple NQ is considerably less demanding computationally than LS. In addition, if the sampling interval $\Delta\lambda$ in the longitude direction is constant, then the NQ SHA algorithm can benefit enormously from the application of *Fast Fourier Transform* (FFT) techniques, as it was pioneered by Colombo (1981).
6. In contrast to the simple NQ, the LS technique produces not only the estimates of the coefficients, but also an estimate of their error variance–covariance matrix (see Eq. 32). This matrix can then be used to propagate the errors of the estimated coefficients onto other quantities that may be computed from them.

Block-Diagonal (BD) Least Squares. From the previous discussion, it becomes clear that a SHA technique that would combine the computational efficiency of the simple NQ, with the rigor and flexibility of LS, is highly desirable. Such a technique would attempt to retain the advantages of both techniques, while avoiding their respective limitations. The Block-Diagonal (BD) Least Squares may be viewed as such a “best of both worlds” type of technique. Colombo (1981) has shown that if:

- (a) The data reside on a surface of revolution (e.g., a rotational ellipsoid or a sphere)
- (b) The grid is complete and the longitude increment is constant
- (c) The data weights are longitude-independent
- (d) The data weights are symmetric with respect to the equator

then, the elements of the normal matrix $\mathbf{N}$, corresponding to the coefficients f_{nm}^S and f_{rq}^S , would be zero as prescribed by (see also Pavlis 1988 for details):

$$[\mathbf{N}]_{f_{nm}^S f_{rq}^S} = 0 \text{ if } m \neq q, \quad (37)$$

$$\text{or if } m = q \text{ and } n - r = 2k + 1.$$

Note that in this notation the order subscript is a signed integer, whose sign identifies the type of coefficient (positive: cosine, negative: sine). If condition (d) does not hold true, then:

$$[\mathbf{N}]_{f_{nm}^S f_{rq}^S} = 0 \text{ if } m \neq q. \quad (38)$$

The sparsity patterns implied by Eqs. 37 and 38 will be referred to as BD1 and BD2 respectively. In addition, a BD3 pattern may be considered, defined by:

$$[\mathbf{N}]_{f_{nm}^S f_{rq}^S} = 0 \text{ if } |m| \neq |q|, \quad (39)$$

which admits nonzero off-diagonal elements across coefficients of different type within a given order. It is instructive to consider the computational efficiency implied by these patterns. Table 1, which is taken from Pavlis, pp. 8–5, in Lemoine et al. (1998), provides relevant statistics for an expansion complete from degree and order 0 to degree and order 360, excluding degree $n = 1$ terms. Such an expansion involves 130,318 unknown coefficients and the upper (or lower) triangular part of the symmetric but fully occupied normal matrix $\mathbf{N}$ has 8,491,455,721 elements in total.

The enormous computational savings that can be inferred from Table 1 make the BD approximations very attractive estimation techniques. These savings, however, come at the expense of the rigor exercised in the implementation of the SHA. Any approximation of a normal matrix by a BD structure should be simple enough to permit efficient numerical implementation, and, on the same time, rigorous enough to maintain the most important characteristics of the full matrix. Therefore, one has to consider carefully whether the approximations leading to the various BD sparsity patterns can be tolerated, given the characteristics of the particular data set that is analyzed. For example, in global gravitational modeling applications, the real-world gravity anomaly data to be analyzed comply *only* with the conditions (a) and (b) above. In fact, to comply even with the (a) and (b) conditions, “filling-in” techniques and analytical continuation have to be employed, since the original data set is neither complete, nor residing on any surface of revolution, since it refers to the Earth’s topography. These aspects were carefully considered in the development of the OSU91A (Rapp et al. 1991) and the EGM96 (Lemoine et al. 1998) gravitational models. In both these models, different SHA techniques were used toward the estimation of different spectral portions of the models. This was due to the fact that different spectral portions of these models were determined on the basis of different gravimetric data sets.

In the case of *band-limited* data, one can show that the LS adjustment approach using a priori information is formally equivalent to LSC (Moritz 1980, p. 166; Colombo 1981, Sect.

2.13). In such a case, the BD approaches discussed previously are the Least Squares counterpart of Colombo’s (1981) Optimal Estimation technique.

BD techniques of varying sophistication have been used to develop GPM2 (Wenzel 1985), DGFI92A (Gruber and Bosch 1992), GFZ95A (Gruber et al. 1996), the GPM98A, B, and C models (Wenzel 1998, 1999), and the EGM2008 model (Pavlis et al. 2008).

Some of the BD structures of the normal matrix that were discussed above arise also in the analysis of data from certain configurations of *Satellite-to-Satellite Tracking* (SST) and of *Satellite Gravity Gradiometry* (SGG). This was also recognized and studied by Colombo (1984, 1989). Schuh (1996) provides a detailed study of the numerical solution strategies applicable to the analysis of such observables. SST data (in the “low-low” configuration) are currently available from the GRACE mission (GRACE 1998), and SGG data are currently being collected from the GOCE mission (ESA 1999). The availability of BD normal matrices resulting from the analysis of SST and SGG data is very important when considering the combination of these matrices with corresponding matrices derived from the analysis of global grids of gravimetric data. Such a combination of BD normal matrices permits the efficient development of global gravitational models to a very high degree (2160), as it was done in the case of EGM2008 (Pavlis et al. 2008).

Summary

Spherical Harmonic Analysis (SHA) is a critical element of the solution of Boundary Value Problems associated with potential fields. SHA is applicable not only to potential fields but also to a rather wide class of functions that are sampled over surfaces which have a one-to-one correspondence with the unit sphere. Least Squares (using either fully occupied or block-diagonal normal matrices), Numerical Quadrature, and Optimal Estimation techniques have been used to perform SHA within gravitational and magnetic field modeling efforts. The organization of the data to be analyzed in the form of geographic grids defined by meridians and parallels enables

Spherical Harmonic Analysis Applied to Potential Fields, Table 1 Statistics of normal matrices related to an expansion complete to degree $N = 360$ (excluding degree $n = 1$ coefficients) using different sparsity patterns

Statistic	Sparsity pattern		
	BD1	BD2	BD3
Total number of nonzero elements	7,905,721	15,746,100	31,362,241
Percentage of full matrix elements	0.09	0.19	0.37
Number of blocks	1440	721	361
Number of unknowns in largest block	181	360	718
Number of elements in largest block	16,471	64,980	258,121

the use of highly efficient numerical algorithms for SHA. In particular, grids with constant longitudinal spacing of data permit the application of Fast Fourier Transform techniques, thereby increasing tremendously the efficiency of the SHA algorithms.

Earthquake statistics; Statistical methods in seismology

Definition

Stochastic process	A process evolving in time governed partly by probability distributions.
Point process	Stochastic process of point events in time or space or both.
Renewal process	Point process in which the probability distribution of the time to the next event depends only on the time since the last event.
Stationary Poisson process	Point process in which the numbers of events in distinct time intervals of the same length are independent and have the same distribution.

Introduction

Statistical seismology is a field of research at the interface of statistical and physical modeling of earthquake occurrence. It is concerned with quantifying and understanding the distribution of earthquakes in time, magnitude, and location. It includes empirical analysis of earthquake catalogues, stochastic modeling of earthquake occurrence, estimation of the probability of earthquake occurrence and of earthquake-induced ground-shaking, and testing the forecasting power of physical and statistical models of seismicity (Vere-Jones et al. 2005). It provides input to the management of seismic hazard and risk. Although efforts have so far focused mainly on the study of earthquake catalogues, there is scope to incorporate other geophysical measurements into the analyses. A free online resource provides an overview of the field (Michael and Wiemer 2010).

Empirical Relations

One of the classical empirical relations of statistical seismology is the Gutenberg and Richter (1944) law, according to which the distribution of earthquake magnitudes M within

a large time-space volume has a probability density proportional to 10^{-bM} , where the parameter b is close to 1. Physical upper limits to earthquake size necessitate tapering of the density at high magnitudes (Kagan 1999). For small space-time volumes and in certain tectonic settings, the b -value can differ markedly from 1. Temporal variation in b -value has been proposed as an earthquake precursor. Since the radiated seismic energy E_S of an earthquake is approximately proportional to $10^{1.5M}$, the Gutenberg–Richter law implies that the distribution of radiated seismic energy has density proportional to $E_S^{-(\beta+1)}$, where $\beta = 2b/3$. Thus, the Gutenberg–Richter law can be viewed as a power law in radiated energy. The existence of such power laws is often taken as evidence of fractality and self-organized criticality in the earthquake process (Bak and Tang 1989).

Earthquakes tend to occur in clusters. A common type of cluster is the main shock – aftershock sequence. The Omori–Utsu law, first noted by Fusakichi Omori in 1894, describes how an aftershock sequence decays over time (Utsu et al. 1995). According to this relation, which is also a power law, the rate of aftershock occurrence is proportional to $(t + c)^{-p}$, where t is the elapsed time following the occurrence of the main shock, and c and p are adjustable parameters, typically with $c \ll 1$ day, and $p \approx 1$. In some large aftershock sequences, the relation can be seen to hold for decades after the occurrence of the main shock.

The area occupied by an aftershock sequence is approximately 10^{M-4} km², where M is the main shock magnitude (Utsu 1961). This is consistent with scaling relations derived for earthquake source dimensions – fault length, width, and displacement – all of which are approximately proportional to $10^{0.5M}$ (Wells and Coppersmith 1994). However, some major earthquakes appear to trigger aftershocks at long distances from the earthquake source. These can be accommodated by a power law in which the aftershock density is proportional to $(d^2 + r^2)^{-q}$, where r is the distance from the source, q is an adjustable parameter, typically about 1.5, and d is a function proportional to $10^{0.5M}$.

According to Båth's law (Båth 1965), the largest aftershock is typically about 1.2 magnitude units smaller than the main shock. This indicates that the main shock and its aftershocks do not by themselves conform to the Gutenberg–Richter relation, the main shock being too large relative to the other earthquakes in the set. The existence of other types of earthquake clusters than main shock – aftershock sequences, such as swarms (which have no main shock) and multiplets (which may have several main shocks) is a confounding element in attempts to systematically examine Båth's relation.

Rules for defining and classifying earthquake clusters are necessarily somewhat arbitrary. They include simple window methods, linking algorithms, and stochastic declustering (Michael and Wiemer 2010).

Data quality is an ever-present issue affecting statistical analysis of earthquake catalogues. It is necessary to establish the quality of a catalogue at the outset, because an analysis can be seriously compromised by changes in the quality of the catalogue over time, such as temporal and spatial variation of the magnitude threshold of completeness. On the positive side, catalogue data are generally improving in both quality and quantity as better seismograph networks and earthquake location techniques are employed, and this is creating opportunities for more detailed analyses.

Precursors

Studies aimed at identifying precursors of large earthquake are faced with a dual challenge: Whereas large earthquakes are relatively rare, the number of degrees of freedom available when attempting to identify precursors is large. Therefore, a careful analysis is required before the conclusion is drawn that a proposed precursory phenomenon is real. A retrospective analysis can be used to define a possible precursory phenomenon, but prospective testing is necessary to confirm it.

Many major earthquakes are preceded by an increase in the rate of occurrence and magnitude of minor earthquakes, in an area not much larger than the major earthquake source and over a time period ranging from months to decades, depending on magnitude. This is called the increase precursory scale increase (Evison and Rhoades 2004). Sometimes, it consists of a sequence of swarms. The magnitude of the largest precursor is typically about one unit smaller than that of the main shock, and the precursor time T_p (the time from the onset of the increase to the main shock) and the area in which the precursors, major earthquake, and aftershocks all take place are both approximately proportional to $10^{0.5M}$. Proposed earthquake precursors for which T_p is proportional to $10^{0.5M}$ are known as precursors of the first kind (Rikitake 1982) and include anomalies in tilt, strain and land deformation, and changes in the relative velocities of seismic P and S waves.

Models of earthquakes as a critical phenomenon have been invoked to suggest that an accelerating moment release (AMR) should occur in an area much larger than the earthquake source in the approach of criticality, i.e., an accelerating occurrence of minor earthquakes leading up to a major earthquake. Another much-studied phenomenon is precursory seismic quiescence (PSQ) – a proposed reduction in the rate of occurrence of minor earthquakes shortly before a major event. There is apparent empirical support for both AMR and PSQ, but the statistical significance has been questioned. A problem in resolving such matters is that these phenomena, like many other proposed precursors, have only been defined anecdotally and never identified with an explicit stochastic model of earthquake occurrence.

Stochastic Models of Earthquake Occurrence

Early examples of stochastic modeling of earthquake sequences were given by Vere-Jones (1970). Modeling of earthquake occurrence has benefited from the development of the theory of stochastic point processes (Daley and Vere-Jones 2003).

The idea of successive episodes of stress accumulation and release, as suggested by the elastic rebound theory of Henry Fielding Reid in 1910, is the basis for most modeling of recurrence of major earthquakes on a fault or fault segment. The time sequence of earthquakes is often modeled as a renewal process, assuming a characteristic magnitude for events on the fault. The recurrence-time distribution is variously taken as exponential (for constant hazard), Weibull, lognormal, or Brownian passage-time. The latter three distributions all imply some degree of regularity in the time intervals between earthquakes, and physical arguments have been advanced in support of each. The limited data so far available on earthquake recurrence on fault segments do not support a clear preference for a particular distribution or afford a real opportunity to test how informative renewal models are in this context. It is important to account for data and parameter uncertainties when applying such models to the estimation of earthquake hazard.

The renewal process model does not allow for interactions between neighboring faults or for variation in the size of successive events. Models involving time and magnitude include the time-predictable and slip-predictable models, in which either the time to the next earthquake depends on the magnitude of the last earthquake or the magnitude of the next earthquake depends on the elapsed time. These models are sometimes applied to the earthquakes in a region. In a stress-release model of Zheng and Vere-Jones (1994), also applicable to the earthquakes in a region, the hazard rate steadily increases over time, but drops upon the occurrence of an earthquake by an amount that depends on its magnitude.

The epidemic-type aftershock (ETAS) model of Ogata (1989) is a nonstationary Poisson process model developed originally as a model of temporal clustering of earthquakes in a discrete region. In this model, each earthquake has its own aftershock sequence, which decays over time according to the Omori-Utsu law. The number of aftershocks is governed by a magnitude-dependent productivity function. Some earthquakes occur independently according to a stationary Poisson process. The ETAS model fits earthquake data much better than a stationary Poisson process and better than a model in which only the larger events have aftershocks.

Stochastic models involving location, as well as time and magnitude, allow for a more realistic representation of the earthquake process, including clustering and long-range interactions between earthquakes.

The ETAS model was extended to include the spatial variable (Ogata 1998) by introducing a distribution for after-shock location, usually a power law of distance similar to that described above. In this form, it can be used to describe the space-time clustering of earthquakes and as a diagnostic tool for physical changes affecting the earthquake process. As a short-term forecasting model, this model performs far better than smoothed seismicity models, which capture the space and magnitude distributions of past earthquakes but are time-invariant. It is successful at forecasting aftershocks, as well as the minor proportion of major earthquakes which are preceded by a foreshock sequence. For a given location, the rate density of earthquake occurrence in this model can fluctuate abruptly over several orders of magnitude. Changes in the parameters of the spatial ETAS model have been used as indirect indicators of stress-changes in regions of the crust.

The Every Earthquake a Precursor According to Scale (EEPAS) model (Rhoades and Evison 2004) is a space-time-magnitude model designed for medium-term forecasting of the major earthquakes. In this model, every earthquake contributes to the future distribution of earthquake occurrence in time, magnitude, and location on a scale determined by its magnitude, through predictive scaling relations associated with the precursory scale increase phenomenon. The EEPAS model rate density can fluctuate slowly in time over about 1.5 orders of magnitude. The EEPAS model outperforms smoothed seismicity models in well-catalogued inter-plate regions such as California, Japan, and New Zealand.

Physics-Based Models

In contrast to models based only on earthquake catalogues, physics-based models of earthquake occurrence also take stress evolution into account. Stress changes can be estimated from earthquake slip models or aseismic sources such as tectonic and reservoir loading and fluid injections. The most prominent model of this type is the Coulomb Rate-State model which accounts for the earthquake nucleation rate in fault populations where each fault obeys the constitutive rate- and state-dependent friction law derived from laboratory experiments (Dieterich 1994; Heimisson and Segall 2018). Applications show the model performs well when the large uncertainties of the involved stress calculations are taken into account (Cattania et al. 2014).

Numerical earthquake simulators generate synthetic earthquake catalogues based on known physical elements, such as stress transfer between faults, friction laws, stress accumulation, and the detailed geometry of fault surfaces (Tullis 2012). Statistical analysis of such catalogues can reveal under what

physical conditions a given statistical model is likely to be appropriate and contribute to physical understanding of empirical relations derived from real earthquake catalogues (Christophersen et al. 2017).

Testing of Forecasting Methods

The stationary Poisson model with characteristic earthquake magnitudes on faults and spatially distributed background seismicity conforming to the Gutenberg–Richter magnitude relation are the basis for most seismic hazard models in practical use. However, an international effort by the Collaboratory for the Study of Earthquake Predictability (CSEP) is providing transparent, prospective testing of time-varying earthquake occurrence models within certain gridded testing regions in California, New Zealand, Europe, Japan, China, the northeast Pacific, southwest Pacific and, at high magnitudes, the entire globe. To be testable, a model must provide estimates of the expected number of earthquakes for future time windows within grid cells delimited by location and magnitude.

The performance of a probabilistic model of earthquake occurrence on a target set of earthquakes in a catalogue independent of the one to which it was fitted is conveniently measured by the information gain per earthquake, defined as the increase in the log likelihood of the earthquake catalogue under the model compared with that under a reference model, divided by the number of targeted earthquakes.

CSEP uses likelihood-based consistency tests, which can identify significant differences between the expected and observed number of targeted earthquakes, and the distributions in time, magnitude, and location of cell expectations and those of the targeted earthquakes. It is also developing consistency tests for models represented only by simulated catalogues of future events (Michael and Werner 2018).

Some earthquake forecasting methods, such as the M8 algorithm, are alarm-based rather than probabilistic. For alarm-based methods, the error diagram (Molchan 1990), in which the proportion of time or space-time for which a certain level of alarm is exceeded is plotted against the proportion of unpredicted earthquakes, is a useful assessment tool.

Operational Earthquake Forecasting

Some forecasting models are sufficiently well tested to be used for official earthquake warnings. There is often a demand for authoritative forecasts of triggered events in the aftermath of a major damaging earthquake (Jordan et al. 2011). Aftershock models incorporating the Omori-Utsu

law, such as ETAS or simpler alternatives, are generally used to provide such short-term forecasts, with a time horizon of weeks, months, or perhaps a year. Hybrid forecasting models, based on expert judgement informed by statistical testing, and incorporating short-, medium- and long-term components, have been used to extend the time horizon out to several decades or longer (Gerstenberger et al. 2016), as is required for the planning of recovery operations following a major earthquake. An ideal operational earthquake forecasting system would be integrated with seismic hazard and risk tools and would be capable of automatically providing forecasts of earthquake occurrence within any desired region for any specified future time-period based on the best-performing models available.

Conclusion

Statistical seismology is concerned with modeling the empirical observations of earthquake occurrence and testing models against observations while trying to throw light on the physics of earthquake generation. A rapid improvement in seismological databases has been a stimulus to recent developments in the field, and this state of affairs is likely to continue. Improved earthquake catalogues and other systematically collected data, such as earth deformation data derived from global navigation satellite systems, offer opportunities for enhanced physical understanding of the earthquake process and more informative stochastic models. At the same time, increased computing power allows for increased detail and complexity in physics-based modeling. The major challenge for statistical seismology is to use the new data, together with physical insights from empirical studies and detailed physical modeling, to develop ever more informative stochastic models of earthquake occurrence that can be applied to mitigating earthquake hazard.

Subduction Zones

Geoffrey A. Abers

Lamont-Doherty Earth Observatory, Columbia University,
Palisades, NY, USA

Definition

Subduction zones are convergent plate boundaries involving at least one oceanic plate. The oceanic plate descends beneath the other into the deep mantle, forming a deep-sea trench, often a volcanic arc subparallel to it, an inclined Wadati–Benioff seismic zone, and other subparallel deforming belts.

Introduction

Subduction zones are a fundamental manifestation of planetary convection at the Earth's surface, and can be viewed as regulating two critical systems:

1. They control the primary material flux from the surface to the Earth's interior. Material at the seafloor subducts to depth, some of which emerges in volcanic arcs. These processes control the long-term budgets of volatiles (H_2O , CO_2 , etc.), and the major accretion of material to continental crust.
2. Forces at subduction zones result in much of the planet's deformation, including the generation of the largest earthquakes and explosive volcanic eruptions over time scales of seconds, to the formation of the deepest seafloor and the growth of continents over millions of years. The negative buoyancy of subducting lithosphere probably represents the largest driver of global plate motions.

All of these processes ultimately result from the Earth releasing heat, and the deformation and thermal structure that results. At the largest scale, subduction regulates the mixing of material throughout the mantle of the lifetime of the planet, and the onset and termination of subduction represent profound geologic events. This article follows subduction zones from trench to depth, emphasizing the two themes of material flux and of large-scale deformation. It focuses on active systems from outer rise to sub-arc depths.

Morphology and Nomenclature

The global subduction oceanic system is over 40,000 km long (Stern 2002), largely but not entirely subducting oceanic plates of the Pacific basin (Fig. 1). For the most part, any

part of this subduction zone exhibits a common morphology (Fig. 2): a downgoing, oceanic plate flexes into a deep-sea trench, beneath a submarine forearc that sometimes includes an accretionary prism. As the plate interface reaches 10–50 km depth, plate motion is accommodated on a shallow-dipping thrust zone, which in many places can generate great earthquakes. Landward of the thrust zone lies a volcanic arc, typically with a sharp front that overlies the region where the Wadati–Benioff zone seismicity reaches 75–180 km depth, with occasional volcanism further in the back-arc. The upper plate beneath and behind the arc varies between those that generate oceanic back-arc basins, exemplified by the Mariana–Izu–Bonin and Tonga systems, and those that undergo long-term convergence and compression, exemplified by the Andes, with a spectrum of behaviors in between (e.g., Lallemand et al. 2005). This characteristic morphology is a consequence of a regular, repeatable balance between forces that drive plate motions, buoyancy of oceanic lithosphere, metamorphic devolatilization, and its rheological/magmatic consequences.

Outer Rise, Trench, and Forearc

The shallow part of subduction systems, where temperatures are relatively cold, are controlled by the mechanics of elastic and brittle deformation. The trench occurs because the downgoing plate is flexed downward, and the shape of the plate seaward of the trench resembles closely that expected for flexure of a thin elastic surface (e.g., Watts and Talwani 1974). The physics of elastic flexure also explains the outer rise – a region of slightly (100–500 m) elevated seafloor that lies seaward of the trench, typically 50–300 km distant (Parsons and Molnar 1976). Strong bending leads to faulting in the outer rise, typically manifest as a series of normal faults with <1,000 m offset, seen on the seafloor and generating earthquakes (Chapple and Forsyth 1979). These normal faults are found seaward of many if not most trenches, and are the most seaward indication of deformation within the subduction zone. They may play an important role in the material cycle as well, since the basins formed by them serve as traps for sediment that can be subducted to great depths (Hilde 1983), and the faults themselves may act as conduits for water to reach into the mantle of the subducting plate, altering the mineralogy (e.g., Ranero et al. 2003). Such alteration of seafloor in the open ocean plays an important role in preconditioning the downgoing plate prior to subduction: the later metamorphic devolatilization of hydrous sediments and altered oceanic lithosphere releases fluids that lubricate the plate boundary, weaken the overlying material, and ultimately drive arc volcanism.

The sediment supply to the downgoing plate varies enormously between trenches near major continental river

Subduction Zones, Fig. 1 The global distribution of subduction zones. (Modified from Syracuse et al. 2010)

Subduction Zones, Fig. 2 Common features of subduction zones

systems and those remote from such sources, leading to several variations in subduction zone behavior and characteristics. In the most extreme cases sediment supply overwhelms the rate at which material is subducted and accreted, so the bathymetric trench becomes a sediment-filled basin. Examples include the Lesser Antilles, Makran, and Cascadia

subduction zones. A first-order distinction exists between subduction zones considered “accretionary,” where a substantial amount of sediment has been offscraped to form an active accretionary prism, and “non-accretionary” subduction zones where all sediment is being subducted bypassing the forearc, and generally sediment supply is low (von Huene and Scholl

1991). The accretionary prisms typically deform internally to form a critical-taper wedge, a geometry in which gravitational stresses created by the bathymetric slope are balanced by internal friction, similar to wedges in front of bulldozers or snowplows (Davis et al. 1983). Accreted material includes deep-sea sediment, but also fragments of bathymetric features such as seamounts on the incoming plate; subduction of relatively rigid seamounts can have a profound effect on the local morphology of the forearc, and may contribute to heterogeneity along the thrust zone at greater depth.

Thrust Zone

As of mid-2010, the nine largest recorded earthquakes, and 22 of the largest 25, occurred on subduction thrust zones or “megathrusts,” including all earthquakes with magnitudes of 9.0 and larger (U.S. Geol. Surv. Web site, <http://earthquake.usgs.gov/>). These great earthquakes also generate most of the largest tsunamis, because they can displace large portions of the seafloor (see entry on ► “Tsunami”). Great earthquakes occur here because the plate-boundary fault system can sustain large rupture areas, and earthquake size scales with rupture area. There are two reasons for the large rupture areas. First, at subduction zones cold material advects downward quickly compared with rates of heat conduction, as discussed below, so temperatures along the fault zone can remain below that of the brittle-ductile transition (or downdip limit of unstable sliding; Scholz 1998) to greater depths than other environments, typically 30–50 km (Tichelaar and Ruff 1993). Second, subduction zone thrusts dip at 5–25°, compared with steeper dips for faults in many other tectonic settings, so a greater fault area exists above the brittle-ductile transition. Both of these reasons allow for faults that can exceed 100 km in the downdip direction (e.g., for the Gulf of Alaska megathrust). Along strike, individual ruptures can extend for more than 1,000 km in some cases, most notably Chile (1960; $M_w = 9.5$) and Sumatra (2004; $M_w = 9.2$). Magnitudes here (M_w) are moment magnitudes (see entry on ► “Earthquake, Magnitude”).

The fault area, and hence the ultimate size of earthquakes, is controlled by updip and downdip changes in material properties. At its updip end, the thrust zone undergoes a transition from aseismic slip on a decollement (subhorizontal plate-boundary fault) to stick-slip behavior or earthquake rupture, at depths of a few kilometers. At these depths the plate interface likely lies at temperatures of 75–150 °C. The causes of this transition likely have to do with compaction, lithification, and low-temperature mineral phase transitions that change the frictional properties of this fault surface (Saffer and Marone 2003). Similarly, the downdip limit can be in many places approximated by a threshold temperature, in this case near 350–500 °C, with notable

exceptions (e.g., Hyndman et al. 1997). Both transitions must be a consequence of change in frictional properties at this depth, with aseismic creep taking place at greater depths (e.g., Scholz 1998). In between, the megathrust fault zone shows a variety of slip behaviors from purely creeping or “decoupled” to fully seismic or “coupled.” In this usage, “coupling” refers to the ratio of fault slip inferred from summing the seismic moment of earthquakes over some time interval, to the total plate motion expected across that boundary over the same time interval. Coupled or “locked” thrust zones can be identified with geodesy, which shows the elastic strain accumulation building up between large earthquakes.

Recent discoveries of slow, silent creep events indicate that the downdip transition (and perhaps the updip one) may be much more complicated (e.g., Rogers and Dragert 2003; Ito et al. 2007; Obara 2002). Continuous geodetic observations have shown that patches of the thrust zone can slip over periods of days to months, in some cases accounting for a large fraction of the plate motion within the patch that slips (usually, adjacent to the locked zone). In some cases these events repeat quasi-periodically at time scales of months to years, although periodicity is not yet established for many regions of slow slip (Schwartz and Rokosky 2007). Often, the slow slip is accompanied by a variety of exotic seismic phenomena, including nonvolcanic tremor, low-frequency earthquakes, very-low-frequency earthquakes, and creep (Ide et al. 2007). In most cases, the tremor seems to come from the plate boundary or just above it and shows motion consistent with thrusting on the plate boundary; these observations are subject of much current research (Gomberg 2010). The physics of these quasi-periodic slip transients remain poorly understood; excess fluid pressure is suspected to play a role.

Kinematics

Subduction zones can be divided between those with little upper-plate deformation, with upper-plate compression, and exhibiting back-arc opening. The highest subduction rates, and indeed the highest relative plate motion rates anywhere, reach 240 mm/year at the northern end of the Tonga subduction system (Bevis et al. 1995). Major-plate motion between Australia and the Pacific Plate is only ~80 mm/year, the remainder being accommodated by spreading in the Lau back-arc system. Subduction can in principle be arbitrarily slow, although the lowest rates associated with an active arc probably occur in the Lesser Antilles (20–25 mm/year convergence; DeMets 2001). A wide range of convergence rates lie in between these end-members with a sharp global peak near 70 mm/year such that half of all subduction zones have arc-normal convergence rates of 53–76 mm/year (Fig. 3).

Subduction Zones,

Fig. 3 Histograms showing common parameters at subduction zones. Each is calculated at arc volcanoes or the nearest point on the plate boundary to them. (Based on data from Syracuse and Abers 2006)

While spreading at mid-ocean ridges is orthogonal to their axes, at subduction zones convergence commonly trends obliquely to trench or arc (e.g., McCaffrey 1992; Fitch 1972). The obliquity, ϕ , is the angle between the normal to trench axis and the plate convergence direction. At low obliquities, convergence occurs in the direction of plate motion but commonly at higher obliquities strain is partitioned between a trench-normal component, represented by thrust faulting on the megathrust, and an along-strike component taken up by internal deformation. The along-strike component may be taken up within the forearc, as arc-parallel strike-slip systems, as sequences of strike-slip faults oblique to the trench axis, or by other means. At many subduction zones the obliquity changes along strike as both plate orientation and location relative to Euler pole change; for example, convergence is trench-normal ($\phi \sim 0$) in the Alaska Peninsula segment of the Aleutian subduction zone, $\phi \sim 45^\circ$ from the trench in the central Aleutians, and plate motion is essentially parallel to the trench ($\phi \sim 90^\circ$) in the far western Aleutians (DeMets et al. 1990). The latter case implies that material no longer descends into the mantle in the far western Aleutians, but translates along strike. A primary consequence of obliquity is

that the trench-normal component of convergence can be significantly less than plate motion rates.

The kinematics of plates at asthenospheric depths may be more complex. While it is convenient to draw flow lines of subducting plates parallel to their dips, assuming steady-state slab geometry, it is not obvious that is the case. In many geodynamic models (e.g., Billen 2008) slabs sink vertically faster than they would if they followed their trajectories, in other words, slabs roll back. Such rollback is probably required to accommodate back-arc opening in many places, although few if any constraints exist on these kinematics. Flow kinematics are complicated by inferences of large along-strike flow inferred from seismic anisotropy (e.g., Russo and Silver 1994; Hoernle et al. 2008; see entry on [“Magnetic Anisotropy”](#)), not easily explained by simple models of wedge flow.

Thermal Structure, Plate Buoyancy, Mantle Flow

At subduction zones, cold oceanic lithosphere advects downward relatively quickly compared with the rate of heat

conduction, leading to some of the largest lateral temperature gradients in the planet. Old, fast-subducting slabs can retain temperatures $<600^{\circ}\text{C}$ in their cores to depths exceeding 100 km, where ambient mantle temperatures are otherwise $\sim 1,400^{\circ}\text{C}$ (e.g., Syracuse et al. 2010; Wada and Wang 2009). The low temperatures lead to relatively large density differences, giving oceanic lithosphere significant negative buoyancy and probably supplying one of the major forces that drive plate motions (e.g., Forsyth and Uyeda 1975). Because temperatures are low, mineral phases that hold significant H_2O are stable to much greater depths than elsewhere, making subduction zones major conveyors of volatiles to the deep earth. Still, volcanism occurs in nearly all oceanic subduction zones, indicating that parts of the system remain warm enough to produce melting. As a slab descends, it induces corner flow in the overlying mantle wedge, which draws warm material from the distal back-arc toward the slab corner (Fig. 4). This advection of warm material ultimately heats the top of the slab, leading to very strong temperature gradients near the slab surface, and driving critical material-transport processes there.

Where the slab surface lies at depths less than 50 km, plate-boundary motion is mostly localized along the megathrust

that defines the plate boundary, so the upper-plate deformation accommodates little of the plate motion (at least the downdip component; oblique slip partitions strike-parallel motion into the upper plate). As a consequence, heat transport in this region can be approximated as the balance between conduction through an overlying, stationary upper plate, and downward advection of cold material along the thrust zone (Molnar and England 1990). Shear heating along the thrust zone may elevate temperatures but its effect seems to be minor in the few places where abundant heat-flow measurements have been made (Cascadia, Japan, Tonga), equivalent to that generated by a fault with shear stress of a few tens of MPa at most (Hyndman and Wang 1995; Von Herzen et al. 2001). Thus, interplate thrust faults are relatively weak, perhaps due to high fluid pressures. One consequence is that metamorphism of subducted material follows a low-temperature high-pressure trajectory through this region, to blueschist facies (Fig. 4).

At greater depth, the overlying material flows and transports heat from the back-arc mantle into the wedge. As this hot material is entrained downward by viscous drag, it rapidly heats the top of the downgoing plate, resulting in dehydration of the top of the downgoing plate. Such heating must happen under or trenchward of the volcanic arc, since many arcs erupt basaltic lavas with chemistry that requires temperatures in excess of $1,200^{\circ}\text{C}$ beneath the arc (Kelemen et al. 2003a). The temperatures predicted for the top of the slab depend upon the assumed rheology of the mantle wedge, but for power-law flows typical of olivine dislocation creep, a narrow ($<25\text{--}50$ km wide) thermal boundary layer should rapidly develop at the top of the slab, leading to slab-surface temperatures of $700\text{--}1,000^{\circ}\text{C}$ directly beneath the volcanic front (Kelemen et al. 2003a; van Keken et al. 2002; Syracuse et al. 2010). This heating appears to be sufficient to drive off most mineral-bound volatiles in the altered oceanic crust and sediment. More complicated modeling that allows secondary flow of buoyant slab-surface material into the wedge (e.g., Gerya and Yuen 2003) might lead to lower temperatures, if such flows are sustainable.

Heat supplied by the mantle wedge continues to conduct into the slab, gradually warming its interior. Simple thermal models (e.g., McKenzie 1969; Molnar et al. 1979) predict that the maximum depth of isotherms should scale with $\Phi = AV\sin\delta$, where A is the age of the incoming lithosphere, V is its downdip velocity, and δ is the slab dip. The quantity Φ , sometimes called the “thermal parameter” (e.g., Kirby et al. 1996), describes in a simple way the overall thermal structure of slabs at great depth, and correlates well with the maximum depth of earthquakes over some depth ranges (Gorbatov and Kostoglodov 1997), indicating a thermal control for the processes that cause deep earthquakes. Ultimately, the negative buoyancy of cold slabs and their ability to descend into the lower mantle must depend upon Φ as well. The negative

Subduction Zones, Fig. 4 Pressure-temperature trajectories for the top of slabs in hot (Cascadia) and cold (Japan) subduction zones, and metamorphic facies predicted for hydrated metabasalts, color coded by H_2O content. (Facies from Hacker et al. 2003; trajectories from Syracuse et al. 2010)

thermal buoyancy of the slab counterbalances the positive buoyancy of subducting crust, since gabbro is much less dense than peridotite, such that the net buoyancy is a function of plate age and thickness of subducting crust (Cloos 1993). For normal (5–8 km) thickness of oceanic crust, lithosphere attains negative buoyancy if more than 10–30 Ma old, while crust thicker than 15–25 km will always resist subduction for any observed age of oceanic crust.

The transition from localized slip along a plate boundary to distributed flow appears to correspond to where the slab reaches 70–90 km depth in many settings (Wada and Wang 2009; Abers et al. 2006; Syracuse et al. 2010). Evidence for this transition comes from heat-flow observations at a small number of arcs (northern Japan and Cascadia), which show a step from very low forearc heat flow to relatively high sub-arc and back-arc heat flow, at this point. Also, seismic attenuation shows a sharp step at this depth, in a manner consistent with a cold “nose” of mantle material overlying the shallower portion of the slab, transitioning rapidly to hot mantle beneath the arc. The cause of this transition likely has to do with the maximum depth at which plate motion can be accommodated by a localized shear zone, and hence rheology of that shear zone; the location of arcs relative to the slab indicates a transition at temperatures about 550 °C (Conder 2005; Syracuse et al. 2010).

Fate of the Downgoing Plate: Devolatilization and Metamorphism

The subducting oceanic lithosphere can be divided into several layers (Fig. 2, inset):

- (a) Deep-sea sediment, of widely variable thickness and composition,
- (b) Variably altered oceanic crust (AOC) – largely the upper, basaltic part where hydrothermal circulation has the largest effect,
- (c) Less altered gabbroic lower crust, and
- (d) Subducting mantle lithosphere some of which may be hydrated to varying degrees.

Although some of this package will be scraped off in accretionary margins, much probably survives to subduct to subarc depths. Arc geochemistry includes signatures of subducted sediment, with lava chemistry that varies systematically in some elements in ways that correlate with variations in sediment chemistry (Plank and Langmuir 1998). This observation requires that most of the sediment, especially that deposited away from the trench, subduct to sub-arc depths. For example, lavas at several arcs include trace amounts of ^{10}Be , a radionuclide with ~1.6 Ma half-life formed in the atmosphere and deposited with the shallowest

sediment (Tera et al. 1986), indicating that the shallowest deep-marine sediment subducts intact and the material reaches the earth’s surface within a few Ma (a couple of half-lives). Finally, seismological evidence also supports the deep subduction of oceanic crust relatively intact, to generate images seen in receiver functions (e.g., Rondenay et al. 2008; Kawakatsu and Watada 2007), high-frequency guided waves (Abers 2000), and other mode conversions (e.g., Helffrich 1996).

In its entirety, this package subducts on the order 2×10^9 Tg/Ma of water at the trench (Hacker 2008), about half of which enters as pore water that is expelled by shallow compaction, and the remainder bound in minerals. Numerous drilling and sampling studies constrain well the H_2O content (and CO_2) of the subducting sediment and AOC, but lower sections are relatively less well known. Perhaps the largest uncertainty in these estimates lies in the water content of subducted mantle lithosphere, a potentially vast reservoir. Peridotite will hydrate to serpentinite and serpentine can hold ~14 wt% H_2O , giving this very thick layer potential to dominate the global water budget. However, it is not yet known how much H_2O reaches mantle depths; probably mantle hydration at mid-ocean ridges is minor because near-ridge mantle temperatures there should exceed that of serpentine stability (~600 °C) but later faulting such as at fracture zones and the outer rise (see “[Thermal Structure, Plate Buoyancy, Mantle Flow](#)”) could be major conduits. Less is known about concentrations of CO_2 and other volatiles degassed by metamorphism. Depending upon serpentinite contributions, the volatile outputs of volcanic arcs either roughly match the inputs, implying near-complete volatile recycling, or are significantly less, implying a long-term flux of H_2O from the surface ocean to deep mantle.

Anhydrous oceanic crust can be expected to undergo a series of phase transitions from gabbro to eclogite. These result in a major density increase; gabbro has a density ~10% lower than that of peridotite at similar temperatures and pressures, so unmetamorphosed oceanic crust has buoyancy that resists subduction, while eclogite (dominated by garnet and pyroxenes) is significantly denser than peridotite. The density increase, in transforming from gabbro to eclogite, may contribute significantly to the negative buoyancy of slabs that drives plate tectonics. However, reaction rates for garnet growth (a major step in eclogite formation) within coarse-grained, anhydrous gabbro may be relatively slow, such that gabbro may persist metastably to considerable depth within subduction zones (Ahrens and Schubert 1975). The presence of water should substantially enhance that reaction rate (e.g., Hacker 1996).

If hydrated, basalt/gabbro (and metasediment) are expected to undergo a lengthy sequence of metamorphic reactions that, generally, release H_2O (Fig. 4). As a consequence, H_2O should be released over a wide range of depths from the thrust zone to

sub-arc mantle, hydrating the overlying mantle wedge (Schmidt and Poli 1998; Hacker 2008). At typical to cold subduction conditions, oceanic crust can be expected to transition through greenschist and blueschist facies, capable of holding up to ~5 wt% H₂O, with major dehydration occurring in the transformation to eclogite during high-pressure heating (Hacker et al. 2003). In warmer subduction zones, defined as those with fairly young incoming plates and slow subduction rates (e.g., Cascadia, southern Japan), descending crust should follow a higher-temperature path perhaps through amphibolite facies, dehydrating as amphibole breaks down at ~2 GPa. Most thermal models with realistic mantle-wedge viscosity structure predict that subducting crust should dehydrate by depths of 100–200 km (e.g., Syracuse et al. 2010), at least in its shallow parts.

The mantle within the subducting plate potentially holds hydrous minerals as well, primarily serpentine but also chlorite, as might entrained material lying above the downgoing plate. These layers should also dehydrate, at temperatures of 600–700 °C for serpentines at <200 km depth (e.g., Schmidt and Poli 1998) with chlorite breaking down at temperatures about 200° higher. Serpentine dehydration temperatures are probably reached in all subduction zones on the slab surface and, hence, above it, although it is possible that a weakly hydrated zone of chlorite stability may persist past slab depths (e.g., Grove et al. 2009). Subducting mantle lithosphere in most subduction zones should be cold enough for serpentine to be stable past the arc (Syracuse et al. 2010), and may dehydrate gradually past that. Water persisting to depths past 200 km has the potential to remain within the mantle to considerable depth, in the “alphabet” phases of dense hydrous magnesium silicates, which have broad stability fields at near-slab conditions (Thompson 1992). Water reaching the transition zone (410–660 km depth) may remain for a long time, as the dominant minerals ringwoodite and wadsleyite can retain wt% water as defects in their nominally anhydrous structure (Kohlstedt et al. 1996). This reservoir has potential to hold several times more water than the current surface ocean; thus, the ability of serpentinized mantle lithosphere to transport H₂O to great depths may be a dominant control on the Earth’s long-term water budget.

As water is released, it ascends into the overlying mantle wedge, crust, back along the thrust zone, and through the forearc (Peacock 1990), potentially hydrating it (Hyndman and Peacock 2003). These pathways provide major controls on rheological properties in all these regions and on the behavior and composition of arc volcanoes. Also, it is often suggested that the dehydration process generates earthquakes at intermediate depths (70–150 km) in subduction zones (Green and Houston 1995; Kirby et al. 1996; Hacker et al. 2003). These processes are discussed extensively in the entry on ► [“Seismicity, Subduction Zone”](#).

Subduction Channel

In many collisional mountain belts and accreted terranes, high-pressure, low-temperature rocks have reached the Earth’s surface after having descended to great depths. In some “ultra-high pressure” (UHP) terranes, mineral assemblages or textures in these rocks record pressures in excess of 3–4 GPa (depths >100 km), indicating that these rocks descended deeply in subduction zones before returning to the surface. In part to explain these observations, a “subduction channel” has been often proposed (Cloos and Shreve 1988). The subduction of weak, hydrated metasediments and altered oceanic crust, and their subsequent shearing and interaction with metamorphic fluids, suggests the presence of a heterogeneous weak zone at the top of the downgoing plate. Initially, material in this channel will be dragged downward by coupling with the subducting plate, but it should be buoyant relative to overlying mantle, and in the right conditions a return flow could develop delivering high-grade metamorphic rocks to the surface. A weak zone is also indicated by the presence of a “cold nose” in many subduction zones in the forearc mantle wedge, a feature that probably requires a weak decoupling layer to depths of 70–90 km on the top of the downgoing plate (e.g., Wada and Wang 2009). The presence of UHP rocks at the earth’s surface indicates that the return-flow process or something similar probably happens in some instances, but it remains unclear if the subduction channel is a common feature of subduction zones.

Melting and the Volcanic Arc

Reviews elsewhere describe the geochemical evidence for the nature of melting beneath volcanic arcs and the generation of arc crust (e.g., Stern 2002; Kelemen et al. 2003b), which are briefly summarized here for their relevance to geophysical observations. Magmas emplaced and erupted at subduction zones span a wide range of compositions. Basalts are found at most subduction zones and indicate that primary melting occurs within the mantle beneath the volcanic arc, since basalts primarily form from melting of peridotites (e.g., Gill 1981). These basalts often differ from those found at mid-ocean ridges or hot spots in several important chemical trends; in particular, many elements that are strongly abundant in subducting sediment and altered crust are found in abundance in many volcanic arc rocks in a manner that correlates with sediment chemistry (Plank and Langmuir 1998). In some arcs there is strong evidence for andesites forming under high pressure, perhaps requiring melting of downgoing crust (e.g., Kelemen et al. 2003b).

Magmatic differentiation within the crust and mixing with preexisting arc basement result in a wide spectrum of volcanic

output. Typically, seismic velocities within arcs show an increase with depth consistent with more silicic, felsic rocks at shallow depths ($V_p = 6.0\text{--}6.4$ km/s) underlain by more gabbroic rocks in the middle-to-lower crust ($V_p = 7.0\text{--}7.4$ km/s) (e.g., Suyehiro et al. 1996; Shillington et al. 2004). Since they are petrologically fractionated from more basaltic parents, the andesitic or granitic rocks observed at mid-to-upper crustal levels should be balanced by more mafic silica-poor residuals, perhaps in the lower crust. However, such lower-crustal cumulates are not very abundant, as interpreted from seismic velocities, exposed arc sections, and within continents formed by arc accretion. In general, there is good reason to think that continents grew from accretion of arcs since they share many geochemical characteristics (Rudnick 1995), but overall continents are significantly more silicic than primary arc basalts. This discrepancy probably requires a significant mass loss in the complementary, mafic cumulates that should form in arc lower crust. Where and how this mass loss occurs remains unclear; it may be that the lower crust in arcs occasionally founders or delaminates back into the mantle, since its density may be higher than that of peridotite, but many other possibilities exist. Geophysical observations of the lower crust and upper mantle have potential to place constraints on the formation and evolution of arc crust, and hence the origins of continental material (e.g., Kodaira et al. 2007; Tatsumi et al. 2008).

Primary magmas emerging from the mantle contain several wt% H_2O and elevated CO_2 , several times higher than in mid-ocean ridge basalts (e.g., Hirschmann 2006). Mantle melting beneath arcs often occurs in the presence of H_2O (Grove et al. 2006), leading to the frequent speculation that dehydration reactions within the subducting slab trigger melting in the overlying mantle wedge, and hence the location of dehydration within the slab controls the location of arc volcanism (e.g., Tatsumi 1986). However, experiments on hydrous metabasalts show that dehydration occurs over a wide range of depths beginning much shallower than the sub-arc mantle wedge (e.g., Schmidt and Poli 1998), so that H_2O should flux the mantle at many depths, not just under the volcanic arc. Also, primary, dry basalts have been found in some arcs, so H_2O is not always required for melting. It may be that the return flow (the incoming limb of wedge corner flow) sufficiently decompresses hot asthenosphere to trigger melting. The relative importance of wet (flux) melting and dry (decompression) melting within arcs remains poorly understood, as do the pathways that magmas take from their locus of formation to volcanic arcs. In particular, it is not obvious why the arc front is a narrow, well-defined feature while the conditions for melting should be more widely spread. The depth to slabs beneath the arc front averages 110 km but varies coherently by a factor of 2 from arc to arc, suggesting some other controlling process probably related to thermal structure (England et al. 2004; Syracuse and Abers 2006).

Seismic Imaging of the Subduction Zone

Although subduction zones exhibit a characteristic surface morphology of trench, forearc, volcanic arc, etc., the evidence that these associations represent subduction of deep material comes primarily from geophysical imaging of deep structure. Early observations of seismic wave propagation in Tonga showed that the Wadati–Benioff zone lies in a cold, low-attenuation structure unlike mantle elsewhere on the planet, and provided some of the first evidence that these were sites of descending cold lithosphere (Oliver and Isacks 1967). Since then, methods of seismic tomography have improved greatly (see ► “[Seismic Tomography](#)”) as has the global data set of earthquake travel times, leading to a clear picture of P-wave high-velocity anomalies that show cold slabs descending through the upper mantle and in some cases into the lower mantle (e.g., Van der Hilst et al. 1997). These data show slabs as seismic anomalies 4–10% faster than surrounding mantle (see compilation by Lay 1997), consistent with thermal models that predict temperatures 400–800 °C colder than surroundings. These images, based on global earthquake travel time data sets, show that in some cases slabs reach the mantle transition zone and flatten out, as if reaching a partial barrier to flow (e.g., Japan) while in other cases they pass through the transition zone delivering subducted material to the lower mantle.

Seismic recordings from networks and arrays in subduction zones provide strong constraints on the subduction zone structure of a scale relevant to slab metamorphism, arc petrogenesis, and wedge flow. For example, as dehydration occurs, densities increase as do seismic velocities; basalts are 10–15% slower than surrounding peridotites while eclogites have similar velocities. Furthermore, serpentinized peridotite can be tens of percent slower than peridotite particularly for shear waves, depending upon the extent of serpentinization (hydration). As a result, seismic imaging has potential to show where and how metamorphism within slabs occurs. For example, with migration of P-to-S scattered waves (see ► “[Seismic, Receiver Function Technique](#)”) subducting crust has been observed to ~45 km depth in Cascadia and depths exceeding 100 km in Alaska and Japan, consistent with expected depths of basalt dehydration and differences in thermal structure (Rondenay et al. 2008). Studies of earthquake travel times and signal attenuation also provide information on structure of the mantle wedge where melting initiates, and have shown a clear hot mantle wedge, with a variety of structures suggesting melt transport pathways. Probably the densest long-lived monitoring effort exists in Japan, although a variety of portable array experiments have illuminated subduction zones in parts of the Andes, Central America, Tonga, the Marianas, Alaska, Cascadia, Greece, and other locales.

One of the more complex suites of seismic observations comes from the anisotropic fabric within the mantle of subduction zones, which results in “splitting” of shear waves into orthogonally polarized fast and slow pulses (see ► [“Magnetic Anisotropy”](#)). Mantle flow in the dislocation creep regime leads to lattice-preferred orientation of olivine, and olivine is moderately (~ 10%) anisotropic, leading to an association between seismic anisotropy and mantle flow. However, observations in many subduction zones lie counter to expectation (e.g., Russo and Silver 1994). Simple models of mantle flow in subduction zones predict “corner flow,” in which mantle on either side of the descending plate is entrained via viscous drag (Fig. 2). To fill the potential void left by the downward advection, mantle far from the subducting slab flows inward toward it, eventually turning and flowing downward. While details of this flow depend upon the viscosity structure and its sensitivity to temperature, stress, water, and other variables, the overall pattern of flow is one in which the maximum strain or stretch should be perpendicular to trench and arc, in the direction of flow. In many subduction zones, anisotropic fabric does not show this pattern, and instead the fast direction for shear wave propagation is more often than not parallel to the trench, at least below and behind the volcanic arc (Fischer et al. 1998). More complicated fabrics are also observed, with sharp 90° changes in fabric between sub-arc mantle and the shallower part of the forearc (e.g., in North Japan and Alaska), and the pattern varies between different subduction zones. Explanations for these unexpected patterns remain a matter of much debate, and include strong along-strike flow, secondary flows within the wedge, influence of melt on fabric, activation of unusual olivine slip systems at some subduction zone conditions, abundance of hydrous, foliated minerals in the forearc, extensive fabric within the downgoing slab, and unexpectedly strong upper-plate fabrics.

Subduction Zone Hazards

The forces present in subduction zones also produce some of the most violent natural hazards known. The interplate thrust zone generates all of the largest earthquakes, which produce strong shaking but also submarine landslides, meter-scale uplift and subsidence, and most of the largest tsunamis. The 2004 Sumatra earthquake represents the primary example of the last 50 years; a magnitude 9.2 earthquake ruptured over 1,000 km of plate boundary, producing an ocean-crossing tsunami that directly resulted in over 150,000 deaths and huge devastation to property. These earthquakes are devastating because subduction zone thrust faults are very large, because they are submarine but can break the sea surface, and because they occur in places with often oversteepened bathymetry. Subduction zones are also site to many of the most violent volcanic eruptions. Large volatile (especially water) contents of subduction zone magmas, compared with

most other settings, lead to magmas rich in gas that exsolve at shallow depths. Magmatic differentiation leads to relatively viscous, felsic magmas that rise slowly and do not degas easily. The combination leads to explosive and sometimes very large eruptions; in the last half century, Mt. St Helens (Cascadia), Pinatubo (Philippines), and Montserrat (Lesser Antilles) all produced violent and well-documented eruptions in subduction zones, among many others. Worldwide, about 500 volcanoes have known historic eruptions, roughly two-thirds in subduction zones.

Summary

Subduction zones represent the primary return of material from the earth’s surface to its interior. In the process of doing so, great earthquakes occur, violent volcanoes erupt, and the largest lateral temperature gradients in the Earth’s interior are generated. At shallow depths, elastic and brittle processes control deformation including most of the planet’s large earthquakes, while at greater depths the subduction system deforms by large-scale ductile flow. Along with oceanic crust, sediment and volatiles enter the trench, lubricating the plate boundary at shallow depths, and then are metamorphosed where slabs descend below hot mantle, releasing H₂O and other volatiles into the overlying mantle wedge. While some of this material may mechanically ascend back to the surface, in the form of high-pressure metamorphic rocks, much feeds explosive volcanism in the volcanic arc or descends into the deep mantle. Melting at sub-arc depths is controlled by a combination of advection via flow of hot mantle from the back-arc, and fluxing by slab-derived fluids, a combination of which produces a sharp volcanic front. Magmas ascend to form arc crust and differentiate, some fraction of which persists to form the basis of continental crust. This transfer of energy and material leads to a rich set of phenomena that play a major role in creating the geologic record.

Surface Waves

Barbara Romanowicz

Berkeley Seismological Laboratory, Berkeley, CA, USA

Collège de France, Paris, France

Definition

Surface waves are elastic waves which propagate along the surface of the earth and whose energy decays exponentially with depth.

Surface waves contain most of the long period energy (periods greater than 20 s) generated by earthquakes and recorded at teleseismic distances. Most prominent on records of moderate ($M \geq 5.5$) earthquakes are the fundamental mode wave trains that have propagated along the direct great circle path between the epicenter and the station. The dispersive and attenuative properties of these wave trains have been used extensively, since the 1950s, to infer crust and upper mantle structure at the regional scale. For earthquakes of magnitude 7 or larger, successive, earth-circling surface wave trains can be followed for many hours (Fig. 1) and are either analyzed individually or, at the longest periods ($T > 250$ s), they are combined over time lengths of tens of hours or days to produce a spectrum of Earth's free oscillations (see ► [“Free Oscillations of the Earth”](#)).

In an isotropic medium, there are two types of surface waves which propagate independently (Fig. 2). Rayleigh waves, polarized in the vertical plane containing the source and the receiver (P-SV energy), have a retrograde elliptical particle motion. These waves have generally good signal-to-noise ratio on the vertical component records and have been studied the most. On the other hand, the analysis of Love waves, polarized horizontally in a direction perpendicular to the propagation direction (SH energy), suffers from the more complex data processing required, and from higher levels of long period background noise on the horizontal component records, due primarily to the effect of atmospheric pressure variations, inducing ground tilts. Love waves, unlike Rayleigh waves, can exist only in a heterogeneous medium (i.e., a layered medium).

The most striking property of surface waves is their dispersive character, with, in general, waves of longer periods

Surface Waves, Fig. 1 Example of vertical component record showing earth-circling Rayleigh wave trains (marked R1...R8) following the M8.8 Maule Chile earthquake of February 27, 2010. This record is from station BKS of the Berkeley Digital Seismic Network (BDSN). The successive wavepackets are well separated from each other at this epicentral distance (86.6°). The long period surface waves are often referred to as “mantle waves.” (Courtesy of Shan Dou)

Surface Waves, Fig. 2 Particle motion for Rayleigh and Love waves. Rayleigh waves have retrograde particle motion confined to the vertical plane of propagation. Love waves have purely transverse motion in the horizontal plane. (After Bolt (1976))

traveling faster, directly reflecting the increase of elastic velocity with depth in the earth's crust and mantle. Indeed, studies of crustal and upper mantle structure progressed rapidly in the 1950s and early 1960s, as the tools developed to measure group and phase velocity dispersion and interpret them in terms of layered mantle and crust models (e.g., Ewing et al. 1957).

In a spherical earth, the theory of generation and propagation of surface waves is intimately linked to that of Earth's free oscillations, leading to the distinction of various modes. The lowest mode is termed fundamental mode, followed by higher modes, or overtones. Fundamental mode Love and Rayleigh waves are generally well separated from other seismic phases on the seismograms, and are well excited by

shallow, crustal earthquakes, while higher modes (i.e., overtones) travel at higher group velocities and appear as compact packets of mixed overtones. They are better excited by deeper earthquakes (Fig. 3).

Surface waves recorded at teleseismic distances contain information about both the characteristics of the earthquake source and the structure of the earth's crust and mantle along the source-station path. Separating the two effects has been one of the long-standing challenges faced by seismologists.

Group and Phase Velocity

The velocity of propagation of surface waves can be described in terms of either group velocity or phase velocity. Phase velocity is the velocity of a specific frequency component of the wave train. Phase velocity derives from the expression of a plane wave of wavenumber k , and angular frequency ω , propagating in the direction x , for example, in one dimension:

$$f(x, t) \sim \exp i(\omega t - kx) \quad (1)$$

It is defined as the velocity of the phase of the component of frequency ω :

$$C(\omega) = \omega/k \quad (2)$$

where ω is the angular frequency and k is the wavenumber. Frequency is related to period of the wave, T , by $\omega = 2\pi/T$, while $k = 1/\lambda$ where λ is wavelength.

Group velocity is the velocity with which the energy travels. The group velocity is derived from considering a wave train containing multiple frequencies:

$$u(\omega, t) = \int A(\omega) \exp i(\omega t - kx) d\omega \quad (3)$$

and finding the point (x, t) where the phase is stationary:

$$d(\omega t - kx)/d\omega = 0 \quad \text{hence} \quad t = xdk/d\omega \quad (4)$$

This leads to the definition of group velocity U as:

$$U(\omega) = d\omega/dk \quad (5)$$

In general, at any given period, the group velocity of surface waves in the earth will be less than the phase velocity. The minimum in the group velocity curve is termed Airy phase, a major feature of many surface wave records. Note that waves with periods shorter than the period of the Airy phase will exhibit reverse group velocity dispersion, with the shorter periods traveling faster. Phase velocity, on the other hand, always increases with period.

Surface Waves, Fig. 3 Example of vertical component record for the October 14, 1996, Solomon Islands earthquake (depth = 19 km, $M_w = 6.7$) at BDSN station ORV showing the arrivals of multiply reflected body wave phases forming a higher-mode Rayleigh wave train in front of the fundamental mode (R1). The Airy phase, corresponding to the group velocity minimum around 230 s, is well visible at the end of the R1 train. The seismogram has been bandpass filtered with cutoff frequencies at 35 and 400 s. (Courtesy of Yuancheng Gung)

Surface Wave Generation and Propagation

The theoretical formulation for the excitation of surface waves and normal modes of the earth, an eigenvalue problem, was developed in the 1960s (e.g., Haskell 1964), much stimulated by the occurrence of the great Chilean earthquake of May 22, 1960 (M 9.5). A computational method, following the original theoretical approach of Saito (1967) based on Runge-Kutta matrix integration method, has long been the main reference for the practical calculation of surface waves and normal modes in laterally homogeneous, elastic, flat, or spherical earth models. Today, a widely used approach for spherical geometry, efficient to relatively short periods (10 s), is based on a propagator matrix method in which minors of sets of solutions are used effectively (Woodhouse 1988). The association of a normal mode formalism to compute dispersion and excitation of surface waves (and complete seismograms), with a moment tensor formalism to describe the earthquake source (e.g., Backus and Mulcahy 1976) led to the rapid development of source studies based on surface waves in the 1980s.

To obtain the frequency spectrum of a single mode surface wave train from the expression of a seismogram obtained by summation of normal modes in a spherically symmetric earth, one uses Poisson's formula (e.g., Aki and Richards 1980), which decomposes the modes into infinite trains of propagating surface waves traveling in opposite directions around the earth. In this process, a high frequency approximation is used, in which the phase velocity (see below) of a surface wave is related to the corresponding normal mode frequency by Jeans' formula:

$$C(\omega) = \frac{a\omega_l}{l + 1/2} \quad (6)$$

where l is the angular order of the mode and ω_l its eigenfrequency, and a is the radius of the earth. In this high-frequency approximation, surface waves propagate along the great circle path between the epicenter and the station and are sensitive to structure only along this great circle.

The spectrum of a single mode propagating surface wave at distance Δ , azimuth θ , and angular frequency ω can be expanded as follows:

$$U(\Delta, \theta, \omega) = U_s(\theta, \omega)S(\Delta)U_p(\Delta, \theta, \omega)F(\omega, \theta_0)D(\omega)I(\omega) \quad (7)$$

where U_s is the source spectrum, U_p contains propagation effects, I is the instrument response, $S(\Delta)$ is the geometrical spreading term, and F and D describe the source process.

The propagation term U_p can be expressed as (e.g., Romanowicz 2002):

$$U_p(\Delta, \theta, \omega) = \frac{1}{(\sin \Delta)^{1/2}} \exp(i\pi/4) \exp(im\pi/2) \times \exp[-i\omega\Delta/C(\omega, \theta)] \exp[-\eta(\omega, \theta)\Delta] \quad (8)$$

where m denotes the number of polar passages and $C(\omega, \theta)$, $\eta(\omega, \theta)$ are, respectively, the average phase velocity and attenuation coefficient along the source-station path.

On the other hand, the source term $U_s(\theta, \omega)$ can be expressed as a linear combination of the moment tensor elements M_{ij} of the source.

Structure Studies Using Surface Waves

Fundamental Mode Studies (Dispersion)

Fundamental mode surface waves are well suited for the study of crust and upper mantle elastic structure, which can be deduced from their group and/or phase dispersion properties. They allow the sampling of vast areas of the globe that are otherwise devoid of seismic stations, such as the oceans.

Many early studies documented the correlation of seismic velocity variations with surface tectonic features, using regional measurements of phase and group velocities of fundamental mode Love and Rayleigh waves in the period range 20–100 s (e.g., Knopoff 1972) or at longer periods, reaching deeper into the mantle (e.g., Toksöz and Anderson 1966). Since the early 1970s, the computation of group velocity has relied on the multiple filtering technique introduced by Dziewonski et al. (1969). This approach, later perfected as the FTAN method (e.g., Lander 1989), involves two steps. In the first step, an “energy diagram” is formed by windowing the seismogram over group arrival time and filtering over an array of specified center frequencies. The resulting amplitudes are then plotted as a function of time and frequency and their values contoured. The group velocity curve is obtained by tracing the loci of maximum amplitude as a function of period. In a second step, the time domain seismogram is filtered using multiple filters centered on the group velocity curve (e.g., Fig. 4).

Phase velocity is obtained from the phase Φ of the Fourier spectrum of a dispersed wave train that has been corrected for the contribution of the source and the instrument:

$$C(\omega) = \frac{X}{t_0 - [\Phi - N - (m/4) - 1/8]/\omega} \quad (9)$$

where t_0 is the start time of the Fourier window with respect to the event's origin time, m is the number of polar passages, and N is an integer arising from the 2π indeterminacy of the phase. This integer is determined first at long periods to obtain reasonable values of phase velocity compatible with well-

Surface Waves, Fig. 4 Example of group velocity dispersion diagrams obtained for the fundamental Rayleigh wave mode on the vertical record of the Chile Ms. 6.8 earthquake of October 15, 1997, at Geoscope station INU, using the FTAN multiple filtering approach. (a) Dispersion diagram before filtering; (b) same after filtering. The group velocity dispersion curve obtained follows the maxima of energy as delineated by the gray scale contours. (c) Corresponding time domain seismogram before (broken line) and after (solid line) variable filtering. The bandpass is 50–400 s. (Reprinted from Romanowicz (2002))

constrained global earth models. The phase velocity curve is then successively continued to shorter periods at fixed N , so as to obtain a smooth curve. This can become a problem at periods shorter than 30 s, where small variations in phase velocity correspond to rapid cycling of the phase.

The contribution of the earthquake source to the phase needs to be known accurately for the computation of phase velocity, less so for group velocity. This can be circumvented by making measurements using the “two-station method,” in which dispersion is measured between two stations approximately aligned with the epicenter on a great circle, thus eliminating the common source phase. If, in addition, the two stations are located within a relatively homogeneous geological province, such measurements are called “pure path” and lead directly to the determination of elastic velocity structure beneath that province. This method has been extended to “many stations” to infer structure beneath an array of stations spanning a geologically homogeneous region.

Noise Cross-Correlation Methodology

A radically different methodology was introduced in the early 2000’s. The medium’s “Green’s function” between two seismic stations can be extracted from cross-correlations of records at both stations over long time periods, without the need for using earthquake data (see ► [“Seismic, Ambient Noise Correlation”](#)). These “noise cross-correlations” have been particularly effective for the measurement of the fundamental mode dispersion between two stations in and around the microseismic frequency band (5–30 s), where the background seismic noise is the most energetic. It has been shown

that this approach leads to results that are as good as those obtained using standard methods, in regions where seismicity is strong and provides good illumination of the structure using “standard” approaches (e.g., Shapiro et al. 2005). This has opened up new horizons for the study of regional crustal structure, especially in seismically quiet regions. The measurement of fundamental mode dispersion by noise cross-correlation, combined with inversion for elastic structure (“Ambient-noise tomography”) has now been applied in many continental regions of the world, leading to higher resolution regional crustal models, especially when combined with information from converted phases at crustal discontinuities, which results in locally layered models of absolute shear velocity in the crust. Combining the noise-derived dispersion data with earthquake-based derived ones allows inversion for shear velocity structure down to upper mantle depths. It has been found that it is important to take into account biases introduced by the nonuniform distribution of noise sources around the study region. This is because most of the noise sources that contribute to the reconstruction come from the interaction of ocean waves generated by storms with the seafloor and have strong seasonal fluctuations (see section [“The Earth’s Background Noise Spectrum: Hum and Microseisms”](#)).

Global Studies of Structure Using Surface Waves

With the advent of digital recording in the mid-1970s and the expansion of global digital long-period and later broadband networks (see ► [“Seismological Networks”](#)), the processing

of the relatively long time series needed to measure surface waves became much easier and opened the way, in the 1980s to large-scale and global studies of upper-mantle structure.

Global studies first proceeded according to a regionalization scheme, in which it was assumed that the depth variation of seismic velocities is the same across each tectonic province. These studies confirmed and extended to longer periods (and hence larger depths) early results on the age dependence of structure in the oceans (e.g., Romanowicz 2002; see also ► [“Earth’s Structure, Upper Mantle”](#)). The constraint of regionalization was soon relaxed, replaced by expansion of lateral heterogeneity into a global basis of spherical harmonics. This revealed, in particular, that the correlation of structure with tectonics disappears below depths of 200–300 km (e.g., Ekström et al. 1997). Dispersion measurements have focused primarily on the fundamental mode, generally in the period range 35–150 s, and thus are generally limited in resolution to depths shallower than ~300–400 km. This approach has led to several generations of global phase velocity maps at discrete frequencies, with increasing spatial resolution (e.g., Fig. 5). In these studies, lateral variations of dispersive properties are now well resolved down to wavelengths of ~1,000–2,000 km. At the long period end, the period range is limited by the difficulty of separating consecutive wave trains, and at the short period end, by the increased complexity of surface wave propagation in the strongly heterogeneous crust and uppermost mantle, resulting in lateral refractions and multipathing. The latter are not taken into account in the simple high frequency, great circle propagation assumptions underlying the construction of dispersion maps.

Inversion of Surface Wave Dispersion Data

Inversion of surface wave dispersion data generally involves two steps. By combining measurements at a given frequency for many different paths crossing a particular region, or, at longer periods ($T > \sim 40$ s) over the entire globe (e.g., Fig. 5), dispersion maps can be obtained by a standard linear inversion procedure, yielding point by point dispersion curves over the region considered.

These dispersion curves can then be inverted to obtain the local variation of elastic parameters with depth, by matching observed dispersion curves to theoretical curves calculated for layered earth models, using inverse theory (e.g., Thurber and Ritsema 2015; see also ► [“Inverse Theory, Linear”](#)). The models thus obtained suffer from some degree of nonuniqueness, as the problem is underdetermined. In particular, surface waves cannot by themselves resolve strong gradients of velocity with depth, so that, in general, some a priori constraints are applied, such as fixing the depth of the Moho, or limiting the extent of low-velocity layers. A major advance was the theoretical contribution of Backus and Gilbert (1968), which made it possible to calculate the resolving kernels and errors associated with the various least squares solutions of the inverse problem. Surface wave dispersion is most sensitive to shear velocities, so that, in general, a priori scaling factors between shear velocity and compressional velocity, on the one hand, and density, on the other, are assumed. These scaling factors rely on laboratory measurements of rock properties and are most reliable for crustal and upper mantle depths.

Surface Waves, Fig. 5 Examples of global Rayleigh wave phase velocity maps (left) and attenuation maps (right) at periods of 50 s (20 mHz, top) and 100 s (10 mHz, bottom), highlighting the diminishing lateral variations of structure with period (i.e., with depth) and the

correlation with tectonics in both velocity and attenuation. Phase velocity is shown in relative perturbations (percent) with respect to the global mean at each period. Attenuation is presented in relative perturbations of Q^{-1} . (After Ma et al. (2016). Courtesy of Zhitu Ma)

Crustal Corrections

A significant issue regarding the inversion of long period fundamental mode surface waves (40–200 s) for upper mantle structure is that of crustal corrections. Indeed, surface waves are sensitive to shallow structure even at long periods, but not sensitive enough for inversion, unless more difficult to measure short periods (down to ~ 10 s) are included. Until recently, most studies simply performed crustal corrections in the framework of linear perturbation theory. However, Montagner and Jobert (1988) showed that the effect of the large variations in crustal thickness is nonlinear, and proposed a more accurate correction procedure based on a tectonic regionalization. Developing accurate crustal models worldwide (see ► “Earth’s Structure, Core”) remains a challenge for large-scale surface wave inversions for structure of the upper mantle, especially in the era of numerical computation of waveforms. In this respect, the availability of large dispersion datasets from noise correlations are very helpful in constraining crustal contributions, especially in densely instrumented regions, such as the continental United States (e.g., Ekström 2017).

Inversion Using Overtones

While they are well separated in the time domain from other mode branches, and therefore well suited for frequency domain single mode analysis techniques, fundamental mode

surface waves have several shortcomings: at intermediate periods (~ 20 – 150 s), their sensitivity to structure below about 200 km is poor, whereas longer period mantle waves, which reach down to the top of the upper mantle transition zone, have poor spatial resolution. In any case, resolving structure in the transition zone, which is also poorly sampled by body waves, requires the inclusion of higher-mode surface waves, whose sensitivity is larger at these depths (e.g., Fig. 6). They are also a powerful tool for investigating structures where low velocity zones may be present (e.g., Kovach and Anderson 1964). In general, however, higher-mode surface waves overlap in the time-frequency domain, and single mode dispersion methods therefore cannot be applied.

In the 1970s, array methods were developed independently by Nolet (1975) and Cara (1978) to extract information from overtones, and applied in the period range 20–100 s to paths across Eurasia and the Pacific Ocean, respectively. These methods require a linear regional array of stations approximately aligned with the epicenter (and not in a nodal direction of the source radiation pattern), in order to separate modes in the (ω, k) domain, where k is the wavenumber. They are limited in application to a few regions of the world with relatively dense, linear arrays. A waveform-based method involving the comparison of observed and synthetic seismograms at a single station was proposed by Lerner-Lam and Jordan (1983). In this approach, branch

Surface Waves,

Fig. 6 Sensitivity with depth of Rayleigh wave fundamental mode (solid line) and first two overtones (broken lines) at a period of 100 s, computed in the PREM model (Dziewonski and Anderson 1981). The fundamental mode sensitivity peaks around 200 km whereas the overtones have significant sensitivity down to the top of the lower mantle. (Courtesy of Yuancheng Gung)

cross-correlation functions (bccf's) are formed between a particular single-mode synthetic and the observed seismograms and used to invert for an average structure along each source-station path. This approach lends itself to the derivation of secondary observables such as group or phase velocity. The main drawback of this methodology is the contamination of the single mode objective function by interference from other mode branches. More recently, van Heist and Woodhouse (1997) proposed a “mode-branch stripping” method based on a bccf approach combined with a frequency-stepping procedure, yielding single mode dispersion and amplitudes. A global multimode dispersion dataset assembled in this fashion has been used in the construction of several generations of global shear velocity models (e.g., Ritsema et al. 2011). See also ► [“Earth’s Structure, Upper Mantle”](#).

Time Domain Surface Wave Inversions

Extracting single mode dispersion information directly from spectra of windowed wave trains is only effective for the fundamental mode, which is well separated on the seismogram, and even in this case, overlapping with overtone wave trains or, at long periods, other orbits of the fundamental mode, can be a problem. A waveform matching approach is therefore desirable, where observed seismograms are compared to synthetics computed for a given reference earth model, and the model is perturbed to improve the fits of the observed and synthetics in the target time window of observation, which can be optimized. In particular, such an approach is suitable both for fundamental mode and overtone surface waves.

For many years, the computation of long period synthetic seismograms relied on asymptotic approximations to normal mode first order perturbation theory, as developed in the 1970s. The most widely used approximation is the “path average approximation,” introduced for waveform modeling by Woodhouse and Dziewonski (1984). The key steps that led to the various formalisms routinely used today are described in Romanowicz et al. (2008). See also ► [“Seismic, Waveform Modeling and Tomography”](#).

Working under the assumption of PAVA, Nolet (1990) introduced “the partitioned waveform inversion” (PWI), in which inversion for elastic structure proceeds in two steps, more closely related to the two-step inversion using dispersion data. Path integral parameters are defined and retrieved by nonlinear waveform fitting over each path, and in a second step, inverted linearly for elastic structure. The advantage of this approach is that it reduces the number of parameters to be fit in the nonlinear part of the inversion. The PWI also includes progressive filtering of data starting at the longest periods (see ► [“Seismic Tomography”](#)). It has been applied for the construction of continental scale as well as global scale models of the upper mantle (e.g., Schaeffer and Lebedev 2013).

Because it includes only coupling of modes along single dispersion branches, the PAVA is rigorously only suitable for single-mode wave trains such as the fundamental mode. The corresponding sensitivity kernels to structure are 1D kernels, that is, they only depend on the laterally averaged structure in the vertical plane between the source and the receiver. When applied to overtones and body waves, coupling across mode branches needs to be included. For a review of these methodologies, see Romanowicz et al. (2008) and Thurber and Ritsema (2015).

Effects of Scattering and the Born Approximation

Until recently, most regional and global models of upper mantle structure derived from surface waves were based on the standard “path average” approximation (PAVA). This is valid only if the wavelength of lateral variations of structure is long with respect to that of the surface waves considered. And it is not strictly appropriate for overtones.

Many observations indicate that lateral heterogeneity is strong enough to cause departures from PAVA. For example, 20 s surface waves sensitive to shallow crustal structure consistently show multipathing (e.g., Capon 1970 or Fig. 7). At longer periods ($T > 100$ s), later arriving trains often show larger amplitudes than the ones preceding them which cannot be explained by lateral variations of attenuation.

Several approaches have been developed to account for these effects and exploit them to obtain better constraints on lateral variations of structure. Woodhouse (1974) introduced the concept of local modes. These are the surface wave modes of a laterally homogeneous model, which locally has the depth distribution of the laterally varying model. If the medium is laterally smooth, the local mode branches propagate as independent wave trains, and their dispersion is modified according to the evolution of the local modes. However, if lateral variations are sharp (e.g., in the presence of a structural discontinuity such as an ocean-continent boundary), the coupling of the local modes cannot be neglected and its strength depends on the width of the structural transition zone (Kennett 1972). For a review see Romanowicz (2002). Kennett (1984) derived a formalism for mode-coupling in 2D slowly laterally varying structures, which was extended to the 3D scattering case, in Cartesian coordinates (e.g., Bostock and Kennett 1992).

In the framework of scattering theory, the use of tools based on the single-scattering Born approximation has gained popularity in the last 5 years. Born scattering is well suited for inversion since the scattered wavefield depends linearly on structural perturbations (e.g., Snieder 1988). The use of Born kernels is widely advocated to take into account the effects on dispersion of off-great circle sensitivity of surface waves (e.g., Zhou et al. 2006). However, the relative merits of

Surface Waves, Fig. 7 Example of vertical component record at BDSN station ORV for an M_w 7.0 earthquake in Turkmenistan showing multipathing of 20–30 s surface waves. The record has been bandpass filtered between 0.001 and 0.03 Hz. The great circle path is shown on the

top plot with a shear wave tomographic model in the background. It arrives to the station from the north, following the coast and along major structural boundaries in the crust that are likely the cause of the multipathing. (Courtesy of Yuancheng Gung)

single-scattering Born sensitivity kernels versus simpler averaging kernels, such as “fat rays” has been debated (e.g., Boschi et al. 2006).

Born is also a poor approximation in the case of strong heterogeneity, or when the region of scattering is large (e.g., Friederich et al. 1993).

Most recently, the introduction to global seismology of the Spectral Element Method (Komatitsch and Vilotte 1998), which provides an accurate representation of the teleseismic wavefield in arbitrary 3D media up to the second surface wave orbit, has provided a new powerful tool for the study of Earth structure, and is progressively being implemented for

waveform modeling of crust and upper mantle structure at the local (e.g., Tape et al. 2010), regional (e.g., Fichtner et al. 2010), and global scale (e.g., French et al. 2013), using relatively long period surface waves (periods longer than 40 s). These studies show that the use of a more accurate wave propagation theory results in the improved retrieval of amplitudes of lateral variations of shear wave velocity, and, in particular, significantly lower values in low velocity zones. For applications at the global scale, this promising new tool presents several challenges: a considerable computational cost, and the necessity of accurate representation of the 3D structure in the crust. Such an approach has more recently

been extended to whole mantle tomography, adding shorter period body waveform information (French and Romanowicz 2014; Bozdag et al. 2017).

Upper Mantle Anisotropy from Surface Wave Studies

Early studies of surface wave dispersion showed that, in many regions, it is not possible to find a single isotropic model that satisfies both fundamental mode Love and Rayleigh wave dispersion simultaneously. This provided some of the earliest evidence for the presence of anisotropy in the crust and upper mantle (e.g., Anderson 1961). This discrepancy can be explained by introducing a transversely isotropic medium with a vertical symmetry axis (radial anisotropy), down to at least 200 km depth. It is in this context that the still widely used Preliminary Reference Earth Model (PREM) was constructed (Dziewonski and Anderson 1981). Gung et al. (2003) showed that radial anisotropy is also present at depths greater than 200 km beneath the lithospheric roots of stable continents and cratons, and explains discrepancies in lithospheric thickness obtained using surface waves of different polarization, thus reconciling lithospheric thickness obtained from seismology with estimates from other geophysical and xenolith data.

Surface wave dispersion also varies with azimuth of propagation, an indication of “azimuthal anisotropy” (e.g., Forsyth 1975). The global azimuthal variations of Rayleigh and Love wave dispersion at long periods (100–250 s) were first mapped by Tanimoto and Anderson (1985), who showed that the fast direction appears to correlate with flow directions in the mantle. Montagner and Tanimoto (1991) developed the first global model of radial and azimuthal anisotropy in the upper mantle based on fundamental mode surface wave data. While some questions remain about trade-offs between lateral heterogeneity and anisotropy in this type of inversion, Montagner and collaborators have shown that they can explain their datasets with fewer parameters when azimuthal anisotropy is considered than when it is ignored.

To first order, asymptotically, the azimuthal variation of phase velocity (Love or Rayleigh waves) is of the form (Smith and Dahlen 1973):

$$C(\omega, \theta) = A_0 + A_1 \cos(2\theta) + A_2 \sin(2\theta) + A_3 \cos(4\theta) + A_4 \sin(4\theta) \quad (10)$$

where θ is the azimuth of the wavenumber vector defined clockwise from north. The coefficients $A_i(\omega)$ depend linearly on the elastic tensor at every point in the medium. Theoretical expressions and how they can be applied for crust and upper mantle studies are reviewed in Romanowicz (2002) and

Montagner (2015). Because Rayleigh waves are sensitive both to shallow crustal and deeper mantle anisotropy, it is important to use a wide frequency range to resolve the depth dependence of anisotropy using surface waves. Montagner and Nataf (1988) introduced “vectorial tomography.” By combining radial and azimuthal dispersion terms, under the assumption that the material possesses a symmetry axis (orthotropic medium), they showed that the 3D model can be described using seven elastic parameters (plus density): the five parameters describing transverse isotropy, and two angles describing the orientation in space of the axis of symmetry. Combining long period waveforms and SKS splitting measurements, Yuan and Romanowicz (2010) showed that azimuthal anisotropy provides a powerful tool to detect layering in the continental lithosphere. More recently, several studies have provided evidence for strong layering in the oceanic lithosphere and upper mantle from radial and azimuthal anisotropy in tomographic inversions of surface wave dispersion (Burgos et al. 2014; Beghein et al. 2014).

Using different seismological tools, including surface wave overtones (e.g., Trampert and van Heijst 2002), it has also been suggested that azimuthal anisotropy is present in the transition zone. To date, the mapped patterns are not well resolved. A recent study proposes the presence of significant anisotropy in the vicinity of the 410 and 660 km discontinuities (Yuan and Beghein 2013).

Other diagnostic effects of anisotropy in long period surface waves are waveform anomalies caused by Rayleigh-Love coupling, which generates “quasi-Love” waves on vertical components and “quasi-Rayleigh” waves on transverse (e.g., Maupin and Park 2015). See also ► [“Magnetic Anisotropy”](#).

Surface Wave Attenuation

Surface wave measurements provide the primary constraints on attenuation structure in the crust and uppermost mantle. In the absence of perturbing effects due to scattering and focusing, the amplitude spectrum of a single mode wave train can be written as:

$$A(\omega) = A_0(\omega) \exp(-\eta(\omega)X) \quad (11)$$

where X is the epicentral distance in kilometers and $A_0(\omega)$ represents the amplitude at the source. The attenuation coefficient $\eta(\omega)$ is related to the quality factor Q through (e.g., Aki and Richards 1980):

$$\eta(\omega) = \frac{\omega}{2C(\omega)Q(\omega)}$$

where C is the phase velocity.

Regional studies of amplitudes of fundamental mode surface waves in the period range 5–100 s and of Lg waves have long established the presence of large variations of Q correlated with tectonic provinces and in particular with the age of the oceans, and with time elapsed since the latest tectonic activity on continents. For a recent review, see Romanowicz and Mitchell (2015). Recently, attenuation structure in the vicinity of the East Pacific Rise and in the back-arcs and wedges of subduction zones obtained from a combination of surface wave and body wave data have revealed highly attenuating zones underlying volcanic arcs, down to the slab surface. See also ► “[Seismic Viscoelastic Attenuation](#)”.

Lateral variations in attenuation at long periods can be an order of magnitude larger than those in elastic velocity. Progress in constraining global 3D anelastic structure of the upper mantle has been slow because of the inherent difficulty of measuring attenuation in the presence of focusing and scattering effects that can be as large as anelastic ones and depend strongly on the short-wavelength details of the elastic structure. The long wavelength 3D attenuation models obtained thus far indicate that lateral variations in attenuation in the first 200–250 km of the mantle are correlated with tectonics. In the transition zone, the long wavelength pattern shifts to one correlated with hotspots and with the structure at the base of the mantle, with high attenuation overlying the two large low shear velocity provinces under Africa and in the Pacific (e.g., Romanowicz and Mitchell 2015). At the global scale, mapping of fundamental mode Rayleigh wave attenuation, taking into account effects of focusing have confirmed a correlation of attenuation in the earth’s upper mantle (Fig. 5; Ma et al. 2016). Most recently, several new global models of 3D anelastic structure of the upper mantle have been produced, using high quality broadband data and improved techniques to account for the scattering and focusing effects on surface wave amplitudes, but the models are only consistent at the longest wavelengths, due to persistent trade-offs with elastic structure.

Source Studies Using Surface Waves

Fundamental mode surface wave spectra contain information about the source moment tensor, source depth (centroid), source process time, and, under favorable circumstances for very large earthquakes, source directivity. Tsai and Aki (1971) first showed that the amplitude spectrum of Rayleigh waves contained the signature of source depth, in the form of a “hole” in the spectrum in the period range 10–100 s, which appears at a period depending on depth, and which also depends on the source mechanism.

In order to correct for propagation, different approaches need to be taken depending on the size of the earthquake and

the period range considered. At very long periods ($T > 180$ s), and for large earthquakes ($M > 6.5$), propagation effects can be accounted for approximately using a spherically symmetric reference earth model and ellipticity corrections. At shorter periods, and for smaller earthquakes, corrections on individual source-station paths need to be known much more accurately (for a review, see Romanowicz 2002). In the last 15 years, the availability of increasingly accurate global 3D tomographic models of the upper mantle has made it possible to extend the period range to shorter periods (down to ~ 120 s) and to efficiently make use of methodologies, based on time-domain waveform inversion that are no longer restricted to the fundamental mode, thus providing more accurate estimation of the source depth. Such a waveform approach was first introduced by Dziewonski et al. (1981), who combined waveforms of mantle waves at periods greater than 120 s with overtone waveforms at periods greater than 80 s. This forms the basis of a now routine procedure that serves to construct the widely used Harvard centroid moment tensor (CMT) catalog (Now “global CMT catalog”, <https://globalcmt.org/>).

The Earth’s Background Noise Spectrum: Hum and Microseisms

The presence of background peaks in the frequency range 2–7 mHz, corresponding to the fundamental spheroidal free oscillations of the earth, in the absence of large earthquakes, was discovered 20 years ago by Japanese scientists (e.g., Kobayashi and Nishida 1998). It was later determined that the vertical component long-period seismic noise spectrum was made up of Rayleigh waves (Nishida et al. 2002) and that the main source of the “hum” was located in the oceans (Rhie and Romanowicz 2004), resulting from nonlinear interactions between the atmosphere (oceanic storms), the oceans, and the solid earth. The “hum” has also been detected on the horizontal components, corresponding to Love waves.

The largest background seismic noise is found in the period range 2–20 s and corresponds to the so-called microseismic peak. Microseisms were studied extensively in the 1950s and determined to be surface waves generated in the oceans. There are two types of microseisms: “primary” and “secondary.” Secondary microseisms are the strongest. Also called “double-frequency microseisms,” they are generated at frequency f by a nonlinear mechanism involving two opposing ocean waves of frequency $f/2$ (Longuet-Higgins 1950). In the last decade, there has been renewed interest in the study of microseisms, in the context of the use of noise cross-correlations for the study of Earth structure, as seen above. Some success has recently been obtained in the prediction of the low frequency hum by modelling of the propagation of ocean infragravity waves and their interaction with the ocean floor (Ardhuin et al. 2015). See also ► “[Seismic Noise](#)”.

Summary

Surface waves propagate along the surface of the earth with exponentially decreasing energy with depth, with waves of longer period reaching greater depths. They contain most of the elastic energy generated by earthquakes at periods greater than 20 s and are dispersive. There are two types of surface waves, Rayleigh and Love waves, with different polarization properties. The fundamental mode surface waves are well separated from other energy arrivals in the time domain and provide the best constraints to date on continental scale and global scale upper mantle structure. They play a particularly important role in constraining the upper mantle structure in the ocean basins where few seismic stations have been installed. While the dispersion of fundamental mode surface waves is a classical tool for the investigation of upper mantle structure, higher modes, or overtones provide constraints at transition zone depths (400–700 km) and deeper. They require more sophisticated analysis tools because they cannot be distinguished from each other readily on the seismogram. Waveform inversion approaches are increasingly favored to handle both fundamental mode and overtone interpretation, and hold increasing promise as numerical methods for the computation of the seismic wavefield in arbitrary 3D structures are being implemented, and can account for complex scattering and focusing effects accurately. In addition to isotropic shear velocity, surface waves provide constraints on the distribution of polarization and azimuthal anisotropy in the upper mantle, as well as on anelastic attenuation. When path effects have been corrected for, surface waves provide robust constraints on the source depth and radiation pattern, as expressed by its moment tensor.

The earth's continuous background noise consists primarily of surface waves, at least at periods longer than 5 s. Notable is the microseismic noise peak around 6–7 s. Most of this energy is generated in the oceans by nonlinear interactions involving wind-driven ocean waves and the seafloor. Recently, a method based on the cross-correlation of noise records has gained popularity and has been applied successfully to resolve crust and uppermost mantle structure. It is particularly useful in seismically quiet regions.

T Waves

Emile A. Okal
Department of Earth and Planetary Sciences, Northwestern
University, Evanston, IL, USA

Definition and Introduction

T phases are defined as seismic recordings of signals having traveled an extended path as acoustic waves in the water body of the oceans. This is made possible by the “sound fixing and ranging” (SOFAR) channel, a layer of minimum sound velocity acting as a wave guide at average depths of 1000 m (Okal 2007). It allows the efficient propagation of extremely small signals over extremely long distances, in practice limited only by the finite size of the ocean basins. The existence of the SOFAR channel results from the dependence of the velocity of sound in water on temperature, pressure, and salinity. As a result, the detailed structure of the channel (including the value of the minimum velocity) varies both geographically (mainly with latitude) and seasonally, but at first order, the SOFAR channel can be regarded as a quasiuniversal feature of the world’s oceans.

At the shoreline of a continent or island, the acoustic wave is converted into a seismic wave which can be recorded by a seismometer or, occasionally, felt by humans. Efficient propagation inside the waveguide requires short wavelengths, in practice frequencies above 3 Hz, and thus T phases generally attenuate fast once converted, although in exceptional geometries they have been detected up to 1000 km inside stable continental shields. Even though records of T waves were reported as early as 1927, they were not identified as hydroacoustic signals until the late 1940s, when results from antisubmarine warfare during World War II were declassified.

Sources of T Waves

T waves can be generated by a diversity of underwater sources, as long as their energy becomes trapped in the SOFAR channel. Most earthquakes in oceanic margins generate strong T phases, since in the presence of a sloping ocean floor, multiple downslope reflections can lead to efficient penetration of the SOFAR (Johnson et al. 1963). However, their generation by earthquakes in abyssal plains deprived of large-scale bathymetry defies the laws of geometrical optics and remains to this day a major theoretical challenge; it is generally thought that abyssal T phases result from scattering along small random heterogeneities of the ocean floor (Yang and Forsyth 2003). Also, T waves are occasionally generated by nonshallow earthquakes, even the deepest ones, even though their source is de facto distant from the ocean column. This excitation is made possible by travel through the subducting oceanic slabs which, being cold, propagate high frequencies with limited attenuation and can deliver them to the water interface for conversion to acoustic waves (Okal 2001a).

Underwater landslides are also T-wave generators. As compared with earthquakes, such sources, which move generally smaller segments of ocean floor over much larger distances, have a considerably longer duration, a lower-frequency spectrum, and thus result in T waves of longer duration but smaller amplitudes (Okal 2003).

By contrast, explosions at sea, which are intrinsically high-frequency, are particularly efficient sources of T waves; in most instances, they involve a shallow source located inside the SOFAR channel, thus providing optimal feeding of acoustic energy into the channel. In particular, seismic reflection experiments are routinely recorded thousands of kilometers away.

Underwater volcanic eruptions are also regular generators of T waves. Because of the diversity of processes involved

during a volcanic sequence, these signals may feature a wide variety of characteristics. The opening of cracks during the formation of magmatic plumbing systems is essentially in the nature of an earthquake, while magmatophreatic explosions at the contact between a lava conduit and the oceanic column are reminiscent of chemical explosions. The steady output of lava into the ocean takes the form of a prolonged noise of low amplitude which may be compared to underwater slumping (Caplan-Auerbach et al. 2001). Finally, the oscillation of magma inside the plumbing system, known to cause volcanic tremor long recorded seismically on subaerial volcanoes, generates harmonic T-wave signals. Supercritical hydrothermal venting during volcanic events has also been documented as the source of monochromatic hydroacoustic signals (Talandier and Okal 1996).

Among the most remarkable T waves ever reported, signals from the eruption of Macdonald Volcano (29°S; 140°W) on 29 May 1967 led to the eventual discovery of this uncharted underwater seamount, and its interpretation as the active member of the Cook-Austral hotspot chain (Johnson 1970).

The collision of large icebergs, during which their masses can rub against each other, has also been documented as a source of T waves, which can exhibit a harmonic character during episodes of stick-and-slip friction between tabular icebergs (MacAyeal et al. 2008). Hydroacoustic waves are also generated during the disintegration of large icebergs, and thus could be used to monitor and assess any possible change in climatic conditions (Li and Gavrilov 2006).

Finally, marine mammals can talk into the SOFAR channel and correspond across hundreds of kilometers, using signals in the range of a few tens of hertz, but specific to each species.

Human Perception

T waves of sufficient amplitude can be felt by shoreline populations. For example, the underwater nuclear test WIG-WAM on 14 May 1955 off the coast of Southern California was felt in Hawaii and even in Japan, 8000 km away. Large events such as the Alaskan earthquake of 10 July 1958 and the deep Bolivian shock of 9 June 1994 were felt in Hawaii, and T waves from the 2004 Sumatra earthquake were felt in the Maldives and possibly on Zanzibar; they could have provided a warning of the impending tsunami in these otherwise aseismic areas, but their populations were unprepared.

Use in Comprehensive Nuclear-Test Ban Treaty Monitoring

Because hydroacoustic waves can detect small sources (especially intra-oceanic ones) at great distances, they have

been included as one of the four technologies used by the International Monitoring System (IMS) of the Comprehensive Nuclear-Test Ban Treaty. Their spectacular efficiency in propagation allows a full coverage of all the Earth's oceans using only 11 receiver sites, 6 of which are hydrophones deployed within the SOFAR channels, and 5 special seismic stations close to shorelines ("T-phase stations"), instrumented for high-frequency seismic recording in the 50–100 Hz range (Okal 2001b).

Acoustic Thermometry of Ocean Climate

This project consisted of using acoustic sources in the 57 Hz range fired in the vicinity of Heard Island, South Indian Ocean, a location allowing the illumination of all three major oceans (Munk et al. 1994). Detection at extreme ranges of up to 17,000 km allowed precise measurement of acoustic velocities, and it was envisioned to repeat these experiments over several decades, to monitor any evolution of sound velocities, as a proxy to changes in temperature, possibly in the context of global warming. Unfortunately, the project had to be halted in the late 1990s under pressure from the environmental lobby.

Quantification

Like other seismic phases, quantitative measurements of T waves can provide information on source parameters. However, absolute measurements (especially of amplitudes) at seismic receivers are difficult to interpret due to the complexity and site specificity of the conversion processes. In addition, the high-frequency nature of the phase results in amplitude saturation at relatively low magnitudes. In this context, quantification of T waves has emphasized duration of wavetrains over amplitude, and relative measurements under common or comparable receiver conditions. Okal et al. (2003) have introduced the concept of T-phase energy flux, *TPEF*, reminiscent of the evaluation of seismic energy from body waves, and which should scale with seismic moment M_0 for regular seismic sources. Any deviation in the ratio $\Gamma = \text{TPEF}/M_0$ identifies anomalous source properties; in particular, slow earthquakes exhibit deficient Γ , a property with some potential in tsunami warning.

The comparison of duration and amplitude of T wavetrains can efficiently discriminate between earthquakes and explosions at sea, based on the strong differences in the scaling of their source processes (Talandier and Okal 2001), although small earthquakes located inside steep volcanic edifices remain a challenge in this respect.

A Few Geophysical Applications

As most of their path is hydroacoustic, T phases propagate at a velocity close to that of sound in water, 1.5 km/s, that gives them late arrivals on seismic records, hence their name “T” for “third.” Such slow velocities allow a remarkable resolving power for source locations, after accounting for small geographic and seasonal variations in SOFAR velocities, and for the contribution of the converted [seismic] segments of the phase.

In this context, the superior detection capabilities of T phases have been used to improve considerably our coverage of low-magnitude seismicity in the oceanic environment, and especially our understanding of small-scale processes at mid-oceanic ridges, notably in conjunction with swarms of volcanic activity (Dziak et al. 1995).

The slowness of T waves also allows to very precisely beam a receiving array (e.g., triangles of hydrophones at sites of the International Monitoring System [IMS]) to back-track the source of T phases, or even of individual fragments of their wavetrains; this procedure was used to obtain a detailed source tomography of the great 2004 Sumatra-Andaman event (e.g., Tolstoy and Bohnenstiehl 2005).

Conclusion

Because of their high-frequency character, T waves provide a valuable complement to more traditional phases in the field of body-wave seismology. Their incorporation into the IMS allows their more systematic recording and opens up a number of new research opportunities.

Tectonic Geomorphology

Sampat Kumar Tandon and Vinee Srivastava
Department of Earth and Environmental Sciences, IISER
Bhopal, Bhopal, India

Definition

“Tectonic Geomorphology” involves two major disciplines of the Earth sciences, tectonics and geomorphology. Tectonics defines the boundary conditions for topographic development as deformation progresses, and prolonged climate-dependent Earth surface processes interact with the tectonic processes to generate modern landscapes (Burbank and Anderson 2011). Tectonic geomorphology relies on data gathered from numerous Earth science disciplines ranging from stratigraphy, structural geology, tectonics, seismology, Quaternary climate change, geochronology, geodesy, remote sensing, and geomorphology.

Tectonic geomorphology in conjunction with seismotectonic and palaeoseismological data helps understand the geological and geophysical aspects of hazard-prone terrains. It helps assess the seismic hazard and seismic risk by identifying active fault zones, and their possible impact on the society and infrastructure in the region. Together with other Earth science disciplines and tools, a

better understanding of the seismic terrain can be obtained, and eventually, the integrated outcomes can be used for disaster management in these tectonically active regions.

Tectonically Generated First-Order (10^3 – 10^2 Km Scale) Landscapes

Geodynamic processes along tectonic boundaries (~1000 km), where horizontal and vertical motion(s) of tectonic plates result in strike-slip, extension, and compression, govern the dynamics of large scale characteristic landscapes as discussed below.

Transform Settings

In transform settings, two plates slide past each other horizontally along strike-slip faults defining a conservative boundary where the lithosphere is neither destroyed nor created. This setting is dominated by fault-parallel simple shear in the horizontal plane. However, a deviation from regional

simple shear occurs near stepovers or bends in the major strike-slip fault (Fig. 1a). Depending on the sense of shear and the direction of bend or step-over along the major fault, zones of transpression or local contraction and transtension or local extension develop in these regions resulting in extensional or contractional structures (Fossen 2010; Cunningham and Mann 2012). Restraining or transpressional bends are associated with pressure ridges, palm tree or positive flower structure, and associated landforms. Releasing or transtensional bends form pull-apart basins, tulip structure or negative flower structure, and associated landforms (Fossen 2010; Cunningham and Mann 2012; Bierman and Montgomery 2013).

Convergent Settings

In convergent settings, two plates collide with each other defining a destructive plate boundary where the lithosphere is subducted and destroyed. The plate collisions can be ocean-ocean, ocean-continent, or continent-continent and are characterized by thrust faulting and distinctive landscape features

Tectonic Geomorphology, Fig. 1 Tectonic landforms associated with tectonic boundaries. (a) “Negative flower or Tulip structure”, “Positive flower structure or Palm Tree structure” in transform setting (modified after Bierman and Montgomery 2013); (b) mountain belts associated with continent-continent collisional setting and trench,

volcanic arc with ocean-continent collision in convergent/compressional setting dominated by thrust faults; (c) rift valley; (d) horst and graben, half graben landforms associated with divergent/extensional setting characterized by normal faults

associated with each such collisional setting (Bierman and Montgomery 2013). In ocean-ocean and ocean-continent, high density oceanic crust subducts beneath less dense oceanic or continental crust respectively resulting in a trench at the boundary. Volcanic island arcs are characteristic landforms associated with ocean-ocean collision, e.g., Japan and many South Pacific islands. Continental volcanic arcs with deformed accretionary wedges are associated with ocean-continent collision such as the Cascade Range in western North America, and Andes Mountains at the western edge of South America. The most studied continent-continent collision example is the Himalaya where collision of Indian-Eurasian plates created a ~2500 km long, wedge-shaped, fold and thrust belt related mountain range (Fig. 1b; Fossen 2010).

Divergent Settings

In divergent settings, two plates diverge away from each other and define a constructive plate boundary where new oceanic lithosphere is created. This setting is characterized by an array of normal faults and consists of distinct landscape features such as rift valleys, horst and graben, and half graben (Fig. 1c, d). Rifting in oceanic lithosphere creates a spreading center or mid-oceanic ridges where new lithosphere is created, e.g., mid-Atlantic ridge separating the South American and African plates (Bierman and Montgomery 2013). Similarly, rifting of continental plates forms a horst and graben structure, e.g., Basin and Range Province, western USA and southwestern Mexico (Fossen 2010).

Signatures of Morphotectonic Landscapes

A landscape can form by tectonic processes ranging from first-order plate scale (10^3 to 10^2 km) features described above to regional scale (10^2 to <1 km) features. New landscapes can be created by deformation, and a preexisting landscape or feature can be modified by deformation leaving behind evidences of recent deformational events. Such evidences can be further subdivided into the following two categories.

Direct Evidences

Direct evidences comprise geomorphic signatures that can be observed, identified, and mapped in the field in a specific tectonic setting. Some characteristic signatures are discussed below.

Geomorphic Markers of Transform Setting

Transform settings characterized by strike-slip faults generate distinctive landforms such as offset streams; these can also be detached from their source at places, creating beheaded streams. Releasing bends and stepovers along a major

strike-slip fault or weakening of rock in a fault or damage zone creates characteristic features such as sag ponds. This can be the result of captured drainage courses or small depressions along the trace of the strike-slip fault due to transtension-related normal faulting (Fig. 2a; Bierman and Montgomery 2013). Similarly, restraining bends or stepovers along a major strike-slip fault can form a topographic ridge known as pressure ridge due to transpression-related thrust faulting.

Geomorphic Markers of Divergent Setting

Normal faults in extensional settings produce distinctive geomorphic features such as offset mountain fronts with bedrock, upland and lowland alluvial plains, and well-marked range fronts. The fault surface is also exhumed as triangular bedrock facets, and hourglass-shaped valleys are formed extending into the range front between the facets (Fig. 2b; Bierman and Montgomery 2013).

Geomorphic Markers of Convergent Setting

Convergent settings constitute a compressional regime characterized by thrust or reverse faults. Thrust faults are also accompanied by folding via fault-bend folding or fault-propagation folding and eventually generate mountains and valleys within fold and thrust belts (Keller and Pinter 2002). These faults and folds are responsible for generating new landforms or uplifting preexisting ones (unpaired or/and tilted terraces, warped topography) (Fig. 2c, d). Reverse faulting can generate steep mountain fronts with fault and fold scarps.

Geomorphic Markers in Multiple Settings

Some geomorphic landforms and features are found in multiple settings:

- (a) **Unpaired strath terraces:** River terraces are geomorphic features which can be either aggradational or degradational. Fill or aggradational terraces are commonly paired and formed due to aggradation of the river-transported sediments along the river course (Keller and Pinter 2002). Strath or degradational paired terraces are formed due to deep incision by a river. However, deformation or uplift of the preexisting terrace due to thrusting or reverse faulting as well as subsidence due to normal faulting can cause recurrent changes in the course of rivers and form unpaired strath terraces (Fig. 2c; Keller and Pinter 2002).
- (b) **Uplifted/tilted terraces and fan surfaces:** A fold and thrust belt e.g. the Himalaya is marked by geomorphic features such as river terraces and alluvial fan surfaces. These geomorphic features can be deformed because of sequential thrusting or reverse faulting which leads to deviation from their natural slope direction. The terraces

Tectonic Geomorphology, Fig. 2 Geomorphic features associated with tectonic boundaries. (a) Transform setting. (Modified after Bierman and Montgomery 2013) (b) Divergent setting. (Modified after Strak et al.

2011). (c, d) Convergent setting. (Modified after Burbank and Anderson 2011; Srivastava et al. 2017). “F” represents a blind fault

and the fan surfaces uplifted by these faults will slope in the regional dip direction of the faults opposite to their natural slope direction (Fig. 2c; Srivastava et al. 2017). Similarly, in an extensional setting, terraces can be tilted due to normal faulting. Terraces or fan surfaces within the transpressional or transtensional zones of strike-slip regime will be either uplifted or tilted.

- (c) **Warped terraces and fan surfaces:** Terraces or fan surfaces can be warped or folded due to activity along a blind thrust or reverse fault, and fault-related folding such as fault propagation or fault-bend folding. In fault propagation folds where propagation velocity of a fault is less than the slip velocity of overlying strata, slip accumulates at the fault tip and generates topography by warping the surface (Fig. 2d; Srivastava et al. 2017). Warping of the surface can also be formed as roll-over anticline where folding is associated with downward movement along a normal fault. Similarly, deformation in transpressional or transtensional zones in strike-slip setting can also warp terraces or fan surfaces.

Indirect Evidences

Geomorphic parameters/indices discussed below are used to assess subtle tectonic activity in all tectonic settings, and formulae used to quantitatively describe them are given in Table 1. These are best used together with direct evidences but can also be used without direct evidence of tectonic activity.

Geomorphic Indices

- (a) **Hypsometric curve and Hypsometric Integral (HI):**

Hypsometric curve describes the elevation distribution over a particular area for a drainage basin. Relative area (a/A) against relative height (h/H) of a portion of a basin over the total basin area is used to construct the curve (Keller and Pinter 2002). The shape of the curve obtained points to the geomorphic processes operating in a basin. Convex curve indicates the dominance of tectonic activity in the basin, convex-concave shape shows equilibrium between tectonic activity and erosional processes, and concave curve shows dominance of fluvial erosional

Tectonic Geomorphology, Table 1 Geomorphic indices used to assess subtle tectonic activity in a basin (compiled from Keller and Pinter 2002 and Schumm 1956)

S. no.	Geomorphic indices	Values	Interpretations
(a)	Hypsometric integral HI = $H_{mean} - H_{min} / H_{max} - H_{min}$ Hmean = mean elevation Hmin = minimum elevation Hmax = maximum elevation Normalized	HI = 0 – Mature HI = 1 – Youthful	Old basin Tectonically active
(b)	Mountain front sinuosity $Smf = Lmf/Ls$ Lmf = the length of the mountain front Ls = straight line length of the mountain front Normalized	Smf = 1.0–1.5 Smf = 1.5–3.0 Smf > 3	Highly active front, Moderately active front Inactive front
(c)	Asymmetry factor/Drainage basin Asymmetry AF = $100 (A_r/A_t)$ Ar = area of the basin to the right of the trunk stream while facing downstream At = total area of the drainage basin Normalized	AF < 50 AF = 50 AF > 50	Basin tilt to the right Symmetric basin Basin tilt to the left
(d)	Basin elongation ratio (Re) $Re = 2 \sqrt{AT/\pi} / L$ AT = diameter of the circle having the same area as the basin L = maximum basin length Normalized	Circular (Re > 0.9) Oval (0.8 < Re < 0.9) Less elongated (0.7 < Re < 0.8) Elongated (Re < 0.7)	Re > 0.75 = Tectonically inactive Re = 0.5–0.75 = Slightly active Re = <0.5 = Tectonically active
(e)	Stream length gradient index $SL = (\Delta H / \Delta L) L$ ΔH = difference in elevation, ΔL = the length of the stream reach where the index is to be computed. L is the channel length from the drainage divide to the center of the reach. Non-normalized	High SL-index, low-resistance rocks High SL-index, high-resistance rocks Low SL-index, low-resistance rocks	Tectonics Lithological

processes in a mature basin. Hypsometric integral (HI) indicates a basin's relief and is used to identify tectonically active regions together with the hypsometric curve (Table 1; Keller and Pinter 2002).

- (b) **Mountain Front Sinuosity (Smf):** Mountain front sinuosity (Smf) distinguishes between straight and sinuous mountain front using the interplay of tectonic and/or erosional processes in mainly convergent/divergent settings (Table 1; Keller and Pinter 2002).
- (c) **Asymmetry Factor (AF):** Asymmetry factor (AF) assesses the symmetry of a basin. Symmetry of a basin and its drainage network depends on a stable setting and uniform lithology. In tectonically active and differentially tilted regions, the AF is used to identify tilted asymmetric basins (Table 1; Keller and Pinter 2002).
- (d) **Basin Elongation Ratio (Re):** Basin elongation ratio quantifies the variation of the shape of a basin from

circular, oval to elongated and its relationship with the tectonic or erosional processes (Table 1; Keller and Pinter 2002).

- (e) **Stream Length Gradient Index (SL):** The stream length gradient index (SL) is used to assess the uplift in a tectonically affected region mainly in convergent settings. The stream length gradient index (SL) determines the relationship between stream power, tectonics, and rock resistance (Keller and Pinter 2002). Anomalously high or low SL values are the result of changes in stream power, slope induced by tectonic deformation or rock resistance due to lithological variation, and results in the occurrence of knick-points along river profiles (Table 1; Keller and Pinter 2002).
- (f) **Valley Floor Width-to-Height Ratio (Vf):** The U- or V-shape of a valley is quantified using valley floor width-to-height ratio. The V-shaped valleys indicate the

Tectonic Geomorphology, Table 2 Global case studies

Divergent setting	
Topal et al. (2016)	Tectonic geomorphology of a large normal Akşehir fault, SW Turkey, indicates presence of triangular facets along the mountain fronts. Subtle tectonic activity has been assessed along the Akşehir fault using uplift patterns computed by vertical slip rate on the fault scarps based on the facet slope in the footwall along the various segments of Akşehir fault which are consistent with the patterns of geomorphic indices along each segment
Copley et al. (2014)	Active faulting within peninsular India represents a significant seismic hazard in central India due to reactivation of Mesozoic Tapi normal Fault as thrust fault as observed through offset alluvial fan surfaces. This indicates one or more magnitude 7.6–8.4 thrust-faulting earthquakes on the Tapi Fault, Maharashtra, India, during the Holocene. Modified drainage pattern in central India and formation of the large west-flowing catchment of the Tapi river are due to downward movement of the footwall of the Tapi Fault
Convergent setting	
Lavé and Avouac (2001)	Geomorphic analysis, active fault bend folding, and upliftment of strath terrace along the Bagmati and Bakeya Rivers indicate that the MFT is the only active structure south of the Lesser Himalaya in central Nepal
Talebian et al. (2016)	Geomorphic evidences, such as warped and incised Quaternary alluvium, and fault scarps were associated with tectonically active blind Pardisan thrust in the central part of Tehran. Rate of uplift was measured using optically stimulated luminescence (OSL) dating on a rare exposed remnant of uplifted alluvial deposits in the hanging wall of Pardisan thrust, Tehran
Srivastava et al. (2016, 2018)	Emergent Main Frontal thrust's (MFT) half-a-kilometer fault zone with well-developed fault core and damage zone together with uplifted gravel cap and MFT induced Mohand Range topography indicated direct evidence of neotectonic deformation along the MFT in the Dehradun recess, NW Himalaya, India
Srivastava et al. (2017)	Geomorphic indices along with their uncertainties computed from real-time kinematic global navigation satellite systems (RTKGNSS), corrected SRTM data together with direct field evidence such as tilted terraces, and warped fan surfaces indicate neotectonic deformation along the Ramgarh thrust in the frontal Gorubathan recess, Darjiling Himalaya, India
Divyadarshini and Singh (2017) and Divyadarshini et al. (2020)	Geomorphic features such as terraces and fan surfaces that were incised, tilted, folded, or uplifted together with stream length index (SL) indicated reactivation/out-of-sequence thrusting signatures in the hanging wall of the MFT. New faults were also identified based on field observations, Hack profile, and SL-indices in Chitwan dun, central Nepal. OSL dating derived ages of the landforms support distinct climate-tectonic coupling events responsible for landscape evolution in Chitwan dun
García-Delgado and Velandia (2020)	Structural and geomorphic indices-based study indicates greater tectonic activity and uplift rates for the northern San Lucas Range, in the Northern Andes
Transform setting	
Arrowsmith and Zielke (2009)	Field evidences, paleoseismic analysis, and high-resolution LiDAR DEM were used to trace the active Cholame segment of San Andreas Fault (SAF) to understand tectonic geomorphology of SAF
Softa et al. (2018)	Transpressional deformation zone, the Eastern Pontides (EP), is the active deformation zone and has a “push-up” geometry in conjunction with the North Anatolian Fault high. The EP exhibits high tectonic activity based on geomorphic indices and more than 0.5 mm/yr upliftment along the thrust faults of the Black Sea Fault (BSF) and Borjomi-Kazbegi Fault (BKF) in the active mountain belt

presence of areas affected by tectonic uplift/subsidence in a given setting. The U-shaped valleys indicate the attainment of erosion at the base level (Table 1; Keller and Pinter 2002).

Tectonic Geomorphology and Paleoseismological Studies of Tectonic-Landforms

Tectonic geomorphology studies are often integrated with palaeoseismological investigations as geomorphic features, studied in the former, are the result of interaction of multiple paleo-seismic events and prolonged Earth surface processes. Paleoseismology is the study of prehistorical earthquakes in terms of location, size, and time; and its aim is to define the earthquake potential of a fault zone and constrain it

chronologically (McCalpin 2009). Evidences of past earthquakes are studied in sediments and rocks in tectonically active regions. Trenching technique is used wherein a trench is dug along an active fault, and geological logs exhibiting characteristics of the rock layers are prepared (cf. Fig. 2a.1, McCalpin 2009). Active faulting traces recognized as offsets of sediment layers due to earthquakes can be observed from the trench walls (McCalpin 2009). If there are traces of multiple faults or fault activity, they can be dated in absolute terms if dateable carbon or human artifacts occur in order to determine the relative age of movements on each fault. Ideal location for trenching along an active fault is near streams, slopes, and ponds which are the loci of sedimentation. Luminescence dating technique includes

thermoluminescence (TL), and optically stimulated luminescence (OSL) methods (Jayagondaperumal et al. 2018 and references therein). It is one of the important methods for dating sediments in paleoseismic research in addition to methods based on radiocarbon and cosmogenic radionuclides. These dating methods are used to determine the timing of fault displacement, calculate slip rates, and estimate earthquake recurrence intervals.

Global Case Studies

Research in Tectonic Geomorphology has evolved rapidly in order to study the interrelationship between tectonics and climate/erosion in different tectonic settings across the globe. An interdisciplinary approach to assessing crustal movements, mechanisms and rates of Earth surface processes, and advances in dating techniques to constrain the ages of these events that form a landscape has furthered exploration in the field of tectonic geomorphology as summarized in Table 2.

Summary

Tectonic geomorphology is evolving fast as new quantitative techniques are being developed that provide the basis to understanding climate/erosion and tectonic interactions in divergent, convergent, and transform settings. It allows the examination of how the tectonic and Earth surface processes interact over a period of time with each other to generate the present-day landscape. Also, the tectonically generated landscapes are useful for making an assessment of the neotectonic/active deformation in orogens like the Himalaya and their densely populated bordering plains. “Tectonic Geomorphology” provides a direct window to assess the hazard in tectonically active regions. Also, with other relevant disciplines such as earthquake geology and seismotectonics, it contributes to seismic hazard risk assessment by identifying active faults and their probable impacts on the population and the infrastructures in the region.

Acknowledgments Authors acknowledge with gratitude the constructive criticism and suggestions by an anonymous reviewer that helped significantly improve the quality of the manuscript. We also thank Tanishka Soni for her help in drafting the figures.

Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat

Christoph Clauser

Institute for Applied Geophysics and Geothermal Energy,
RWTH Aachen University, Aachen, Germany

Synonyms

Enthalpy of fusion; Enthalpy of solidification; Specific heat capacity; Thermal capacity; Volumetric heat capacity

Definition

Specific heat capacity c . Physical property defining the amount of sensible heat that can be stored in or extracted from a unit mass of rock per unit temperature increase or decrease, respectively. Isobaric and isochoric specific heat capacities are defined at constant pressure and volume, respectively; dimension: $\text{J kg}^{-1} \text{K}^{-1}$.

Thermal capacity (also volumetric heat capacity) ρc . It is the product of isobaric specific heat capacity and density. Physical property defines the amount of sensible heat that can be stored in or extracted from a unit volume of rock per unit temperature increase or decrease, respectively; dimension: $\text{J m}^{-3} \text{K}^{-1}$.

Latent heat L (also enthalpy of fusion or solidification H). The enthalpy H or latent heat L of fusion or solidification defines the heat energy needed for the corresponding phase change of any amount of substance while the temperature remains constant during the process. When it is referenced to a unit of mass, it is called the “specific” heat of fusion h , while the molar heat of fusion h_{mol} refers to the enthalpy change per amount of substance.

Thermal Storage Properties

The thermal regime of the Earth is defined by its heat sources and sinks, the heat storage and transport processes, and their corresponding physical properties. The storage properties are discussed following. The transport properties, thermal conductivity and thermal diffusivity, are dealt with in this volume in the companion entry ► “Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity”.

Heat can be stored as sensible heat and enthalpy of transformation. In the Earth, sensible heat is defined by the heat capacity of rocks, and the enthalpy of transformation by their latent heat of fusion.

Heat is transmitted within the Earth mainly by diffusion (in the steady state: conduction), advection, and radiation. Generally, heat diffusion dominates heat radiation within the lithosphere of the Earth, at temperatures below 1000 K. For sufficiently large flow rates, convection-driven heat advection, however, can be equally or even more efficient than diffusion. The heat diffusion–advection equation for a porous medium is:

$$\frac{\partial(\rho c_p T)}{\partial t} = \nabla \cdot \left(\underbrace{\lambda \nabla T}_{q_{\text{dif}}} - \underbrace{(\rho c_p)_f T \mathbf{v}}_{q_{\text{adv}}} \right) + \underbrace{A}_{\text{generation}}, \quad (1)$$

where T is temperature in K, t time in s, ρ density in kg m^{-3} , c isobaric specific heat capacity in $\text{J kg}^{-1} \text{K}^{-1}$, λ thermal conductivity in $\text{W m}^{-1} \text{K}^{-1}$, $\mathbf{v}$ specific fluid discharge (volume flow rate per unit cross section area) in m s^{-1} , and A (radiogenic) heat generation rate in W m^{-3} ; subscript “f” refers to fluid properties. Diffusive bulk storage and transport properties for heat in rocks governing this equation are thermal capacity ρc_p , also referred to as volumetric heat capacity, and thermal conductivity λ . Advection is governed by the thermal capacity and specific discharge of the flowing fluid, $(\rho c_p)_f$ and $\mathbf{v}$, respectively.

Heat advection does not require very large flows for becoming as or more efficient than heat diffusion. This is often the case in sedimentary basins (see, e.g., Clauser et al. (2002) for a literature review). But fluid-driven heat advection may be also important in crystalline rocks and on a crustal scale (e.g., Clauser 1992). The nondimensional Péclet and Nußelt numbers, Pe and Nu , are ratios of specific heat flows q_{adv} and q_{dif} (Eq. 1) indicating the efficiency of advective heat transport (driven by fluid flow) versus heat conduction for given flow geometries. For instance, assuming a flow of magnitude v over a distance L and a temperature difference $T_1 - T_0$ one obtains:

$$\begin{aligned} Pe &= \frac{q_{\text{adv}}}{q_{\text{dif}}} = \frac{(\rho c)_f v (T_1 - T_0)}{\lambda T_1 - T_0 / L} = \frac{(\rho c)_f v L}{\lambda}; \\ Nu &= \frac{q_{\text{adv}} + q_{\text{dif}}}{q_{\text{dif}}} = \frac{q_{\text{adv}}}{q_{\text{dif}}} + 1 = Pe + 1. \end{aligned} \quad (2)$$

Thus, advection or diffusion (in the steady state: conduction) dominates for $Pe > 1$ or $Pe < 1$, respectively (in terms of the Nußelt number for $Nu > 2$ or $Nu < 2$, respectively). At temperatures above 1000 K, heat is propagated increasingly as radiated electromagnetic waves, and heat radiation, begin to dominate diffusion (see ► “Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity”, this entry).

A great amount of petrophysical data has been published in the past by individual researchers interested in particular properties. Usually, these data collections are sorted

according to petrographically defined rock types. But rock type, unfortunately, is a weak descriptor for physical properties: Any rock type shows significant variability in characteristics which influence its physical properties, such as (but not limited to), porosity, cementation, and mineral content. This causes also the physical properties to vary accordingly, some by factors others even by orders of magnitude. Thermal rock properties, generally, vary by a factor within the same order of magnitude.

This variability limits the value of individual, rock-type-specific data measured on single samples, unless they originate exactly from the formation (or even location) of interest. In all other cases, a statistical approach may help to account for this intrinsic variability by characterizing physical rock properties by the mean values and standard deviations of populations of a sufficiently large number of individual measurements. Recently, a large number of petrophysical data were compiled into a publically available, digital petrophysical property data base (Bär et al. 2020). This data, while still incomplete in spite of its large number of more than 75 000 individual measurements, may serve both as a source of individual data from specific locations and for calculating means and standard deviations for larger volumes of rock.

Heat Capacity

Heat can be stored and delivered as sensible heat or as latent heat required or liberated by phase changes. This and the next two paragraphs are concerned with sensible heat. Following this, latent heat will be discussed.

Sensible heat capacity C is defined as the ratio of heat ΔQ required to raise the temperature of a mass M of rock by ΔT . For each molecule of mass m , this temperature increase requires an energy of $(f/2) k \Delta T$, where f is the number of degrees of freedom of the molecule and $k = 1.380\,650\,4(24) \times 10^{-23} \text{ J K}^{-1}$ is the Boltzmann constant. For a body of mass M , a temperature increase of ΔT requires an energy of $\Delta Q = (M/m) (f/2) k \Delta T$. Thus the heat capacity of the body at constant volume is:

$$C_V = \frac{\Delta Q}{\Delta T} = \frac{f}{2} k \frac{M}{m} = \frac{f}{2} k N_A = \frac{f}{2} R \quad (\text{J K}^{-1}), \quad (3)$$

where the Avogadro number $N_A = 6.022\,141\,79(30) \times 10^{23} \text{ mol}^{-1}$ equals the number of molecules or atoms in one mole of substance and $R = k N_A = 8\,314\,472(15) \text{ J mol}^{-1} \text{ K}^{-1}$ is the molar gas constant (numerical values for N_A , R , k , and all other physical constants used in this entry are from CODATA 2006). For solids, $f = 6$, corresponding to the three degrees of freedom of potential and kinetic lattice vibration energy in each space direction. Accordingly, the heat capacity of one mole of substance (the molar heat capacity at constant volume) is constant:

$$C_{V,\text{mol}} = 3kN_A = 3R = 24.94 \quad (\text{J mol}^{-1} \text{ K}^{-1}). \quad (4)$$

Isobaric heat capacity $C_{p,\text{mol}}$ is larger than isochoric heat capacity $C_{V,\text{mol}}$ because additional work is required for volume expansion. Both are related by:

$$C_{p,\text{mol}} = C_{V,\text{mol}} + R = \frac{f}{2} + \frac{2}{2} R \quad (\text{J mol}^{-1} \text{ K}^{-1}). \quad (5)$$

With $C_{V,\text{mol}}$ from Eq. 4 and assuming, as above, $f = 6$, this yields:

$$\begin{aligned} C_{p,\text{mol}} &= 3R + R = 4R = 33.26 \quad (\text{J mol}^{-1} \text{ K}^{-1}) \\ &\text{or :} \\ R &= C_{p,\text{mol}} - C_{V,\text{mol}} \end{aligned} \quad (6)$$

Equation 4, the *Dulong–Petit law*, is satisfied well for heavy elements. In contrast, molar heat capacities of lighter elements remain below this upper limit, and the lower the temperature the smaller $C_{V,\text{mol}}$.

Below the Debye temperature, Θ_D , heat capacity varies with temperature. Θ_D tends to zero as T^3 as absolute temperature approaches zero. Θ_D falls in the range between 85 K and 450 K for most substances and between 200 K and 1000 K for most minerals (Stacey and Davis 2008, Table 1). Therefore, heat capacity in the Earth can be well explained by classical Debye theory, in particular in the mantle and except for a thin crustal layer near the Earth's surface. There are, however, exceptions such as beryllium ($\Theta_D = 1440 \text{ K}$) and diamond ($\Theta_D \approx 1800 \text{ K}$). These are caused by the so-called freezing of

Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, Table 1 Debye temperature Θ_D and mass number A of selected elements (Kittel 2004)

Element	Mass number A	Θ_D (K)
Carbon	6	2230
Aluminum	13	428
Silica	14	645
Titanium	22	420
Chromium	24	630
Manganese	25	410
Iron	26	470
Nickel	28	450
Copper	29	343
Zinc	30	327
Silver	47	215
Cadmium	48	209
Tin	50	200
Tantalum	73	240
Tungsten	74	400
Platinum	78	240
Gold	79	165
Lead	82	105

vibrational or rotational degrees of freedom, which, at low temperature, cannot absorb heat any more. Therefore heat capacity tends to zero close to absolute zero.

Isobaric and Isochoric Specific Heat Capacity

Specific heat capacity c of a substance is defined as heat capacity C related to unit mass:

$$c = \frac{\Delta Q}{M \Delta T} = \frac{f}{2} \frac{k}{m} = \frac{f}{2} \frac{k}{A_r m_u} \quad (\text{J kg}^{-1} \text{K}^{-1}), \quad (7)$$

where $m_u = 1.660\,538\,782(83) \times 10^{-27}$ kg is the atomic mass constant, defined as $1/12$ of the atomic mass of the carbon isotope ^{12}C , and A_r the atomic mass of a substance relative to m_u . Isobaric specific heat capacity c_p is larger than isochoric specific heat capacity c_v because additional work is required for volume expansion. Their ratio, the adiabatic exponent, is:

$$c_p/c_v = (f + 2)/f. \quad (8)$$

Alternatively, isobaric specific heat capacity c_p can be expressed by enthalpy $H(T, p) = U + pV$, a state function of temperature and pressure, where U , p , and V are internal energy, pressure, and volume, respectively. In a closed system, the change in internal energy dU is the sum of the change in heat dQ and the work dW delivered: $dU = dQ + dW$. If we only consider volume expansion work, $dW = -p dV$, the change in enthalpy dH becomes:

$$\begin{aligned} dH(T, p) &= dE + p dV + V dp = dQ + V dp \\ &= \left(\frac{\partial H}{\partial T} \right)_p dT + \left(\frac{\partial H}{\partial p} \right)_T dp. \end{aligned} \quad (9)$$

Comparing coefficients, we obtain:

$$\frac{dQ}{dT} = \left(\frac{\partial H}{\partial T} \right)_p = c_p. \quad (10)$$

Thus, Eq. 10 defines isobaric specific heat capacity c_p as the first derivative of enthalpy with respect to temperature. Comparison of Eqs. 7 and 10 shows that both expressions are equivalent for $dQ = \Delta Q/M$, and the isobaric enthalpy change ΔH is equal to the specific heat content $\Delta Q/M$.

Isobaric- and isochoric-specific heat capacity are related to compressibility $\beta = \Delta V/(V \Delta p)$ and its inverse, incompressibility or bulk modulus $K = V \Delta p/\Delta V$, by $c_p/c_v = \beta_T/\beta_S = K_S/K_T$ (e.g., Stacey and Davis 2008), where subscripts T and S indicate isothermal and adiabatic conditions, respectively. Inserting the thermodynamic relation $\beta_T = \beta_S + \alpha^2 T/(\rho c_p)$ (e.g., Birch 1966) between isothermal and adiabatic

compressibility yields the relative difference between isobaric and isochoric specific heat capacity:

$$c_p/c_v = 1 + \alpha \gamma T, \quad (11)$$

where $\alpha = \Delta V/(V \Delta T)$ is the volume expansion coefficient,

$$\gamma = \frac{\alpha K_S}{\rho c_p} = \frac{\alpha K_T}{\rho c_v}, \quad (12)$$

the dimensionless Grüneisen parameter, and ρ density. Inserting the expressions for α and K into Eq. 12 yields:

$$\gamma = \frac{1}{\rho c_p} \frac{\Delta V}{V \Delta T} \frac{V \Delta p}{\Delta V} = \frac{\Delta p}{\rho c_p \Delta T}. \quad (13)$$

Thus, the Grüneisen parameter γ is the relative pressure change in a material heated at constant volume.

For solids, i.e., $f = 6$, the absolute difference between isobaric and isochoric specific heat capacity follows from Eqs. 11 and 8:

$$c_p - c_v = \frac{K_T \alpha^2 T}{\rho} = \frac{3}{4} \frac{K_S \alpha^2 T}{\rho}. \quad (14)$$

For crustal rocks ($\gamma = 0.5$; $\alpha = 20 \mu\text{K}^{-1}$; $T < 10^3$ K; $\rho = 2\,600$ kg m $^{-3}$; $K_S < 75$ GPa (Dziewonski and Anderson 1981; Stacey and Davis 2008)), and the difference between isobaric and isochoric specific heat capacity is less than $9 \text{ J kg}^{-1} \text{K}^{-1}$ or 1 % according to Eqs. 14 and 11, respectively. Thus, the distinction between isobaric and isochoric specific heat capacity is negligible for crustal rocks at temperatures below 1000 K. However, it need be made for mantle rocks. From here on, “specific heat capacity” will always refer to isobaric specific heat capacity, denoted simply by the letter c without the subscript “p.”

This classical treatment of heat capacity is sufficient for temperatures above the Debye temperature. In the Earth, temperature exceeds the Debye temperature everywhere except in the crust (Stacey and Davis 2008). Therefore, in experiments at room temperature and atmospheric pressure, we observe deviations from the values predicted by Eqs. 3 to 14, which are based on the classical Dulong–Petit theory. The lower the temperature, lighter the element, and stronger the lattice bonding become, the larger are these deviations. Clearly, interpretation of heat capacity below the Debye temperature is beyond classical mechanics and requires quantum mechanical treatment. This is, however, beyond the scope of this entry, and interested readers are referred to standard physics textbooks (e.g., Tipler and Mosca 2007). Therefore, heat capacity at crustal temperatures should not be calculated from Eqs. 3 and 14 but rather be measured or calculated from appropriate, quantum mechanical equations.

Čermák and Rybach (1982) compiled data on isobaric specific heat capacity for different rock-forming minerals and different igneous, metamorphic, volcanic, and sedimentary rocks as well as the corresponding variations with temperature.

Measuring Techniques

Specific heat capacity c can be measured directly or derived as the isobaric derivative of enthalpy H with respect to temperature. Specific heat capacity of rocks varies with temperature, pressure, porosity, and saturants. Accordingly, in situ values may deviate from laboratory data according to temperature, pressure, and type and content of pore fluid.

Numerous steady-state and transient calorimetric methods are available for measuring specific heat capacity. The most popular are mixing or drop calorimeters and heat flux differential scanning (DSC) calorimeters. The first method yields an absolute value; the second one is a comparative method. All of these methods and their details are discussed in the literature (e.g., Hemminger and Cammenga 1989; Brown 2001; Haines 2002) to which interested readers are referred. The isobaric enthalpy change (or specific heat content) ΔH of solids may be determined by the method of mixtures using a Bunsen-type calorimeter, in which the unknown isobaric enthalpy change of a sample relative to a base temperature, e.g., 25 °C, is compared to the corresponding known isobaric enthalpy change of platinum (Kelley 1960; Somerton 1992). Popov et al. (2016) provide a recent appraisal of different methods for thermal property testing in the laboratory at atmospheric pressure, in particular for specific heat capacity

Calculated Heat Capacity

When no direct measurements can be performed, the isobaric enthalpy change and specific heat capacity of rocks can be calculated according to Kopp's law, Eq. 15, as the arithmetic mean of the individual mineralogical and fluid contributions weighted by the mass fractions n_i of the N individual phases relative to total rock mass:

$$\Delta H = \sum_{i=1}^N n_i \Delta H_i; \quad c = \sum_{i=1}^N n_i c_i; \quad 1 = \sum_{i=1}^N n_i. \quad (15)$$

Based on data for various minerals (e.g., Kelley 1960; Berman and Brown 1985; Somerton 1992; Waples and Waples 2004), the isobaric enthalpy change ΔH or specific heat capacity c can be computed from Eq. 15 for any rock consisting of an arbitrary number of minerals with given volume fractions.

Temperature Dependence

Derived from measured variation of isobaric enthalpy change ΔH with temperature of various oxides, Kelley (1960) suggested a second-order polynomial for fitting ΔH from which $c_p = (\partial H / \partial T)_p$ can be easily calculated. Somerton (1992) and Clauser (2006) report ΔH and c values of various rock-forming oxides and pore fluids. An alternative approach is fitting heat capacity measured at different temperatures directly to polynomials of various degrees (e.g., Maier and Kelley 1932; Berman and Brown 1985; Fei and Saxena 1987; Holland and Powell 1996; Robertson and Hemingway 1995). Waples and Waples (2004) provide a discussion of the various approaches. The polynomial proposed by Berman and Brown (1985),

$$C_{p,\text{mol}} = k_0 + k_1 T^{-0.5} + k_2 T^{-2} + k_3 T^{-3} \quad (T \text{ in K}), \quad (16)$$

is valid for a large temperature range and yields no values incompatible with the Dulong–Petit law for high temperatures. Table 2 lists values for the temperature coefficients k_i in Eq. 16 determined from fits of heat capacity of selected minerals measured at different temperatures.

As an alternative, Waples and Waples (2004) propose a statistical approach describing the general temperature dependence of all rocks and minerals, which can be rescaled easily for individual rocks and minerals. To this end, measured specific heat capacity c_p was normalized by the corresponding normalizing value $c_{p,n}$ at 200 °C (473.15 K), a temperature at or near which data was available. The resulting polynomial regressions yielded much better coefficients of determination R^2 for data measured on nonporous rock ($R^2 = 0.93$) than for those measured on minerals ($R^2 = 0.62$) while the trends were similar. The regression on the combined data for minerals and nonporous rocks yields an expression for the normalized specific heat capacity of a mineral or nonporous rock at arbitrary temperature T with a coefficient of determination $R^2 = 0.65$:

$$c_{p,n}(T) = 0.716 + 1.72 \times 10^{-3} T - 2.13 \times 10^{-6} T^2 + 8.95 \times 10^{-10} T^3 \quad (T \text{ in } ^\circ\text{C}). \quad (17)$$

Equation 17 can be rescaled for any mineral or nonporous rock at any temperature T_2 provided a value $C_p(T_1)$ measured at temperature T_1 is available, for instance from any of the compilations of Berman and Brown (1985), Fei and Saxena (1987), Berman (1988), Holland and Powell (1996), or Robertson and Hemingway (1995):

$$c_p(T_2) = c_p(T_1) \frac{c_{p,n}(T_2)}{c_{p,n}(T_1)}. \quad (18)$$

Additionally, Waples and Waples (2004) consider the variation of specific heat capacity with lithology, where

Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, Table 2 Coefficients for calculating isobaric molar heat capacity $C_{p,\text{mol}}$ ($\text{J mol}^{-1} \text{K}^{-1}$) (From Eq. 16; Berman 1988)

interested readers find a specific discussion regarding coals of different carbon content or maturity.

Mottaghy et al. (2005) used a second-order polynomial in temperature to fit the variation of isobaric specific heat capacity with temperature measured on a suite of metasedimentary, volcanic, magmatic, and metamorphic rocks:

$$c_p(T) = A_0 + A_1 T^1 + A_2 T^2 \quad (c_p \text{ in } \text{J kg}^{-1} \text{K}^{-1}, 1^\circ\text{C} \leq T \leq 100^\circ\text{C}). \quad (19)$$

The average values for the coefficients A_0 , A_1 , and A_2 determined from a regression of $c_p(T)$ measured over a temperature range of $1^\circ\text{C} \leq T \leq 100^\circ\text{C}$ on 26 samples from seven boreholes are: $\bar{A}_0 = 747.177 \text{ J kg}^{-1} \text{K}^{-1}$; $\bar{A}_1 = 1.862 \text{ J kg}^{-1} \text{K}^{-2}$; and $\bar{A}_2 = -0.002 \text{ J kg}^{-1} \text{K}^{-3}$.

Based on a composition of 30 % quartz, 60 % feldspar (albite), and 10 % phyllosilicates (5 % phlogopite and 5 % annite), Whittington et al. (2009) suggest average “bulk crustal” molar-specific heat capacity equations based on end-

member mineral data for two temperature ranges, separated by the transition at 846 K ($\sim 573^\circ\text{C}$) between α - and β -quartz:

$$C_{p,\text{mol}}(T) = \begin{cases} 199.50 + 0.0857 T - 5.0 \times 10^{-6} T^{-2}; & T \leq 846 \text{ K} \\ 229.32 + 0.0323 T - 47.9 \times 10^{-6} T^{-2}; & T > 846 \text{ K} \end{cases} \quad (C_{p,\text{mol}} \text{ in } \text{J mol}^{-1} \text{K}^{-1}) \quad (20)$$

Assuming an average molar mass of $0.22178 \text{ kg mol}^{-1}$, this yields the variation of isobaric specific heat capacity c_p with temperature shown in Fig. 1.

Volumetric Heat Capacity: Thermal Capacity

When heat capacity is related to unit volume rather than to unit mass or unit amount of substance, it is referred to as volumetric heat capacity or thermal capacity. It can be calculated as the product of specific heat capacity c and density ρ or as the ratio of thermal conductivity λ and thermal diffusivity κ by

Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, Fig. 1 Variation of specific heat capacity c_p , the phonon components of thermal diffusivity and thermal conductivity κ_p and λ_p , respectively, and thermal capacity $\rho c_p = \lambda_p/\kappa_p$ with temperature in an average crust according to Eq. 20, and Eq. 31 in

► “Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity” (this entry) for c_p and κ , respectively, assuming molar mass = 0.221 78 kg mol⁻¹ and $\rho = 2\,700$ kg m⁻³ (after Whittington et al. 2009)

$$\rho c = \lambda / \kappa . \quad (21)$$

Again, Kopp’s law yields the rock’s bulk thermal capacity $(\rho c)_b$ as

$$(\rho c)_b = (1 - \phi) (\rho c)_s + \phi \sum_{i=1}^N S_i (\rho c)_i, \quad (22)$$

where ϕ is porosity and $(\rho c)_s$ thermal capacity of the rock skeleton. S_i and $(\rho c)_i$ are saturation and thermal capacity of the i^{th} fluid phase in the pore space. The skeleton thermal capacity itself may be calculated again from Kopp’s law for a given mineral assemblage and the corresponding volume fractions of the solid phase from Eq. 15. Because of the low density of air and gas – about three orders of magnitude lower than that of water and rock – the contribution of the gas phase to thermal capacity can often be ignored. In this case, $N = 2$ for the fluid phases water and oil or $N = 1$ for water only. Expressions for the density of various fluids are reported in Clauser (2006). Data on density of various minerals and rocks are listed, e.g., in Wohlenberg (1982a, b) or Olhoeft and Johnson (1989). Using Eqs. 17 and 18, Waples and Waples

(2004) analyzed a substantial collection of density and specific heat capacity data from various authors and transformed specific heat capacity and thermal capacity to a uniform reference temperature of 20 °C (Table 3).

The mean thermal capacity of “impervious” rocks was found at 2.300(46) MJ m⁻³ K⁻¹ by Roy et al. (1981). This is acceptably close to the mean of 2.460(65) MJ m⁻³ K⁻¹ found by Waples and Waples (2004) for inorganic minerals.

Based on density, specific heat capacity, and thermal conductivity measured at room temperature, Mottaghy et al. (2005) determined thermal capacity as inverse slope of a regression of diffusivity on thermal conductivity according to Eq. 21. All values fell well within ± 20 % of the average of 2.3 MJ m⁻³ K⁻¹ recommended by Beck (1988).

Mottaghy et al. (2008) determined average values for thermal capacity according to Eq. 21 for metamorphic and magmatic crystalline rocks as the inverse slope of a linear regression of values of thermal diffusivity versus thermal conductivity measured at temperatures in the range 20 °C $\leq T \leq$ 300 °C:

$$\kappa(T) = \frac{\lambda(T)}{m + nT}, \quad (T \text{ in } ^\circ\text{C}). \quad (23)$$

Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, Table 3 Typical values or ranges for density ρ , isobaric specific heat capacity c_p , and thermal capacity ρc_p of selected rocks at 20 °C (Waples and Waples 2004, Petrunin et al. 2004)

Rock	ρ (kg m ⁻³)	c_p (J kg ⁻¹ K ⁻¹)	ρc_p (kJ m ⁻¹ K ⁻¹)

Regression of data measured on seven samples collected along a profile crossing the Eastern Alps from north to south and on nine samples from the northern rim of the Fennoscandian Shield near the Kola ultra-deep borehole SG-3 yielded $m = 2\,066(70) \text{ kJ m}^{-3} \text{ K}^{-1}$, $n = 2.2(4) \text{ kJ m}^{-3} \text{ K}^{-2}$, $R^2 = 0.97$ and $m = 2\,404(91) \text{ kJ m}^{-3} \text{ K}^{-1}$, $n = 3.6(5) \text{ kJ m}^{-3} \text{ K}^{-2}$, and $R^2 = 0.92$, respectively. This yields a range of thermal capacity for the Alpine and Fennoscandian data of about $2.1 \text{ MJ m}^{-1} \text{ K}^{-1}$ to $2.7 \text{ MJ m}^{-1} \text{ K}^{-1}$ and $2.4 \text{ MJ m}^{-1} \text{ K}^{-1}$ to $3.5 \text{ MJ m}^{-1} \text{ K}^{-1}$, respectively, in the temperature range $20^\circ\text{C} \leq T \leq 300^\circ\text{C}$.

The product of an average density of $2\,700 \text{ kg m}^{-3}$ for the crust and isobaric-specific heat capacity calculated for an average molar mass of $0.221\,78 \text{ kg mol}^{-1}$ according to Eq. 20 (Whittington et al. 2009) yields the variation of thermal capacity ρc_p (Eq. 21) with temperature shown in Fig. 1. Its increase with temperature by about a factor of 1.7 in a temperature interval of 1 000 K demonstrates that the effect of temperature is stronger for the phonon component of thermal diffusivity κ than for phonon thermal conductivity λ_p due to the increase of specific heat capacity. Assuming a constant density throughout the crust implies that the increase

and decrease in density due to the increase in pressure and temperature, respectively, partly cancel each other and that these changes are small compared to those of specific heat capacity and thermal diffusivity.

Latent Heat

Solidification of magma and melting of rocks as well as freezing and thawing of water in soils or rocks liberate or consume heat, respectively. The like applies to mineral phase changes such as those associated with the seismic discontinuities at 410 km, 520 km, and 660 km in the transition zone from 400 km to 600 km between the upper and lower mantle. These mineral phases are chemically identical but differ with respect to crystal structure and therefore elastic properties. This is why this transition is seen in the seismic wave field. Phase transitions require a certain pressure p and temperature T , but also a specific relation between these two state variables expressed by the “Clapeyron slope” $dp/dT = \Delta S(p,T)/\Delta V(p,T)$ (the inverse of the Clausius–Clapeyron equation), where S and V are entropy and volume,

Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat, Table 4 Comparison of isobaric specific heat capacity c_p and latent heat of melting L of granite, basalt, seawater, and freshwater (Stacey and Davis 2008 supplemented)

	Granite	Basalt	Seawater	Freshwater	Dry air (15 °C, 1000 hPa)
c_p (kJ kg ⁻¹ K ⁻¹)	0.83	0.88	3.99	4.18	1.006
L (kJ kg ⁻¹)	420	420	335	333.55	196

respectively. This means that the depth where a certain phase transition occurs varies with the ambient temperature in the crust. Positive and negative values for the Clapeyron slope are associated with exothermic and endothermic reactions, respectively.

Phase changes generally consume or deliver much more latent heat than can be stored or delivered as sensible heat: It requires a temperature increase of more than 500 K to equal by sensible heat the amount of latent heat required to melt 1 kg of granite, and still an increase of more than 80 K to equal by sensible heat the amount of latent heat required to melt 1 kg of sea ice (Table 4).

The *discontinuity at 410 km* is generally associated with the transition in olivine from α -olivine to β -spinel, also named wadsleyite (e.g., Stacey and Davis 2008). At expected pressure and temperature of 14 GPa and 1600 K, respectively, corresponding values for the Clapeyron slope vary between 2.9 MPa K⁻¹ and 4.8 MPa K⁻¹ (Bina and Helffrich 1994; Katsura et al. 2004; Stacey and Davis 2008). The *discontinuity at 520 km* is associated with the transition from β -spinel (wadsleyite) into γ -spinel, also named ringwoodite (e.g., Stacey and Davis 2008). At an expected pressure of 18 GPa, a temperature increase, such as by an ascending plume, would require a higher pressure for this transition according to inferred Clapeyron slopes of 4.0 MPa K⁻¹ to 5.3 MPa K⁻¹ (Helffrich 2000; Deuss and Woodhouse 2001). A second transition occurs between garnet and calcium-perovskite (CaSiO₃), where the iron in garnet goes into Ilmenite, and its CaSiO₃-component into calcium-perovskite. This reaction has a negative Clapeyron slope. The two slopes of different signs may shift the depth for two transitions into opposite directions, which is observed as a splitting of the 520 km discontinuity. The *discontinuity at 660 km* defines the transition into the lower mantle. It is caused by the transition of γ -spinel (ringwoodite) into magnesium-perovskite (MgSiO₃) and ferrous periclase (magnesiowüstite, (Fe,Mg)O). At an expected pressure of 23.5 MPa, this endothermic transition is associated with a Clapeyron slope of -2.8 MPa K⁻¹ (Stacey and Davis 2008).

The latent heat L that corresponds to these additional heat sources and sinks can be elegantly combined with the specific sensible heat capacities of the liquid and solid rock, c_l and c_s , respectively, into an effective bulk specific heat capacity c_{eff} . This effective specific heat capacity then accounts for the

entire enthalpy change, including latent heat. In this approach, the latent heat effects are assumed to occur between the solidus and liquidus temperatures T_1 and T_2 , respectively. The heat liberated by a solidifying (“freezing”) liquid phase is obtained by weighting the corresponding contributions by the mass fractions of liquid and solid phases, ϕ_{liquid} and ϕ_{solid} , respectively. The change of specific enthalpy $h = H/m$, where m is the mass of the rock volume then becomes

$dh_{\text{freezing}} = \{(\phi c)_{\text{liquid}} + (\phi c)_{\text{solid}}\} dT + L d\phi_{\text{liquid}}$, and the effective heat capacity c_{eff} is:

$$c_{\text{eff}}^{\text{freezing}} = \frac{dh}{dT} = (\phi c)_{\text{liquid}} + (\phi c)_{\text{solid}} + L \frac{d\phi_{\text{liquid}}}{dT}. \quad (24)$$

Conversely, when considering melting the solid phase, the enthalpy change of the rock volume is $dh_{\text{melting}} = \{(\phi c)_{\text{liquid}} + (\phi c)_{\text{solid}}\} dT + L d\phi_{\text{solid}}$, and the effective heat capacity in this case c_{eff} is:

$$c_{\text{eff}}^{\text{melting}} = \frac{dh}{dT} = (\phi c)_{\text{liquid}} + (\phi c)_{\text{solid}} + L \frac{d\phi_{\text{solid}}}{dT}. \quad (25)$$

Summary

Understanding the thermal regime of the Earth requires appreciation of properties and mechanisms for storage, transport, and generation of heat within the Earth. Both experimental and indirect methods are available for inferring specific or molar heat capacity and, with additional information on density, also thermal capacity (or volumetric heat capacity). In the temperature and pressure ranges where they occur, phase changes consume or deliver characteristic amounts of latent heat (or enthalpy of fusion or solidification), depending on whether they are endothermic or exothermic. Latent heat may be combined with specific heat capacity into an effective heat capacity.

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity

Christoph Clauser

Institute for Applied Geophysics and Geothermal Energy,
RWTH Aachen University, Aachen, Germany

Synonyms

Heat conductivity; Thermal conductivity; Thermal diffusivity

Definition

Thermal conductivity (also: heat conductivity) λ : Physical property governing heat diffusion in the steady state. It defines how much heat flows across a unit cross section of rock along a unit distance per unit temperature decrease per unit time; dimension: $\text{W m}^{-1} \text{K}^{-1}$.

Thermal diffusivity κ : Physical property governing transient heat diffusion. It is defined by the ratio of thermal conductivity and thermal capacity, i.e., by the ratio of heat flowing across the face of a unit volume and the heat stored in the unit volume per unit time; dimension: $\text{m}^2 \text{s}^{-1}$.

General Remark

A great amount of petrophysical data has been published in the past by individual researchers interested in thermal rock properties. Usually, these data collections are sorted according to petrographically defined rock types. But rock type, unfortunately, is a weak descriptor for physical properties: Any rock type shows significant variability in characteristics which influence its physical properties, such as (but not limited to) porosity, cementation, mineral content, etc. This causes also the physical properties to vary accordingly, some by factors and others even by orders of magnitude. Thermal rock properties, generally, vary by a factor within the same order of magnitude.

This variability limits the value of individual, rock type-specific data measured on single samples, unless they originate exactly from the formation (or even location) of interest. In all other cases, a statistical approach help accounting for this intrinsic variability by characterizing physical rock properties by the mean values and standard deviations of populations of a sufficiently large number of individual measurements. An example of this approach is the nationwide

survey performed in the Republic of Korea where thermal conductivity measurements on 1 560 rock samples were combined into statistical moments for ten, eight, and seven major types of igneous, metamorphic, and sedimentary rocks, respectively (Shim et al. 2010).

Recently, a large number of petrophysical data were compiled into a publically available, digital database (Bär et al. 2020) comprising thermal, mechanical, electrical, and magnetic rock properties. Each data point is supplemented by a reference (if available) and information on sample location, petrographic analysis, and chronostratigraphic age. This data, while still incomplete in spite of its large number of more than 75 000 individual measurements, is another valuable source of individual data from specific locations but also useful for calculating means and standard deviations for larger volumes of rock.

Thermal Conductivity

Fourier's law of heat conduction defines the vector of specific heat flow q_i , i.e., heat flow normalized by area, as the product of the thermal conductivity tensor λ_{ij} and the temperature gradient vector $\partial T/\partial x_j$:

$$q_i = -\lambda_{ij} \frac{\partial T}{\partial x_j}. \quad (1)$$

Temperature measurements are usually performed along vertical profiles in boreholes, yielding only the vertical component of the temperature gradient. To a good approximation, thermal conductivity in some, particularly volcanic and plutonic, rocks is isotropic. In this case, heat will flow predominantly vertically, and it is sufficient to consider only the vertical component of Eq. 1. In contrast, thermal conductivity of many sedimentary and metamorphic rocks is strongly anisotropic, and lateral heat flow may be significant. Hence, information on anisotropy is often required, demanding laboratory measurements in different directions. Anisotropy occurs over a wide range of scales, from microscopic, over laboratory and macroscopic, to tectonic.

Heat transport in most of the Earth's crust and mantle is diffusive and caused by (1) scattering of quantized lattice vibrations, the phonons and (2) by diffusive (as opposed to ballistic) radiation of photons. These two processes are described by phonon thermal conductivity λ_p and radiative thermal conductivity, λ_r , respectively, the sum of which is often termed effective thermal conductivity, λ_{eff} . In most polycrystalline material, heat radiation starts to dominate at temperatures above 2 500 K. In single crystals and glasses with little or no scattering (e.g., obsidian), however, radiation

may become important at much lower temperatures of 500 K–1 000 K. In the metallic core, scattering of electrons provides a third heat transfer mechanism (Fig. 1).

The following text deals mostly with phonon thermal conductivity. Radiative heat transfer is discussed in the paragraph on radiative thermal conductivity and in the chapter on thermal diffusivity.

Measuring Techniques

Thermal conductivity can be measured in the laboratory on rock samples, i.e., cores or cuttings or in situ either in boreholes or with marine heat flow probes with a shallow penetration of three to twenty meters. There are numerous steady-state and transient techniques available for measuring thermal conductivity, the most prominent being the “divided bar,” “needle probe,” “optical scanning,” and “(laser) flash,” all of which are suitable to determine also the anisotropy of thermal conductivity. These methods are described in, for instance, Parker et al. (1961), Kappelmeyer and Haenel (1974), Beck (1988), Davis (1988), Somerton (1992), Schilling (1999), Popov et al. (1999b), Beardsmore and Cull (2001), and Blumm and Lemarchand (2002). Among these techniques, the transient ones, e.g., line-source methods (needle probes and half-space line-sources) and optical scanning, are also suitable for determining thermal diffusivity. Popov et al. (2016) provide an appraisal of different methods for thermal property testing in the laboratory at atmospheric pressure, in particular for thermal conductivity and thermal diffusivity.

As with most other petrophysical properties, in situ thermal conductivity may deviate significantly from laboratory values, even if the effects of temperature, pressure, and pore fluid are accounted for. This scale dependence involves different aspects: In situ measurements represent an

average over a much larger rock volume than laboratory measurements performed on small samples and cannot resolve small-scale variations. A subsequent upscaling may be necessary to identify the appropriate representative elementary volume (REV) for which reasonable transport parameter averages can be defined. Jorand et al. (2013) discuss results of some frequently used averaging methods and, based on a detailed laboratory study, compares them with simulated values obtained from numerical thermal petrophysics.

Indirect Methods

When no data are available or no direct measurements can be performed, thermal conductivity can be inferred indirectly, either from mineralogical composition and saturating fluids or from correlations with other physical properties. While some of these methods are based on well-defined physical models, others are purely empirical.

Estimation from mineralogical composition and saturating fluids: Thermal conductivity of rocks may be estimated from their mineral and fluid content. Thermal conductivity of minerals varies much less than in rocks, due to their well-defined composition. As the bulk thermal conductivity of porous rocks varies with different saturants, it may be also of interest to know rock thermal conductivity for other saturants than those used in the laboratory measurement. Numerous models based on volume fractions of the individual mineral and fluid phases have been proposed, all with specific advantages and disadvantages: Some overestimate while others underestimate systematically the true bulk thermal conductivity. Most of them are valid only within a specific range of volume fractions (or porosities) and yield unreasonable results outside. To overcome this problem, additional parameters may be introduced in order to incorporate rock structure into a mixing law (see below).

The parallel and series models for thermal resistance of layered media are easy to understand, but have the disadvantage of being rather special cases, applicable mostly to bedded sediments. They correspond to the well-known weighted arithmetic and harmonic means, λ_{ari} and λ_{har} , Eqs. 2a and 2b, and are related to heat flowing parallel or perpendicular to bedding, respectively. They define upper and lower limits for all other models, sometimes also referred to as the Voigt upper bound and Reuss lower bound, respectively. Thus they constrain the maximum variance of possible predictions. The arithmetic mean between the two is known as the Voigt-Reuss-Hill average, λ_{VRH} (Eq. 2c). It is useful for estimating an effective thermal conductivity, while the arithmetic and harmonic means are used to define a range for possible values.

The weighted geometric and square root means λ_{geo} and λ_{V} (Eqs. 2d and e; e.g., Beardsmore and Cull 2001),

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Fig. 1 Different types of material in the Earth and associated mechanisms of heat transport (Redrawn after Hofmeister et al. 2009)

respectively, are associated with a mixture of different fluid and mineral phases of unspecified geometry. In many cases, both means successfully explain the data and are therefore widely used for lack of more specific information on the geometric arrangement of the individual volume fractions. In the special case where $N = 2$ and $n_1 = n_2 = 0.5$, the arithmetic, harmonic, and geometric means are related by $\lambda_{geo} = \sqrt{\lambda_{ari} \lambda_{har}}$.

Effective medium theory (Bruggeman, 1935) provides the effective medium mean λ_{eff} (Eq. 2f) which is useful for macroscopically homogeneous and isotropic rocks consisting of randomly distributed grains and pores.

The upper and lower Hashin-Shtrikman bounds λ_{HS}^+ and λ_{HS}^- (Eq. 3; Hashin and Shtrikman 1962), respectively, provide tighter constraints for the predictions of different models other than the arithmetic and harmonic means. The arithmetic average of both defines the Hashin-Shtrikman mean (Eq. 2g). Geometrically, the lower Hashin-Shtrikman bound λ_{HS}^- corresponds to a rock model consisting of grains suspended in a fluid and is close to the geometric mixing law. In contrast, the upper Hashin-Shtrikman bound λ_{HS}^+ may be related to a well-lithified rock with spherical, fluid-filled pores and is close to

the square root mean. Figure 2 illustrates the geometries corresponding to these different models.

If λ_i denotes the thermal conductivity and n_i the volume fraction of the i -th phase relative to the total volume ($1 = \sum n_i$), these seven weighted means are defined by:

$$\begin{aligned} (a) \quad & \lambda_{\max} = \lambda_{\text{ari}} = \lambda_{\parallel} = \sum_{i=1}^N n_i \lambda_i; \\ (b) \quad & \lambda_{\min} = \lambda_{\text{har}} = \lambda_{\perp} = \left(\sum_{i=1}^N \frac{n_i}{\lambda_i} \right)^{-1}; \\ (c) \quad & \lambda_{\text{VRH}} = \frac{1}{2} (\lambda_{\parallel} + \lambda_{\perp}); \quad (d) \quad \lambda_{\text{geo}} = \prod_{i=1}^N \lambda_i^{n_i}; \\ (e) \quad & \lambda_{\sqrt{}} = \left(\sum_{i=1}^N n_i \sqrt{\lambda_i} \right)^2; \quad (f) \quad \lambda_{\text{eff}}^{-1} = \sum_{i=1}^N \frac{3 n_i}{2 \lambda + \lambda_i}; \\ (g) \quad & \lambda_{\text{HS}} = \frac{1}{2} (\lambda_{\text{HS}}^+ + \lambda_{\text{HS}}^-); \end{aligned} \quad (2)$$

where:

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Fig. 2 Geometrical arrangement of layers, mineral grains, and pores assumed in different models for calculating mean bulk thermal conductivity of a composite medium:

arithmetic (λ_{ari}), harmonic (λ_{har}), geometric (λ_{geo}), and square root ($\lambda_{\sqrt{}}$) means, Hashin-Shtrikman upper and lower bounds, λ_{HS}^+ and λ_{HS}^- , respectively, and effective medium mean λ_{eff}

$$\lambda_{HS}^+ = \lambda_{\max} + \frac{A_{\max}}{1 - \alpha_{\max} A_{\max}},$$

$$\text{with : } A_{\max} = \sum_{i=1; \lambda_i \neq \lambda_{\max}}^N \frac{n_i}{\alpha_{\max} + 1/(\lambda_i - \lambda_{\max})},$$

$$\lambda_{\max} = \max(\lambda_1, \dots, \lambda_N) \quad \alpha_{\max} = \frac{1}{3\lambda_{\max}};$$

$$\lambda_{HS}^- = \lambda_{\min} + \frac{A_{\min}}{1 - \alpha_{\min} A_{\min}},$$

$$\text{with : } A_{\min} = \sum_{i=1; \lambda_i \neq \lambda_{\min}}^N \frac{n_i}{\alpha_{\min} + 1/(\lambda_i - \lambda_{\min})},$$

$$\lambda_{\min} = \min(\lambda_1, \dots, \lambda_N), \quad \alpha_{\min} = \frac{1}{3\lambda_{\min}}.$$

(3)

For a two-component system consisting of pore fluid and

solid rock with thermal conductivities λ_f and λ_s , respectively, Eq. 3 simplifies to (Hashin and Shtrikman 1962; Horai 1971):

$$\lambda_{HS}^+ = \lambda_s + \frac{\phi}{\frac{1}{\lambda_f - \lambda_s} + \frac{1-\phi}{3\lambda_s}}; \quad \lambda_{HS}^- = \lambda_f + \frac{1-\phi}{\frac{1}{\lambda_s - \lambda_f} + \frac{\phi}{3\lambda_f}}. \quad (4)$$

Generally, for a two-component system consisting of pore fluid and solid rock with thermal conductivities λ_f and λ_s , respectively, the implicit definition of λ_{eff} in Eq. 2f can be resolved:

$$\lambda_{\text{eff}} = \frac{1}{4} \left\{ 3 \phi (\lambda_f - \lambda_s) + 2 \lambda_s - \lambda_f + \sqrt{9 \phi^2 \lambda_s^2 + 18 \phi \lambda_s \lambda_f - 18 \phi^2 \lambda_s \lambda_f - 12 \phi \lambda_s^2} \right. \\ \left. + \lambda_f^2 - 6 \phi \lambda_f^2 + 4 \lambda_s \lambda_f + 9 \phi^2 \lambda_f^2 + 4 \lambda_s^2} \right\}. \quad (5)$$

Figure 3 compares the variation of thermal conductivity of a two-component system with volume fraction for these different mixing laws defined by Eqs. 2 to 5. By and large, and in particular for such a two-component system, thermal conductivity of a multiphase rock determined according to these models can be ordered as:

$$\lambda_{\perp} = \lambda_{\text{har}} < \lambda_{HS}^- < \lambda_{\text{VRH}} < \lambda_{\text{geo}} < \lambda_{HS} < \lambda_{\text{eff}} \\ < \lambda_{\sqrt{}} < \lambda_{HS}^+ < \lambda_{\text{ari}} = \lambda_{\parallel}. \quad (6)$$

While only these nine models are presented and discussed here, various other mixing models are available which take into account additional factors, such as the shape of grains and voids. Several models assume spheroidal pores specifying the aspect ratio of the spheroids (Korvin 1978, 1982; Schulz 1981; Zimmerman 1984, 1989; Buntebarth and Schopper 1998; Popov et al. 2003). These models require information on the geometry of the internal rock structure and differ in the way of averaging over a representative elementary volume. Horai (1991) tested the results of predictions from several different mixing models on a remarkable data set in which porosity virtually varies from 0 % to 100 %. As can be expected, most of the models tested were valid only for certain porosity ranges. Only the two-phase models of Fricke-Zimmerman (Fricke 1924; Zimmerman 1989) and Schulz (1981) treating pores as spheroidal inclusions in a homogeneous and isotropic material are valid over the entire range of porosity. However, they require additional

information on the spheroids' aspect ratio or orientation. Given the typical ratios of rock and fluid conductivities we observe in nature, i.e., less than 10, most of the conductivity models tested work to within an accuracy of 10 % to 15 %.

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Fig. 3 Variation of thermal conductivity λ of a two-phase rock with porosity ϕ according to the means in Eqs. 2–5 for solid and fluid thermal conductivities of $\lambda_{\text{solid}} = 6 \text{ W m}^{-1} \text{ K}^{-1}$ and $\lambda_{\text{fluid}} = 0.6 \text{ W m}^{-1} \text{ K}^{-1}$, respectively: arithmetic (λ_{ari}); Hashin-Shtrikman upper bound (λ_{HS}^+); square root ($\lambda_{\sqrt{}}$); effective medium (λ_{eff}); Hashin-Shtrikman (λ_{HS}); geometric (λ_{geo}); Voigt-Reuss-Hill average (λ_{VRH}); Hashin-Shtrikman lower bound (λ_{HS}^-); harmonic (λ_{har})

Based on 1 325 individual measurements on sedimentary rocks and oceanic basalts in dry and saturated condition (λ_{dry} , λ_{sat}), Fig. 4 compares the variation of the ratio $\lambda_{\text{dry}}/\lambda_{\text{sat}}$ with porosity measured with that predicted by the arithmetic, upper Hashin-Shtrikman, square root, geometric, lower Hashin-Shtrikman, and harmonic mixing laws, λ_{ari} , λ_{HS}^+ , λ_{v} , λ_{geo} , λ_{HS}^- , and λ_{har} , respectively (Eqs. 2 to 4). It is evident that no single mixing law applies equally well to all rock types. But it appears that the geometric and square root model, on average, provide the best general fits to the data. It is also clear that the upper and lower Hashin-Shtrikman means λ_{HS}^+ and λ_{HS}^- , respectively, provide much tighter bounds than the arithmetic and harmonic means, λ_{ari} and λ_{har} , respectively.

Correlations with other physical properties: Physical properties measured in well-logs can be used to infer estimates for in situ thermal conductivity. The approach is based on an extension of the mixing-model approach to the borehole scale: The volume fractions n_i of the N different mineral (or fluid) phases are either taken directly from induced gamma ray spectroscopy logs (Williams and Anderson

1990) or determined from a joint analysis of a suitable number J of geophysical logs, such as gamma ray (GR), sonic slowness (DT, the inverse of velocity), gamma density (DEN), and neutron porosity (NPHI) (e.g., Hartmann et al. 2005; Goutorbe et al. 2006). Let $\mathbf{x}$ and $\mathbf{b}$ be vectors composed of the N volume fractions n_i and the J theoretical log responses R^j with respect to the N different phases, respectively. Then, each element R^j of vector $\mathbf{b}$ is the cumulative response of the j -th log to all phases weighted by their volume fractions:

$$R^j = \sum_i^N n_i R_i^j, \quad \text{where: } \sum_i^N n_i = 1 \quad \text{and} \quad (7)$$

$$\mathbf{x} = \begin{pmatrix} n_1 \\ \vdots \\ n_N \end{pmatrix}, \quad \mathbf{b} = \begin{pmatrix} R^1 \\ \vdots \\ R^J \end{pmatrix}.$$

Arranging the specific responses R^j of each log to the N rock phases as rows of a matrix $\mathbf{A}$:

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Fig. 4 Variation of thermal conductivity ratio $\lambda_{\text{dry}}/\lambda_{\text{sat}}$ (measured in dry and saturated condition) with porosity ϕ for different rock types. Numbered open circles represent means based on measurements on 1 058 sedimentary rock samples (Kobolev et al. 1990; Popov et al. 1995, 1999a; see also Clauser 2006): (1) 21 limestones; (2) 54 limestones; (3) 13 quartz sandstones; (4) 44 quartz siltstones; (5) 35 conglomerates; (6) 141 quartz sandstones; (7) 33 claystones; (8) 99 polymictic sandstones; (9) 30 quartz sandstones;

(10) 22 claystones; (11) 65 quartz siltstones; (12) 99 quartz siltstones; and (13) 241 quartz siltstones. Shown for comparison are data measured on 58 oceanic basalts (diamonds) and 179 shaly and limy sandstones (crosses). Curves labeled arithmetic, HS^+ , square root, geometric, HS^- , and harmonic, correspond to the arithmetic, upper Hashin-Shtrikman, square root, geometric, lower Hashin-Shtrikman, and harmonic mixing laws, λ_{ari} , λ_{HS}^+ , λ_{v} , λ_{geo} , λ_{HS}^- , and λ_{har} , respectively (Eqs. 2–4) (Clauser 2006)

$$\mathbf{A} = \begin{bmatrix} R_1^1 & \cdots & R_N^1 \\ \vdots & \ddots & \vdots \\ R_1^J & \cdots & R_N^J \end{bmatrix}, \quad (8)$$

the direct and inverse problems can be written as

$$\mathbf{Ax} = \mathbf{b} \text{ and } \mathbf{x} = \mathbf{A}^{-1}\mathbf{b}, \quad (9)$$

respectively. Thus, in the direct problem, the log response vector $\mathbf{b}$ is computed from the volume fraction vector $\mathbf{x}$ and the specific log response matrix $\mathbf{A}$. In the inverse problem, in contrast, the volume fractions $\mathbf{x}$ are computed from the log responses $\mathbf{b}$ and the inverse of the specific log response matrix $\mathbf{A}^{-1}$. Thus, for N solid rock constituents, solving the inverse requires $N - 1$ logs. The void or fluid-filled space does not count here because it is the difference of one and the sum of the solid rock volume fractions. If more logs are available, making the problem overdetermined, the inverse problem must be solved in a least-squares sense. Once the volume fractions are known and assigned appropriate, representative thermal conductivities, an appropriate mixing model can be applied to compute rock thermal conductivity. Generally, the geometric and square root means, Eqs. 2d and 2e, have often turned out useful, but other mixing models may be more appropriate in specific cases.

Assigning representative thermal conductivities to the solid rock constituents is not trivial. Tabulated values of rock thermal conductivity should be used only if they characterize specimens taken from the logged formations. In all other cases, these formations or their outcrops need to be sampled and these specimens tested in the laboratory. If measurements are performed at ambient conditions, the values need to be corrected for the effect of temperature, and in some cases also for pressure.

In general, the effect of temperature is more pronounced than that of pressure. However, for greater depth and little or less consolidated rocks, it also needs to be accounted for. If commercial log interpretation software is used to perform the inversion, the theoretical log responses R_i^j with respect to the N different rock constituents are usually supplied by the software. Alternatively, values for the theoretical log responses R_i^j can be obtained from the literature (e.g., Crain 1986).

Variability: By combining this approach with a sufficient number of laboratory measurements, statistical moments of thermal conductivity, such as mean, standard deviation, median, quartiles, etc., can be derived for geological units (see, e.g., Jorand et al. 2015). These should comprise similar kinds of rock in a volume that can be reasonably characterized by the available number of samples and borehole logs. This way, they characterize the variability of thermal conductivity in rocks of the same kind and can be used as input in stochastic simulations of heat transport.

A complementary approach is based on the dependence of thermal conductivity on mineral content and porosity. If the volume fractions of each solid and fluid component in the rock are known, application of a suitable mixing model yields bulk thermal conductivity within an acceptable error bound. This approach, however, does not yield information on the anisotropy of thermal conductivity and, therefore, is particularly suited for isotropic rocks. In a recent study applying this approach to low-permeability, isotropic plutonic rocks, Fuchs et al. (2018) found the harmonic mean to be superior compared to others.

Thermal Conductivity of Minerals and Rocks

Thermal conductivity of minerals is much better constrained than that of rocks, due to the well-defined crystal structure and chemical formula for each mineral. Substantial collections of mineral thermal conductivities were compiled by Birch (1942), Clark (1966), Horai and Simmons (1969), Dreyer (1974); Roy et al. (1981), Čermák and Rybach (1982), Carmichael (1984), Popov et al. (1987), Diment and Pratt (1988); Somerton (1992), Clauser and Huenges (1995), and Clauser (2006).

Rocks are less well defined. In fact, rock type is a rather poor descriptor for physical properties as it rarely characterizes the dominating factors for any given property. With respect to thermal conductivity of any rock type, these comprise mineral content, porosity, pore fluid, saturation, and anisotropy. As these factors vary within each rock type, the variation of rock thermal conductivity was characterized in a statistical manner in Clauser (2006, 2009) according to the four main diagenetic classes of rocks: sedimentary, volcanic, plutonic, and metamorphic. This discussion is summarized here.

For *sedimentary rocks* (Fig. 5a), thermal conductivity is mainly controlled by porosity and type of sediment, i.e., clastic or chemical. For *volcanic rocks* (Fig. 5b), porosity is the controlling factor on thermal conductivity: Both mean and median of the high- and low-porosity histograms differ by nearly a factor of two, and the high-porosity distribution is skewed toward low conductivities. Plutonic and metamorphic rocks are generally much less porous. Here, the controlling factor is the dominant mineral phase. For *plutonic rocks* (Fig. 5c), the feldspar content determines the shape of the histogram: Rocks enriched in feldspar (i.e., >60 %) display a nearly symmetrical conductivity distribution about a lower mean conductivity than rocks with low feldspar content. In spite of these differences, the means and medians for both distributions are nearly identical. For *metamorphic rocks* (Fig. 5d), the quartz content controls thermal conductivity: Both mean and median of the distributions for high and low quartz content differ by nearly a factor of two, similar as for *volcanic rocks* (Fig. 5b) with regard to porosity. While the histogram for high quartz content rocks (mostly quartzites) is nearly symmetrical, the low quartz content histogram is strongly skewed toward low conductivities.

Radiative Thermal Conductivity

In addition to heat conduction, heat radiation emitted from hot bodies propagates through a sufficiently transparent and little absorbing medium as electromagnetic waves with velocity

$$c_m = \frac{c_0}{n} = \Lambda_m \nu_m, \quad (10)$$

where Λ_m and ν_m are radiation wavelength and frequency in the medium, and $n = c_0/c_m$ is the ratio of the speed of light in

vacuum and in the medium, i.e., the real part of the index of refraction (Table 1).

Radiation theory is based on Planck's distribution law defining the spectral radiance L_Λ or L_ν of a black body in the wavelength or frequency interval $d\Lambda_m$ or $d\nu_m$ in the medium in terms of the corresponding wavelength Λ or frequency ν in vacuum, respectively:

$$L_\Lambda(\Lambda_m, T) d\Lambda_m = \frac{2h c_0^2 n^2(\Lambda, T)}{\Lambda^5 (e^{h c_0/(\Lambda k T)} - 1)} d\Lambda^{-1}, \quad (W m^{-2} sr^{-1} m^{-1} = W m^{-3} sr^{-1}),$$

$$L_\nu(\nu_m, T) d\nu_m = \frac{2h \nu^3 n^2(\nu, T)}{c_0^2 (e^{h \nu/(k T)} - 1)} d\nu, \quad (W m^{-2} sr^{-1} Hz^{-1} = W s m^{-2} sr) \quad (11)$$

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Table 1 Refractive index n of selected substances

Substance	$n = c_0/c_m$ (at 589 nm)
Air	1.0003
Water (H ₂ O)	1.33
Magnesium fluoride (MgF ₂)	1.38
Calcium fluoride (CaF ₂)	1.43
Rock salt (NaCl)	1.54
Quartz (SiO ₂)	1.54
Glass	1.5–1.6
Carbon disulfide (CS ₂)	1.63
Corundum (Al ₂ O ₃)	1.76
Zircon (ZrSiO ₄)	1.92
Sulfur (S)	2.00
Zinc sulfide (ZnS)	2.37
Diamond	2.42
Carborundum (SiC)	2.55
Rutile (TiO ₂)	3.10
Galena (PbS) (at 590 nm)	3.90

where $h = 6.626\ 068\ 96(33) \times 10^{-34}$ J s is the Planck constant, $k = 1.380\ 650\ 4(24) \times 10^{-23}$ J K⁻¹ the Boltzmann constant, and $d\Lambda = n\ d\Lambda_m$. Radiance is the radiant energy flux emitted per unit solid angle in a given direction per unit projected area of a source. According to Wien's displacement law, the maximum of spectral radiance increases with temperature and decreases with wavelength (or increases with frequency) of radiation. Hofmeister (2005) estimated the variation of $n(v, T)$ with temperature and frequency and found both to be very small suggesting that n is approximately constant in the visible frequency range.

The intensity of radiation I is related to the incident intensity I_0 , radiation path x , and opacity ε , by $I = I_0 e^{-\varepsilon x}$, where opacity $\varepsilon = 1/\ell$ is the inverse of the mean free path ℓ of radiation which defines the average distance that photons travel before they are absorbed or scattered. In general, opacity is a function of the radiation wavelength. Opacity in an absorbing and scattering medium comprises contributions from both of these processes:

$$\varepsilon = \alpha + \varsigma, \quad (12)$$

where α and ς are absorption and scattering coefficients, respectively. The scattering coefficient ς is usually identified with the inverse of the grain size, suggesting orders of magnitude ranging from 10^2 m⁻¹ to 10^6 m⁻¹. The absorption coefficient α may be as large as $\alpha = 7\ 000$ m⁻¹, but values below $\alpha = 1\ 500$ m⁻¹ are reported for absorption coefficients in single crystal olivines with different proportions of forsterite (Mg₂SiO₄) and fayalite (Fe₂²⁺ SiO₄) (Fo₉₄Fa₆ – Fo₈₆Fa₁₄) in the two pass bands at 0.5 μ m and 0.5 μ m–6.0 μ m (e.g., Shankland et al. 1979; Clauser 1988; Hofmeister 2005). The width and level of these pass bands

depend critically on the iron content in the minerals. The complex index of refraction m of all materials is defined by $m = \sqrt{\varepsilon_r \mu_r} = n - i \cdot k$, where ε_r and μ_r are (complex) relative electrical permittivity and relative magnetic permeability, respectively, $n = c_0/c_m$ is the real and k the imaginary part of the index of refraction (sometimes also called extinction coefficient), and $i = \sqrt{-1}$ is the imaginary unit. The absorption coefficient α is related to the complex index of refraction k by:

$$\alpha = \frac{4\pi}{\Lambda} k, \quad (13)$$

where Λ is the radiation wavelength (Aronsson et al. 1970).

Radiation therefore becomes important for rocks with a larger free mean path of radiation corresponding to smaller values of opacity or absorption coefficient and scattering coefficient. This holds in particular at larger wavelength, in the infrared part of the absorption spectrum's transmission window between about 0.5 μ m and 6.0 μ m.

Radiated heat is diffused when photons emitted by mineral grains are scattered or absorbed by neighboring grains. If the mean free path of radiation ℓ is small compared to the distance to material discontinuities (like grain boundaries) and for moderate temperature gradients (i.e., no large anisotropy in the intensity of radiation), an effective thermal conductivity

$$\lambda_{\text{eff},ij} = \lambda_{p,ij} + \lambda_{r,ij} \quad (14)$$

replaces λ_{ij} in Eq. 1, where $\lambda_{p,ij}$ and $\lambda_{r,ij}$ are phonon and radiative thermal conductivities, respectively.

Rosseland (1930) and Clark (1957) defined the radiative thermal conductivity based on the temperature derivative of the spectral radiance of a blackbody. Following practice in engineering, Hofmeister (2005) accounts in this expression additionally for the emissivity $\eta \leq 1$ of a grainy material by applying the temperature derivative and the subsequent integration to the product of emissivity η and spectral radiance L_v , yielding

$$\lambda_r = \frac{4\pi}{3} \int_0^\infty \frac{1}{\varepsilon(v, T)} \frac{\partial(\eta(v, T) L_v(v, T))}{\partial T} dv. \quad (15)$$

Different practical expressions were derived depending on which parameters can be assumed as independent of temperature or frequency (see, e.g., Clark 1957; Shankland et al. 1979; Schärmeli 1982; Clauser 1988; Hofmeister 1999, 2005; Hofmeister et al. 2009). Based on grain size δ and attenuation,

$$A = \frac{\ln(I_0) - \ln(I_t)}{\delta} \approx \alpha, \quad (16)$$

where α is the absorption coefficient and I_0 and I_t are incident and transmitted intensities, respectively, Hofmeister (2005)

suggests the following expressions for emissivity and opacity:

$$\eta = 1 - e^{-\delta \cdot \alpha(v)} = 1 - e^{-(\ln(I_0) - \ln(I_r))}, \quad (17)$$

$$\varepsilon = \frac{1 + \delta \cdot \alpha}{\delta},$$

and estimates values for the product $\delta \cdot \alpha$ based on the interface reflectivity $R(\%)$ between two neighboring grains. Values for $\delta \cdot \alpha$ considered realistic for the mantle range between 5 and 10 (corresponding to a range for R between 0.07 % and 0.05 %) with a preferred value of 7 (i.e., $R = 0.01$ %).

The “gray body” approximation assumes opacity and emissivity as finite, constant, and independent of radiation wavelength. If the real part of the refractive index n and the spectral radiance L_λ or L_ν are also independent of temperature and wavelength, Eq. 15 simplifies into:

$$\lambda_r = \frac{4\pi\delta}{3} \int_0^\infty \frac{1 - e^{-\delta \cdot \alpha(v)}}{1 + \delta \cdot \alpha(v)} \frac{\partial(L_\nu(v, T))}{\partial T} dv = \frac{8\pi\delta n T^3 k^4}{3 c_0^2 h^3} \sum_{\text{lower}}^{\text{upper}} \int \frac{1 - e^{-\delta \cdot \alpha(v)}}{1 + \delta \cdot \alpha(v)} \left(\frac{n e^x x^4 + 2 T x^3}{e^x - 1} \frac{\partial n}{\partial T} \right) dx \quad (\text{W m}^{-1} \text{ K}^{-1}) \quad (19)$$

where $x = h \nu / (k T)$ and $dx = h d\nu / (k T)$, and the summation extends over the transparent regions above and below the strong absorption bands in the visible part of the spectrum. The second term of the sum in the integrand vanishes if $\partial n / \partial T \approx 0$, as suggested by Hofmeister (2005). Because α varies nonlinearly with frequency or wavelength, and because the cutoff frequencies in the integral in Eq. 19 depend on δ and α , Hofmeister (2005) evaluated the integral numerically for polynomials in T whose exponents ranged from 0 to 6. This yielded a relationship between radiative thermal conductivity and temperature differing from the purely cubic one in Eq. 18.

Variation with Temperature

Since the pioneering experiments of Eucken (1911), thermal conductivity of minerals and rocks is known to decrease with temperature, generally with its inverse. Eucken’s empirical result was corroborated theoretically by Peierls (1929) based on Debye’s (1914) theory of phonon scattering. Eucken (1911) observed in his experiments in contrast to crystals an increase in thermal conductivity of amorphous siliceous glass, a clear indication of radiative heat transfer.

The decrease is primarily due to the decrease of phonon (or lattice) thermal conductivity λ_p with temperature and to a smaller degree to thermal cracking. Since the thermal expansion coefficient increases with temperature (but differently for all minerals), differential expansion may create contact resistances between mineral grains. The effect of contact resistance is less pronounced in water-saturated than in dry rocks,

$$\lambda_r = \frac{16 \eta \sigma n^2 T^3}{3 \varepsilon}, \quad (18)$$

where $\sigma = 5.670 400(40) \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$ is the Stefan-Boltzmann constant. An order of magnitude of λ_r can be estimated from Eq. 18 by (i) assuming an emissivity of $\eta = 0.99$, (ii) neglecting scattering and identifying opacity with the absorption coefficient $1000 \text{ m}^{-1} < \alpha < 1 500 \text{ m}^{-1}$ of olivine (Fo92Fa8) at 1 700 K, and (iii) assuming a typical silicate value of $n = 1.6$ for the refractive index (Table 1). This yields a range for radiative thermal conductivity at 1 700 K of $2.5 \text{ W m}^{-1} \text{ K}^{-1} < \lambda_r < 3.8 \text{ W m}^{-1} \text{ K}^{-1}$.

Inserting Eqs. 16 and 17, and the temperature derivative of the spectral radiance (11) as provided by Shankland et al. (1979) into Eq. 15 yields radiative thermal conductivity as:

the condition in which most rocks are tested at elevated temperatures. For single-mineral aggregates, a linear relationship between temperature and thermal resistivity λ^{-1} discriminates between contributions which depend on temperature T and others which don’t, such as micro-cracks, grain boundaries, shape, and orientation of crystals and their fragments:

$$\lambda^{-1}(T) = c_1 + c_2 T, \quad (20)$$

where λ is in $\text{W m}^{-1} \text{ K}^{-1}$ and T is in K. By measuring thermal conductivity λ and plotting its inverse (thermal resistivity λ^{-1}) versus temperature, constants c_1 and c_2 are obtained from intercept and slope of a linear regression. Table 2 provides values for the constants c_1 and c_2 in Eq. 20 which may be used to infer the temperature dependence of thermal resistivity for some single-mineral aggregates (Clark 1969).

Based on measurements on 113 samples of metamorphic rocks from the KTB research borehole in Germany in the temperature range 50 °C–200 °C, Buntebarth (1991) determined mean values for the constants c_1 and c_2 in Eq. 20 for gneissic and metabasitic rocks. The arithmetic means determined from measurements on 66 gneiss samples are $\bar{c}_1 = 0.16(3) \text{ W}^{-1} \text{ m K}$ and $\bar{c}_2 = 0.37(14) \times 10^{-3} \text{ W}^{-1} \text{ m}$. The corresponding means determined from measurements on 36 metabasite samples are $\bar{c}_1 = 0.33(3) \text{ W}^{-1} \text{ m K}$ and $\bar{c}_2 = 0.22(14) \times 10^{-3} \text{ W}^{-1} \text{ m}$.

In contrast to phonon conductivity λ_p , the radiative contribution λ_r to thermal conductivity generally increases with

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Table 2 Values of c_1 and c_2 in Eq. 20 for single-mineral aggregates. (Data: Clark (1969))

Mineral	T (°C)	$c_1 \times 10^3$ (W ⁻¹ m K)	$c_2 \times 10^3$ (W ⁻¹ m)
Halite, NaCl	0–400	–52.55	0.788
Periclase, MgO	100–800	–21.50	0.127

^aSingle SiO₂ crystal, heat flow $\perp$ to optical axis

the cube of temperature (see above). Thus, measurements of thermal conductivity as function of temperature generally first decrease with temperature until, from about 1000 °C–1200 °C onward, the radiative component balances and sometimes even reverses this decrease.

The temperature dependence of rock thermal conductivity was characterized in a statistical manner in Clauser (2006, 2009) according to the four main diagenetic classes of rocks: sedimentary, volcanic, plutonic, and metamorphic. This discussion is summarized here (Fig. 6).

For *sedimentary rocks* (Fig. 6a) up to 300 °C, there is a reduction by nearly a factor of two, both for physical and chemical sediments. Above 300 °C, while the decrease in thermal conductivity is less, it is more pronounced for chemical sediments than for physical sediments. However, there are very few data for this temperature range, which makes this last observation statistically weak. Above 300 °C, the mean thermal conductivity of sediments varies between 1.0 W m⁻¹ K⁻¹ and 1.5 W m⁻¹ K⁻¹.

Volcanic rocks (Fig. 6b) vary quite differently with temperature depending on their opacity, i.e., on how well they transmit thermal energy by radiation. Due to this additional “radiative thermal conductivity,” volcanic glasses and rocks with small iron content show an increase in thermal conductivity for temperatures above 800 °C–1 000 °C (e.g., Clauser 1988; Hofmeister et al. 2009). In contrast, thermal conductivity of opaque rocks, particularly those with a high iron content, decreases with temperature. An inversion of this trend is indicated by few available high-temperature measurements (above 1 300 °C) but with too few measurements for a statistical appraisal. At about 1 000 °C, thermal conductivity of these rocks is only about 50 % of their room temperature value. Again, there are few data points above 700 °C.

Plutonic rocks (Fig. 6c) show no strong radiative contribution. At temperatures above 600 °C, thermal conductivity decreases only very little. However, in these rocks, the variation of thermal conductivity with temperature depends on their feldspar content. For rocks enriched in feldspar, thermal conductivity up to 300 °C decreases little, while for those poor in feldspar, the decrease is stronger, becoming more

gentle above 300 °C, decreasing further by 20 % over the next 1 000 K. The different behavior of rocks with high feldspar content is due to the increase in thermal conductivity with temperature of some plagioclase feldspars (e.g., Höfer and Schilling 2002; Petrunin et al. 2004) which compensates the decrease in thermal conductivity with temperature observed for most other minerals and rocks. Other notable exceptions are fused silica as well as volcanic and silica glasses.

For *metamorphic rocks* (Fig. 6d), the decrease of thermal conductivity with temperature depends on the content in the dominant mineral phase, similar as for plutonic rocks. For quartzites, the decrease is strong, by nearly a factor of three up to a temperature of about 500 °C with only a very mild further decrease above this temperature. For rocks poor in quartz, the decrease in conductivity is not quite as strong, amounting, up to 300 °C, to about one-third of their room temperature value. Then it remains roughly constant up to 500 °C and decreases again to about one-third of their room temperature value up to 750 °C.

In summary, for moderate temperatures, thermal conductivity of rocks is well described by a linear relationship with the inverse of temperature, similar as in Eq. 20. For this temperature range, several approaches are available for inferring thermal conductivity at elevated temperatures. Based on the analysis of available tabulated data of thermal conductivity as function of temperature, Zoth and Hänel (1988) suggested the following form:

$$\lambda(T) = A + \frac{B}{350 + T}, \quad 0^\circ\text{C} \leq T \leq 800^\circ\text{C}, \quad (21)$$

where average values of the coefficients A and B for different rock types are given in Table 3.

Linear relationships between temperature and thermal resistivity, such as Eqs. 20 and 21, discriminate between temperature-dependent contributions and other factors, which are independent of temperature, such as micro-cracks, grain boundaries, pore volume, mineralogical composition, shape, and orientation of crystals and their fragments.

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Fig. 6 Variation of thermal conductivity with temperature for (a) sedimentary, (b) volcanic, (c) plutonic, and

(d) metamorphic rocks. Color shading indicates a range defined by plus and minus one standard deviation, and N is the number of data at each temperature (Clauser 2009)

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Table 3 Values for constants A and B in Eq. 21 for different rock types (Zoth and Hänel 1988)

Rock type	$T (^{\circ}\text{C})$	A ($\text{W m}^{-1} \text{K}^{-1}$)	B (W m^{-1})
1. Rock salt	-20 - 0	-2.11	2 960
2. Limestones	0-500	0.13	1073
3. Metamorphic rocks	0-1 200	0.75	705
4. Acidic rocks	0-1 400	0.64	807
5. Basic rocks	50-1 100	1.18	474
6. Ultrabasic rocks	20-1 400	0.73	1 293
7. Rock types (2)-(5)	0-800	0.70	770

Sass et al. (1992) and Vosteen and Schellschmidt (2003) distinguish between the effects of composition and temperature. They propose a general empirical relation for $\lambda(T)$, the thermal conductivity in $\text{W m}^{-1} \text{K}^{-1}$ at temperature T in $^{\circ}\text{C}$, as a function of λ_0 , the thermal conductivity at 0°C :

$$\lambda(T) = \frac{\lambda_0}{a + \left(b - \frac{c}{\lambda_0}\right)T} \quad \text{or} \quad \frac{\lambda_0}{\lambda(T)} = \underbrace{a}_{\text{intercept}} + \underbrace{\left(b - \frac{c}{\lambda_0}\right)}_{\text{slope}} T.$$

(22)

For different rock types, the slopes and intercepts of this equation can be determined from linear regressions of Eq. 22 yielding a mean intercept $\bar{a}$ and its uncertainty Δa .

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Table 4 Coefficients a , b , and c in Eq. 22 and associated uncertainties Δa and σ_b , σ_c ; Δa is the error of the mean intercept $\bar{a}$ for all rock types of the linear regressions of the

normalized thermal resistance $\lambda_0/\lambda(T)$ as a function of temperature T ; σ_b and σ_c are the errors defined by the linear regression of the slopes ($b-c/\lambda_0$) as a function of the thermal resistance $1/\lambda_0$ (see Eq. 22)

Rock type	$\bar{a}$ (—)	Δa (%)	$b \times 10^3$ (K ⁻¹)	$\sigma_b \times 10^3$ (K ⁻¹)	$c \times 10^3$ (W m ⁻¹ K ⁻²)	$\sigma_c \times 10^3$ (W m ⁻¹ K ⁻²)	T (°C)	References
Basement rocks I (from felsic gneiss to amphibolite)	1.007	—	3.6	—	7.2	—	0–250	Sass et al. (1992)
Basement rocks II (magmatic and metamorphic)	0.99	1	3.0	1.5	4.2	0.6	0–500	Vosteen and Schellschmidt (2003)
Sediments	0.99	1	3.4	0.6	3.9	1.4	0–300	Vosteen and Schellschmidt (2003)

Coefficients b and c and associated uncertainties σ_b and σ_c are determined from a second linear regression of the different slopes ($b - c/\lambda_0$) as a function of $1/\lambda_0$ (Table 4).

Since thermal conductivity is usually measured at room temperature, λ_0 is expressed as a function of λ_{25} , the room temperature thermal conductivity, by Sass et al. (1992) for crystalline rocks (felsic gneiss to amphibolite) as:

$$\lambda_0 = \lambda_{25} \left(1.007 + 25 \left(0.0037 - \frac{0.0074}{\lambda_{25}} \right) \right). \quad (23)$$

Vosteen and Schellschmidt (2003) find for magmatic and metamorphic rocks:

$$\lambda_0 = 0.53 \lambda_{25} + 0.5 \sqrt{1.13 \lambda_{25}^2 - 0.42 \lambda_{25}}, \quad (24)$$

and for sedimentary rocks:

$$\lambda_0 = 0.54 \lambda_{25} + 0.5 \sqrt{1.16 \lambda_{25}^2 - 0.39 \lambda_{25}}. \quad (25)$$

Hofmeister (1999) provided a detailed analysis of heat transport based on an analysis of phonon lifetimes obtained from infrared reflectivity. It accounts for the variation of the phonon contribution λ_p to thermal conductivity with both temperature T and pressure p as well as for the pressure-dependent radiative contribution λ_r . It allows approximating the thermal conductivity at conditions in the Earth's mantle if:

$$\lambda_r = \begin{cases} 0.01753 - 1.0365 \times 10^{-4} T + 2.2451 \times 10^{-7} T^2 - 3.407 \times 10^{-11} T^3 & \text{(a)} \\ 8.5 \times 10^{-11} T^3 & \text{(b)} \end{cases}, \quad (27)$$

where T is in Kelvin. These two relationships are shown in Fig. 7.

Figure 1 in the companion entry ► “Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent

(1) $K'_0 = dK_T/dp$, the pressure derivative of the isothermal bulk modulus K_T is constant; (2) the variations of the bulk modulus with temperature and pressure are mutually independent; (3) the pressure derivative of the thermodynamic Grüneisen parameter γ (Eq. 12 or 13 in the entry ► “Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat”, this volume) is constant: $d\gamma/dp = f$. For mantle material, γ varies from 1 to 1.4, K'_0 from 4 to 5, and $f \approx 0$ vanishes. According to Hofmeister (1999) and within the uncertainty of these parameters, thermal conductivity in the mantle is:

$$\lambda(T, p) = \lambda_r + \lambda(298K, 101.33 \text{ kPa}) \cdot \left(\frac{298}{T} \right)^a \cdot \frac{1 + K'_0 p}{K_T} \cdot e^{-\frac{(4\gamma+1/3)}{298} \int_{298}^T \alpha(T') dT'}, \quad (26)$$

where T is absolute temperature, $\lambda(298 \text{ K}, 101.33 \text{ kPa})$ is thermal conductivity at room temperature and atmospheric pressure, $\alpha(T)$ is volume coefficient of thermal expansion as a function of temperature, and the exponent a is the fitting parameter. The radiative contribution λ_r in (26) may be approximated by Eqs. 15, 18, or 19. Hofmeister (1999) provides alternative expressions for λ_r (in W m⁻¹ K⁻¹) for ferrous minerals (Eq. 27a) and dense silicates and oxides (Eq. 27b):

Heat” (this volume) shows the variation of phonon thermal conductivity λ_p with temperature in an average crust of density $\rho = 2700 \text{ kg m}^{-3}$ molar mass of $0.22178 \text{ kg mol}^{-1}$. It is derived from $\lambda = \kappa \rho c$ as the product of thermal capacity ρc_p

and thermal diffusivity κ calculated according to Eq. 20 (in the entry ► “Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat”, this volume; Whittington et al. 2009). Due to the balancing increase of specific heat capacity with temperature, the decrease in thermal conductivity with temperature is less than in thermal diffusivity by a factor of about 1.3. Assuming a constant density throughout the crust, this implies that the increase and decrease in density due to the increase in pressure and temperature, respectively, partly cancel each other and that these changes are small compared to those of specific heat capacity and thermal diffusivity.

For mantle minerals, such as olivine and its high-pressure polymorphs, the β - and γ -spinel wadsleyite and ringwoodite, respectively, Xu et al. (2004) fitted phonon thermal conductivity measured to 1 373 K and 20 GPa to an exponential equation in temperature yielding values for the exponent between $-0.406(35)$ and $-0.537(11)$ suggesting that fitted phonon thermal conductivity varies with $T^{-1/2}$ (Table 5).

Variation with Pressure

The effect of pressure on phonon thermal conductivity λ_p is different in two distinct pressure ranges. First, fractures and micro-cracks (developed during stress release after sampling) begin to close with increasing pressure. This reduces thermal contact resistance as well as porosity which is usually filled with a low-conductivity fluid. This process ends when a pressure of about 15 MPa is reached. A compilation of measurements on various sedimentary, volcanic, plutonic, and metamorphic rocks (Clauser and Huenges 1995) indicates that this effect accounts for an increase of about 20% relative to thermal conductivity at atmospheric pressure. A further pressure increase to 40 MPa does not affect thermal conductivity significantly. If pressure is increased further, however, a second process becomes effective, the reduction of intrinsic porosity, i.e., voids which are not created by stress release. For granite and for metamorphic rocks, data indicate an increase of thermal conductivity by about 10% within the pressure range 50 MPa–500 MPa.

For mantle minerals, such as olivine and its high-pressure polymorphs, the β - and γ -spinel wadsleyite and ringwoodite, respectively, Xu et al. (2004) determined values for the pressure coefficient between 0.022 GPa^{-1} and 0.032 GPa^{-1} for phonon thermal conductivity measured to 1373 K and 20 GPa (Table 5). A table of numerical values for the pressure derivatives of phonon thermal conductivity measured by a variety of authors was compiled by Hofmeister et al. (2009). Most values of the pressure coefficient fall into the range 0.04 GPa^{-1} – 0.36 GPa^{-1} , exceeded only by values of 0.69 GPa^{-1} and 0.5 GPa^{-1} for sulfur and quartz_{⊥c} (measured perpendicular to the optical c -axis), respectively. Osako et al. (2004) fitted thermal conductivity measured to 1100 K and 8.3 GPa on isotropic, single-crystal garnet and anisotropic olivine (Fo₉₃Fa₇; in three crystallographic directions) as upper and lower mantle constituents, respectively, to a linear equation in pressure (Table 6). A pressure dependence of garnet and olivine was found to be on the order of 4% per GPa to 5% per GPa and 3% per GPa to 4% per GPa, respectively.

In contrast, radiative thermal conductivity λ_r was found to vary much less with pressure than temperature (Clark 1957).

In particular, this holds once the spectral radiance overlaps the infrared pass band in the absorption spectrum, i.e., at temperatures above 1900 K (Hofmeister 2005).

Variation with Other Factors

Apart from temperature and pressure, thermal conductivity also varies with porosity, pore fluid, saturation, dominant mineral phase, and anisotropy. These effects are summarized here from the detailed discussion in Clauser (2006).

For large *porosity* (i.e., $\phi > 1\%$), thermal conductivity of the saturating fluid affects significantly the bulk rock thermal conductivity. The influence varies with the thermal conductivity of the saturants, e.g., water, oil, natural gas, air. The resulting bulk thermal conductivity can be estimated from a suitable mixing model, e.g., Eqs. 2–4.

The effect of partial *saturation* is different for porous or fractured rocks. In porous rocks, porosity comprises both bulk pore space and bottlenecks formed by the contact between individual grains. Dry bottlenecks act as thermal contact resistances between grains, while the bulk pore volume contributes proportionally to the effective rock thermal conductivity. In fractured rocks, in contrast, there are no bottlenecks between grains as in porous rocks, and the small void volume in the fractures corresponds to the bulk pores space of porous rocks.

Figure 8 illustrates these two effects for a water-saturated medium-porosity sandstone and a low-porosity granite: Starting completely dry with an unsaturated conductivity of about 60 % of the saturated value, a level of 85 % is reached for the sandstone at about 10 % saturation. The 15 % conductivity residual is then spread almost linearly over the remaining 90 % of saturation. Physically this observation indicates that the filling of intergranular bottlenecks, accounting for only about 10 %–15 % of the total porosity, significantly reduces the contact resistances between the individual grains. The replacement of low conductivity air by the more conductive fluid in the major part of the pore volume accounts

Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity, Fig. 8 Variation of thermal conductivity with partial saturation for a sandstone (circles; $\phi = 18\%$) and granite (squares; $\phi = 1\%$) saturated with water and standard deviations (bars); values normalized by reference thermal conductivities shown in legend (Clauser 2006 based on data of Reibelt 1991)

for the second effect. If only fractures contribute to the total porosity, as in the granite, there are no bottlenecks and only the second effect is observed: Starting completely dry with an unsaturated conductivity of about 85 % of the saturated conductivity, a quasi linear increase is observed due to the replacement of low conductivity air until the 100 % level is reached for complete saturation.

Anisotropy of sedimentary and metamorphic rocks is due to the conditions during their formation. Anisotropy occurs on several scales: (1) On the microscopic scale, many minerals are intrinsically anisotropic; (2) on the laboratory scale, thermal conductivity of many rocks is also anisotropic. However, even if rocks are composed of anisotropic minerals, random orientation of the crystals within the rock may render the rock's bulk thermal conductivity isotropic on a macroscopic scale; (3) on a still larger scale, if rocks

are exposed to folding, orogenic, or other tectonic processes, thermal conductivity of the resulting rock formation may be anisotropic.

As a result, thermal conductivity parallel to the direction of layering or foliation, $\lambda_{\parallel}$, is greater than thermal conductivity in the perpendicular direction, $\lambda_{\perp}$. The anisotropy factor, the ratio $\lambda_{\parallel}/\lambda_{\perp}$, generally falls into the range 0.9–3, with most values between 1 and 2 (e.g., Clauser and Huenges 1995; Popov and Mandel 1998; Popov et al. 1999a, b; Clauser 2006; Davis et al. 2007). For sedimentary rocks, a general trend has been reported of decreasing $\lambda_{\perp}$ with anisotropy factor $\lambda_{\parallel}/\lambda_{\perp}$, but no such trend was identified for metamorphic rocks (Clauser 2006).

Thermal Diffusivity

Thermal diffusivity is required in the analysis of transient heat transfer. A sizable compilation of room temperature data of phonon thermal diffusivity κ_p measured on various mantle minerals is given by Hofmeister et al. (2009) from measurements by various groups.

If both conductivity and thermal capacity are known, thermal diffusivity κ can be calculated from $\kappa = \lambda/(\rho c)$. As for steady-state thermal conduction, transient heat diffusion in most of the Earth's crust and mantle is caused by scattering of quantized lattice vibrations, the phonons, and by diffusive (as opposed to ballistic) radiation of photons. These two processes are described by phonon thermal conductivity λ_p and radiative thermal conductivity λ_r , respectively, the sum of which is often termed effective thermal conductivity, λ_{eff} . As thermal diffusivity is the ratio of thermal conductivity and thermal capacity, it is also influenced by the variation of density and specific heat capacity. This is of particular interest with respect to the variation with temperature.

Measuring Techniques

All of the transient laboratory methods used to determine thermal conductivity are useful to determine thermal diffusivity as well. More recently, heat pulse (Schilling 1999; Höfer and Schilling 2002; Gibert et al. 2003) and laser flash methods (Parker et al. 1961; Blumm and Lemarchand 2002; Hofmeister 2006) have been used for measurements at high temperature. Compared to other methods, their advantage lies in a reduction or even complete absence of physical contacts between samples on the one hand and temperature sensors and heat sources on the other hand. While most methods measure the effective diffusivity comprising contributions from phonon conduction and diffused heat radiation, the laser flash method yields the diffusive component without contributions from heat radiation. This difference becomes important particularly at high temperatures (for a critical assessment, see, e.g., Hofmeister et al. 2009).

Variation with Temperature

Thermal diffusivity κ of rocks varies even more strongly with temperature than thermal conductivity λ . This is caused by the opposite behavior of thermal conductivity and thermal capacity (ρc) with respect to temperature. Because of several self-compensating factors, thermal capacity (ρc) with few exceptions generally varies within $\pm 20\%$ of $2.3 \text{ MJ m}^{-3} \text{ K}^{-1}$ for the great majority of minerals and rocks (Beck 1988). This is confirmed by a linear regression of thermal diffusivity on thermal conductivity which was measured on a suite of meta-sedimentary, volcanic, magmatic, and metamorphic rocks together with density and specific heat capacity (Mottaghy et al. 2005):

$$\kappa = \frac{\lambda}{\rho c} = \frac{\lambda}{2.3} \\ = 0.44 \lambda \quad (\lambda \text{ in } \text{W m}^{-1} \text{ K}^{-1}; \kappa \text{ in } 10^{-6} \text{ m}^2 \text{ s}^{-1}). \quad (28)$$

A linear regression of thermal capacity as a function of temperature yields also a linear relationship. This allows to determine thermal diffusivity $\kappa(T)$ at any temperature, based only on the known variation of thermal conductivity $\lambda(T)$ with temperature (Mottaghy et al. 2005):

$$\kappa(T) = \frac{\lambda(T)}{2.1340 + 0.0044 T} \quad (T \text{ in } ^\circ\text{C}; \kappa \text{ in } 10^{-6} \text{ m}^2 \text{ s}^{-1}). \quad (29)$$

Thus, thermal diffusivity can be derived from thermal conductivity and vice versa. For the suite of rocks studied by Mottaghy et al. (2005), thermal conductivity decreased by 4 %–7 % in the range 1–100 °C while thermal diffusivity decreased by 18 %–22 %.

Thermal diffusivity was measured at temperatures of up to 550 °C by Ray et al. (2006) on a suite of 16 samples comprising Archean granulitic rocks which are considered a major component of the middle and lower continental crust. Phonon scattering was found to dominate heat transport with radiative diffusion of photons setting in at 450 °C for most, but not all rocks. Based on their measurements, Ray et al. (2006) propose an equation by which thermal diffusivity $\kappa(T)$ at elevated temperature below 450 °C can be derived from room temperature values κ_{rt} :

$$\kappa(T) = 0.7 + 144 \frac{\kappa_{\text{rt}} - 0.7}{T - 150} \quad (T \text{ in K}; \kappa \text{ in } 10^{-6} \text{ m}^2 \text{ s}^{-1}). \quad (30)$$

They also proposed an additional cubic term T^3 in Eq. 30 by which the radiative contribution above 450 °C is fitted. However, this assumes a similar variation with temperature of thermal conductivity and thermal diffusivity and neglects the additional variation of thermal capacity. This, in fact, makes

thermal diffusivity vary stronger with temperature than thermal conductivity, which is why the T^3 -term is omitted here. Whittington et al. (2009) measured the phonon component κ_p of thermal diffusivity at temperatures of up to 1260 K on garnet schist, leucogranite, and welded rhyolitic ash-flow tuff using laser flash analysis. This characterizes purely the phonon heat transfer component without any radiative contribution, in contrast to the values discussed above. Below and above the transition between α - and β -quartz at 846 K ($\sim 573^\circ\text{C}$), the data are reasonably fitted by:

$$\kappa_p(T) = \begin{cases} -0.062 + \frac{567.3}{T}; & T \leq 846 \text{ K} \\ 0.732 - 0.000135T; & T > 846 \text{ K} \end{cases} \quad (T \text{ in K}; \kappa \text{ in } 10^{-6} \text{ m}^2\text{s}^{-1}) \quad (31)$$

assuming an average molar mass of $0.22178 \text{ kg mol}^{-1}$ and an average density of 2700 kg m^{-3} for the crust (see Fig. 1 in the entry ► “Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat”, this volume). The leucogranite and rhyolite samples were homogeneous and isotropic. The schist was anisotropic owing to alternating mica- and quartz-rich layers, which required testing in the directions parallel and perpendicular to foliation.

For mantle minerals, such as olivine and its high-pressure polymorphs, the β - and γ -spinel wadsleyite and ringwoodite, respectively, Xu et al. (2004) fitted phonon thermal diffusivity measured to 1373 K and 20 GPa to an exponential equation in temperature yielding values for the exponent between

$-0.563(35)$ and $-0.793(17)$ suggesting that fitted phonon thermal conductivity varies with temperature as $T^{-1/2}$ to T^{-1} (Table 5).

Pertermann and Hofmeister (2006) measured thermal diffusivity on oriented single crystals and polycrystalline samples of olivine-group minerals with the laser-flash method at temperatures of up to about 1500°C . They fitted the data by a second-order polynomial in T :

$$\kappa_p(T) = a + bT^{-1} + cT^{-2} \quad (T \text{ in K}). \quad (32)$$

Values for the fitting coefficients a , b , and c are shown in Table 7.

Osako et al. (2004) fitted thermal diffusivity measured to 1100 K and 8.3 GPa on isotropic, single-crystal garnet and anisotropic olivine ($\text{Fo}_{93}\text{Fa}_7$; in three crystallographic directions) as upper and lower mantle constituents, respectively, to a linear equation in inverse temperature (Table 6). They found a strong anisotropy in olivine which they assume to prevail throughout the olivine stability field in the mantle down to 410 km.

Variation with Pressure

Tommasi et al. (2001) measured thermal diffusivity in the crystallographic [100] and [010] directions parallel and perpendicular to a strain-induced foliation, respectively, as a function of temperature at atmospheric pressure on spinel lherzolites and spinel harzburgite. These rocks are considered representative for the subcontinental and suboceanic mantle,

Fo: forsterite, FoCo: Co-doped forsterite.

respectively. They found an anisotropy in thermal diffusivity on the order of 25 % with the maximum aligned in the direction of strain. Support of their experimental findings was provided by corroborating petrophysical modeling.

For mantle minerals, such as olivine and its high-pressure polymorphs, the β - and γ -spinel wadsleyite and ringwoodite, respectively, Xu et al. (2004) fitted phonon thermal diffusivity measured to 1 373 K and 20 GPa to a linear equation in pressure yielding a pressure coefficient of $0.036(4) \text{ GPa}^{-1}$ (Table 5).

Osako et al. (2004) fitted thermal diffusivity measured to 1 100 K and 8.3 GPa on isotropic, single-crystal garnet and anisotropic olivine ($\text{Fo}_{93}\text{Fa}_7$; in three crystallographic directions) as upper and lower mantle constituents, respectively, to an exponential equation in pressure (Table 6). The pressure dependence of garnet and olivine was found to be on the order of $4 \% \text{ GPa}^{-1}$ to $5 \% \text{ GPa}^{-1}$ and $3 \% \text{ GPa}^{-1}$ to $4 \% \text{ GPa}^{-1}$, respectively.

Variation with Other Factors

Micro-cracks and grain boundaries give rise to increased thermal resistance and to a reduction of the mean free path of radiation due to scattering of radiation. It is somewhat debated below which grain size the effect is negligible: Based on the agreement between diffusivities measured on minerals and rocks, Gibert et al. (2003) concluded that the effect of grain boundaries, thermal cracking, and secondary phases is negligible. Along the same lines, Seipold (1998) argued that grain size is much larger than the phonon mean free path and therefore grain boundaries should not interfere with heat diffusion. Branlund and Hofmeister (2008) confirm this for quartzites, but find diffusivities measured on chert, agate, and chalcedony to be lowered by grain boundaries. They propose that grain sizes greater than $1 \mu\text{m}$ should not affect heat transfer.

Additional advective heat transfer was identified by Seipold and Schilling (2003) due to the release of water adsorbed at the inner surfaces of voids (i.e., pores and cracks) in rocks at about 450 K and by dehydration of serpentinite at 850 K. Both processes create high local overpressures which are relieved by cracking when the overpressure exceeds the tensile strength of the rock. The resulting flow is then accompanied by a corresponding advective heat transfer. This phenomenon was observed and studied in laboratory experiments (Seipold and Schilling 2003) but has implications for the lower crust and upper mantle with respect to recrystallization processes involving the discharge of fluids. These “crustal burps” provide the only conceivable way how some fluids from the mantle or lower crust may find their way to the Earth’s surface. The example discussed by Seipold and Schilling (2003) involves liberating water of crystallization during the conversion of serpentinite into forsterite and talc, followed by the formation of enstatite. As this involves heat advection as a

separate heat transfer mechanism, this process is better addressed separately and not parameterized into some sort of “effective” heat transport property not directly linked to a physical process.

Summary

Understanding the thermal regime of the Earth requires appreciation of properties and mechanisms for storage, transport, and generation of heat within the Earth. Both experimental and indirect methods are available for inferring the corresponding rock properties. Steady-state heat conduction or transient heat diffusion are the dominant transport processes in the Earth’s crust, except when fluid flow is sufficient for significant heat advection. For most crustal and mantle rocks, heat radiation sets in at temperatures above about 450°C and becomes significant only at temperatures above $1\,200^\circ\text{C}$. At temperatures above $2\,500^\circ\text{C}$, heat radiation becomes a dominant mechanism.

Time-Dependent Seismic Hazard Assessment

Zhongliang Wu

Institute of Earthquake Forecasting, China Earthquake Administration, Beijing, China

Definition

Seismic hazard refers to the potential for earthquake-related phenomena, resulting from a combination of source, path, and site effects on seismic vibrations. *Time-dependent seismic hazard assessment* takes into account the temporal variations associated with all these factors, especially the source factor related to the preparation and occurrence of earthquakes.

Time-Dependent Seismic Hazard

In a general sense, *seismic hazard* refers to any physical phenomenon associated with an earthquake (such as ground motion, ground failure, liquefaction, and even tsunamis). In a specific sense, *seismic hazard* is defined as the potential for earthquake-related phenomena, resulting from a combination of source, path, and site effects on seismic vibrations (Main 1996). Entry *seismic hazard* describes in detail the scientific basis and practical issues of seismic hazard assessment, which also deals with the issues related to time-dependent seismic hazard.

The time-dependent features of seismic source, path of seismic wave propagation, and site effects all contribute to the necessity and difficulty of time-dependent seismic hazard assessment. But in seismology, the most important contribution to such necessity and difficulty is from the complexity of earthquake preparation and occurrence, that is, the complexity of seismicity.

Traditional seismic hazard assessment, for example, the global seismic hazard map (GSHAP, Giardini et al. 2003), did not consider time-dependent factors. On the other hand, however, seismic hazard assessment has to be time-dependent since seismicity patterns are characterized by a variety of fluctuations, as described by the entries *Characteristic Earthquakes and Seismic Gaps*; *Seismic Quiescence and Activation*; *Earthquake, Foreshocks*; and *Earthquake, Aftershocks*, respectively. It has been shown for a long time by geological, paleoseismic, and historical records that two modes of seismicity, namely, power-law distribution of frequency-magnitude relation (the Gutenberg-Richter's law) and characteristic earthquakes, can switch to each other over time. It has been shown theoretically that seismic response of a fault system to steady tectonic loading can exhibit persisting fluctuations in the form of self-driven switching between the characteristic earthquake mode and the truncated power law distribution mode (Ben-Zion et al. 1999). Accordingly, tools have been developed and tested for time-dependent seismic hazard assessment.

Time-Dependent Seismic Hazard: Practical Tools and Case Examples of Application

Probabilistic Approach. Probabilistic seismic hazard assessment (PSHA), the quantification of probability that a specific level of ground motion will be exceeded in a given window of space and time, assumes that earthquake occurrence follows a Poisson process. When considering the variation of seismicity, the log-normal model of earthquake occurrence (Nishenko and Buland 1987) and the Brownian passage time (BPT) renewal model (Matthews et al. 2002) are generally used for probabilistic seismic hazard analysis. In the Uniform California Earthquake Rupture Forecast (UCERF, Field et al. 2014) which was time-independent, time-dependent factors were considered by using the BPT model (Field et al. 2015). For shorter time scales in which clustering of earthquakes has to be taken into account, the Epidemic Type Aftershock Sequence (ETAS) model (Ogata 1989) was used for time-dependent seismic hazard assessment (Field et al. 2017). Tools of statistical seismology, potentially capable of describing the time-dependent behavior of seismicity, play an essential role in such expansion from time-independent to time-dependent. Details of *Statistical seismology* are described by the corresponding entry.

Neo-deterministic Approach. In an approach to deterministic seismic hazard assessment (DSHA), referred to as neo-

deterministic seismic hazard assessment (NDSHA, Panza et al. 2001; XeRiS 2019), knowledge of seismic source, seismic wave propagation within heterogeneous Earth medium, and site effects on seismic ground motion is used for the quantification of earthquake scenarios. Considering the temporal variation of seismicity, the original DSHA is combined with intermediate-term earthquake prediction (Peresan 2018). In this approach, intermediate-term (i.e., several months) and middle-range (i.e., few hundred kilometers scale) predictions of mainshocks above a pre-assigned threshold – based on seismicity “alarms” generated by predictive algorithms like the CN algorithm and the M8 algorithm (Keilis-Borok and Soloviev 2003) – are used as the input of time-dependent seismic hazard assessment. The quintessence of the related predictive algorithms lies in the capturing of the “time of increased probability of earthquakes” by analyzing the state of seismicity, which determines the range of applicability (as well as the limits) of these algorithms. As a further development, the time-dependent seismicity is constrained by geodetic data (Panza et al. 2013) in which velocity variations and related strain accumulations detected by GNSS observation are used to reduce the geographic extent of the “alarms,” developing from “intermediate-term medium-range forecast” to “intermediate-term narrow-range forecast.”

Hybrid/Empirical Approach: The difficulty of time-dependent seismic hazard assessment is entangled with the difficulty of earthquake prediction (Kanamori 2003) which is described, from different perspectives, by the entries *Earthquake Precursors and Prediction*, and *Earthquake Prediction, M8 Algorithm*, respectively. In recent years, significant progress has been made in the study of earthquake predictability (Keilis-Borok 2002; Schorlemmer et al. 2018), providing time-dependent seismic hazard assessment with more solid scientific basis. Empirical approaches are still needed when dealing with multidisciplinary information and sometimes “big data.” An example of such empirical or hybrid approach is the time-dependent seismic hazard assessment in China. This is implemented by a series of scientific practices, represented by corresponding scientific products, with different time scales from the decade scale “Key Regions for Enhanced Monitoring and Preparedness” to the 1-year scale “Annual Consultation on the Likelihood of Earthquakes” (Wu 2018). In such practices the “alarm” areas are determined by a combination of statistics-based, precursor-based, and physics-based models, and the experiences of experts, based on panel discussion (called as “consultation”) oriented at the decision-making considering the (incomplete and multidisciplinary) information, play an important role. In the past, these practices were more related to earthquake forecast. But in recent years, such forecasts have been interconnected to seismic hazard and the engineering/social countermeasures for seismic risk reduction.

Seismic hazard assessment, no matter time-independent or time-dependent, needs test against real earthquakes (e.g.,

Nekrasova et al. 2014). The complexity of such test lies in three aspects: (1) the understanding of the quantities to be assessed (e.g., maximum ground motion with a certain probability of exceedance) as well as the “probabilities” expressed in the assessment; (2) the working assumption of “background” distribution of earthquakes and/or ground motion parameters; and (3) the statistical tools for evaluating the performance of an assessment or forecast based on small number of “real” earthquakes (generally a single earthquake).

Conclusions and Discussion

In the perspective of disaster resilience, *seismic disaster risk* is determined by the intersection of seismic hazard, exposure, and vulnerability. Seismic hazard assessment is basically the characterization of the “seismic hazard input” of seismic disaster risk. Due to the complexity of earthquake preparation and occurrence, the complexity associated with the propagation and attenuation of seismic waves, and the characteristic frequency range within which the seismic ground motion and engineering structures interact, seismic hazard assessment is both a scientific and a technical challenge in seismology (Somerville and Morivaki 2003). When time-dependent factors are taken into consideration, the challenge is even greater.

This entry focuses on the concept and recent progress of the study on *time-dependent seismic hazard*. By case examples the probabilistic, deterministic, and hybrid/empirical approaches are briefly introduced. In the related field, there is still much to be done toward the readiness of time-dependent seismic hazard assessment in answering the increasing needs of social sustainability.

However, in the perspective of seismic disaster risk reduction, time-dependent seismic hazard assessment does provide a new horizon to the study of earthquake forecast and prediction, a notoriously difficult scientific problem in seismology (AAAS 2005). As a matter of fact, quite a few approaches to time-dependent seismic hazard assessment (e.g., Field et al. 2017) have logical connection to the concept “operational earthquake forecast” (Jordan et al. 2011). Seen from the representation of seismic disaster risk by seismic hazard, exposure, and vulnerability, traditional earthquake prediction tried to identify the increase of seismic hazard and provide warnings to the society. The society in turn reduces the exposure (by organized evacuation, such as the case of the 1975 Haicheng earthquake) so that seismic disaster risk may be significantly mitigated. Thinking this problem in an alternative way, when seismic hazard with different spatiotemporal scales is assessed, countermeasures can be taken more efficiently to reduce either the exposure (such as in the planning of land use, with decade time scale) or the vulnerability (such as engineering reinforcement, with annual time scale). In the context of time-dependent seismic hazard, therefore, seismic disaster risk reduction for disaster resilience becomes

practical (or “operational”) based on the presently accessible, although still limited, knowledge of earthquake physics and capability of forecast of the behavior of earthquakes.

Time-Reversal in Seismology

Carène Larmat and Clarence S. Clay (Deceased)
Geophysics Group, EES-17, MS D542, Los Alamos National Laboratory, Los Alamos, NM, USA

Definition

Time-reversal Imagine filming the ripples formed when a pebble is dropped into a pond and playing the movie backward. You will observe the ripples converging back to the original impact. This is the fundamental concept behind time-reversal. It relies on the invariance of the wave propagation equation. In the absence of loss terms, the wave equation only contains second-order space and time derivatives. This

implies that if $u(x, t)$ is a wavefield solution, then $u(x, -t)$, $u(-x, t)$, and $u(-x, -t)$ are also solution of the equation; therefore, the wavefield can be reversed. The reversal can be achieved either by instant reversing of the wavefield over the entire space (Loschmidt 1876) or by using a **time-reversal mirror** (TRM). The latter refers to a surface surrounding the original source, on which the signal is recorded during the forward propagation, and then, from which, this signal is rebroadcast. The signal is read backward to impose the reversal. The wavefield created will be an approximate reverse version of an original wave propagation movie and converges back onto the source point. In practice, the mirror corresponds to a set of receivers. The necessary number of receivers and type of signal for a successful reversal is discussed later in “Modern Time-Reversal” and “Time-Reversal and Complexity.”

Time-reversal applications

In geophysics, time-reversal is typically used to image the source of the wavefield. However, time-reversal has also been used for applications requiring wave energy to be focused onto a specific point in space and time, such as lithotripsy, medical imaging, etc. Another way to interpret time-reversal is the establishment of a favored path between a pair of points in space (the source and the receiver), so it can be used to establish communication lines in complex media or allow nonlinear imaging that requires a strong acoustic signal to be applied on the imaged area.

Reciprocal time-reversal

The principle of source-receiver reciprocity states that if the source and a receiver were to be interchanged, the same waveform will be observed. There are applications that require the focus of energy on the receiver rather than the source. In this case, a pulse is first sent from a source point and recorded on a receiver. This signal is reversed and rebroadcast from the source point and observed to focus on the receiver.

History

Time-Reversal Before Modern Electronics

The story of experimental time-reversal starts in the 1950–1960s in a cluttered room of the Hudson Laboratory of Columbia University where Antares Parvulescu tested his

idea of time-reversed transmissions. A microphone was placed about 25 ft from a loudspeaker, from which a series of short impulses were sent one second apart. A sequence of the signal due to the room reverberations were received at the microphone and tape-recorded. The tape was then played backward to obtain “time-reversed signals” called then “matched signals.” It was played by the loudspeaker (so this is a reciprocal time-reversal experiment). The sound created was an indiscernible rushing noise over the experiment room, except at the microphone. The scope at the microphone displayed a signal that looked like the auto correlation of the reverberation signal. When the scientists (including Clarence Clay) indeed brought their ears to the microphone, they heard a simple “click,” indicating that localization in space and time of the wave energy did occur! This result was first published in a terse abstract (Parvulescu 1961) and is further documented in Parvulescu 1995 and in Chap. 7 of the book of Tölstoý and Clay (1966 and its revision in 1987).

In 1961–1962, Parvulescu and colleagues decided to take this experiment to sea despite the thought at the time that transmission in the ocean was not stable enough to allow time-reversal. Two oceanographic research ships, the Gibbs and Allegheny, with deep anchoring capability were stationed in the oceanic trench, the Tongue of the Ocean. Fig. 1a shows the setting of the experiment. The received signals at the Allegheny, lengthened by multiple reverberations, were radioed back to the Gibbs to be transmitted from the source (this was again a reciprocal time-reversal experiment). Fig. 1b shows the peak of pressure created on the hydrophone. The report of this first “field” time-reversal experiment is documented in Parvulescu and Clay (1965). Details of further experimentations can be found in Chaps. 4–8 of Tölstoý and Clay (1966).

Time-Reversal in Seismology, Fig. 1 (a) Ship positions and instruments used for the marine experiment. Gibbs has the source, and Allegheny has the receiver (HYD). (b) Signal received at the hydrophone when performing a reciprocal time-reversal between the two ships in an oceanic trench. (Figures from Parvulescu and Clay 1965; Tölstoý and Clay 1966)

Modern Time-Reversal

In the late 1980s, advances in micro-electronics, storage capacity, and automated signal processing led to the development of transducer arrays which were used as TRM by Mathias Fink and colleagues at the Laboratoire Ondes et Acoustique (LOA) of the University of Paris VII (Fink 1992). Finite-size arrays of transmit receive transducers served as TRM and have been the basis of countless studies by this group (e.g., Fink et al. 2000; Fink 2006). Their work is the experimental and theoretical roots of time-reversal. Since, the number of applications of time-reversal is staggering, ranging from nondestructive evaluation (e.g., Ulrich et al. 2008a, b) and communication (e.g., Lerosey et al. 2004) to medical imaging (e.g., Fink and Tanter 2010).

Computers and scientific computing have also been a driver to the development of modern time-reversal. In the 1980s, George McMechan and colleagues at the University of Texas modified imaging techniques developed for exploration geophysics. They changed the algorithms to image the primary source of the wavefield instead of imaging the geologic reflectors and independently rediscovered time-reversal. They use a 2D numerical model, purely acoustic, representing a 15 by 12 km vertical slice of a California formation and successfully imaged the source of a small 1983 aftershock earthquake in California using data from a local dense network (McMechan 1982).

For references and more technical details about time-reversal, such as theoretical limit, one-channel time-reversal, and one-bit time-reversal, see the reviews by Fink et al. 2000; Fink 2006; Anderson et al. 2008; and Larmat et al. 2010.

Location of Seismic Sources

Since the late 1990s, several groups have performed time-reversal location of seismic events (see Anderson et al. 2008; Larmat et al. 2010), harnessing the developing computing power. These applications have demonstrated that contrary to what was thought by McMechan, time-reversal does work with “sparse” rebroadcasting networks (i.e., with receivers far more than one wavelength apart). Fig. 2 shows the time-reversal result from a 2001 magnitude-5 glacial earthquake in Greenland by Larmat et al. (2008). Glacial earthquakes were discovered in 2003 by Ekström et al. (2003) as long-period signal barely above the noise level. The signal from 146 stations scattered in the Northern hemisphere were filtered between 0.01 and 0.02 Hz, time-reversed and rebroadcast into a 3D Earth model. The figure shows the snapshot of the vertical component of the time-reversed displacement at the moment of the focus (actually the vertical component normalized by the maximum value reached on the snapshot). The focus appears as a two-lobe pattern of opposite polarity indicating the origin of the seismic signal. The two-lobe

Time-Reversal in Seismology,

Fig. 2 One hundred and forty-six vertical displacement signals of a glacial earthquake were time-reversed and sent back in a 3D Earth model. The vertical component (v_z) of the created time-reversal signal at the moment of the focus displays a two-lobe pattern of opposite polarity consistent with a single-force vector as the source mechanism. (Adapted from Larmat et al. 2008)

pattern reveals that the nature of the source excitation was a single-force vector, which is consistent with recent source analysis by Tsai et al. (2008). Had the source been a simple monopole, the focus would have manifested itself as a single point (see details in Larmat et al. 2008).

The signal generated by glacial earthquakes is in general embedded in the noise. Therefore, this example is a demonstration of the insight of Brian Kennett (1983) who foresaw the utility of time-reversal as a location method for source of very faint or transient signal or complex sources. Time-reversal has recently been used to locate tremors (Steiner et al. 2008; Larmat et al. 2009; Lokmer et al. 2009). Time-reversal is currently a very active research topic for monitoring microseismicity, either natural or man-made. Time-reversal analysis is computationally intensive for such applications and authors have been developing new imaging conditions to extract the signal of interest and reduce efficiently the four-dimensional space (time and space) that needs to be monitored. Auto-correlation, cross-correlation, and hybrid conditions involving correlation and stacking have been proposed (e.g., Nakata and Beroza 2016; Artman et al. 2010).

Related Seismic Methods

Other location methods are based on the core idea of sending back some recorded signals to a given point in space and time. All **back-projection**-related methods can be seen as simplified time-reversal procedures for which the backward propagation is reduced to shifting the time-series by predicted arrival times (e.g., Kao et al. 2005) instead of performing the full waveform rebroadcast that is time-reversal.

Time-reversal ideas are also used in subsurface imaging. The exploration methods used by McMechan have evolved into **reverse-time migration** (e.g., Baysal et al. 1983). The **adjoint methods** (Tromp et al. 2005) use backpropagation to

compute finite-frequency kernels which represent the sensitivity of waves to the subsurface structure.

Seismic interferometry is another research topic which uses the concept of time-reversal. Under certain conditions, the cross-correlation of the signal recorded at two receivers is the superposition of the Green function between the two receivers and its time-reversed version (see ▶ [“Seismic, Ambient Noise Correlation”](#) and the review by Snieder and Wapenaar 2010, and the pioneer paper of Claerbout 1968). Time-reversal can also be expressed as a cross-correlation of two wavefields, typical of a **matched filter**, whose output is optimal in some sense. Whatever the Green function, the time-reversal wavefield is maximal at the focus time and at the source point (Fink et al. 2000, p. 1946). Applications derived from this interpretation of time-reversal consist in locating seismic sources, such as trapped miners, by comparing live recorded signals with a database of pre-recorded Green functions (Hanafi et al. 2009).

Time-Reversal and Complexity

The earth and oceans are complex environments in which transmitted signals quickly become difficult to interpret: for example, instead of a single pulse for the first arrival, the P-wave is accompanied by a coda train due to the scattering within the crust. Contrary to many location methods based on simple paradigms, time-reversal thrives with complexity. In a homogeneous and purely acoustic medium, only one phase will be recorded on a single receiver from a source point. Introduce a reflecting interface and two phases will be recorded: the primary and a copy of the source impulse due to the reflection on the interface. The two combined phases contain more information about the source location than the primary phase alone. All these different phases will converge and add up onto the source point when traveling backward. Several studies (e.g., Dowling and Jackson 1992; Fink et al.

2000; Blomgren et al. 2002) have actually demonstrated the width of the focus is smaller in randomly heterogeneous media than in the homogeneous case (implying better resolution on the location). This is referred as *super-resolution* (Fink 2006; Lerosey et al. 2007). The second important point for complex media is that any arbitrary time-segment will return to the source. Time-reversal doesn't need any interpretation of the signals.

These unique facets of time-reversal explains the wide use of the method in very different disciplines handling with complex media: e.g., target detection method and communication in underwater acoustics, nondestructive evaluation (i.e., location of defects in intact specimens), improved imaging and destruction of stones/tumors in medicine, and source location and imaging techniques in geophysics.

Summary

Seismic source study has been subject to a shift from event-based temporary observation to continuous monitoring based on dense seismic networks. Seismologists now study a wealth of signals due to less energetic sources than earthquakes such as tremors and microseismicity. Glacial earthquakes, landslides, Earth hum, and meteorological phenomena such as hurricanes belong to a group of events that defines “environmental seismology,” a term coined by the French seismologist Jean-Paul Montagner. Microseismic noise is now used for imaging the Earth. Due to their emergent nature, these signals represent a challenge to classical location methods based on triangulation. Time-reversal as a method and time-reversal ideas are emerging as a promising framework to foster future location and imaging methods. The success of time-reversal as a source location method shall rely on the coverage of seismic networks, the accuracy of high-resolution velocity models, and the performance of numerical schemes to be used for the backward propagation. Still open questions are the convergence and resolution power of time-reversal under various conditions. Our ability to observe and model scattering phenomena will be part of the answer.

TOPO-EUROPE: From the Deep Earth to the Surface of Continental Europe and Its Margins

Sierd Cloetingh and TOPO-EUROPE Working Group
Tectonics Group, Department of Earth Sciences, Utrecht
University, Utrecht, The Netherlands

Definition

Linking different spatial and temporal scales in coupled deep Earth and surface processes is a prime objective of the multidisciplinary international research program TOPO-EUROPE. The research approach of TOPO-EUROPE integrates active collection of new data, reconstruction of the geological record, and numerical and analog modeling. The results of the program focus on closely interrelated topics: deep Earth, lithospheric structure, mantle-lithosphere interactions, and sedimentary basins and geo-resources. Quantitative understanding of topographic evolution in space and time requires study of processes from the upper mantle through the lithosphere and crust and acting on the Earth's surface. The overview presented here demonstrates the opportunities for further understanding of topography through integrated studies of the full Earth system across space and timescales.

Introduction

One of the important developments in Solid-Earth science over the past decade has been recognition of the importance of linking deep Earth dynamic processes with surface and near-surface geologic processes (e.g., Cloetingh et al. 2007, 2013). Deep Earth research, encompassing fields such as seismology and mantle geodynamics, has traditionally operated distinctly from fields focusing on dynamics of the Earth's surface, such as sedimentology and geomorphology. However, these endeavors have in common the study of Earth's topography and the prediction of its origin and rates of change. Observables from surface studies, such as basin stratigraphy, geomorphology of landscapes, changes in surface elevation, and changes in sea level, provide some of the principal constraints on geodynamic and tectonic models. Conversely, deep geodynamic processes give rise to the topography, erosion, and sediment generation that are the basis of surface geology. The lithosphere, due to its stratified rheological structure, acts as a nonlinear “filter” for deeper sources, attenuating long deformation wavelength and creating new, shorter wavelength deformation, giving a surface response more complex than that of the mantle source.

Surface manifestations of these deep geodynamic processes modified by multifaceted mantle-lithosphere interactions have societal impact by (1) creating natural hazards, such as earthquakes and mass movements, and (2) controlling the distribution of natural resources such as fossil fuels or geothermal energy. The relevance of research conducted in both the deep Earth and surface regimes is thus enhanced through a focus on their interaction.

Long-term processes such as mantle flow drive the system of mantle-surface interaction. However, short-term processes such as erosion and climate tune the response. The continental lithosphere transforms deformation generated at its base by mantle flow, but surface processes control many of the observables such as topography, sediment, and exhumation rates, and thus further filter the source and even tune the response through cyclic processes such as climate. However, little is known on how far these interactions may go, or how these different processes are coupled or feed back into the dynamic system. Many modelling or theoretical studies show that erosion and sedimentation should have an impact on the subsurface evolution of crustal deformation, changing flow patterns and magnitudes in the ductile crust and mantle through changing gravitational stresses or kinematics.

This leads to many questions that remain to be tested. For instance, what is the impact of erosion and surface mass redistribution on mantle flow? What is the influence of protracted precipitation regimes on mountain building? and what is the budget of subduction in terms of sediments and water recycling? What is the sediment and tectonic load incidence on thermicity and sediment blanketing and on foreland

flexure? How and on what timescales does the build-up of topography impact atmospheric circulation processes? How does the creation of topography modify shallow crustal stress fields and how does this impact seismicity and fault kinematics? How can we differentiate between geodynamic, tectonic, and surficial displacements of the Earth's surface if all processes are active? These and many other questions are still unsolved.

Tectonic, surface, and external forcing processes are responsible for the growth and decay of continental topography and sedimentary basins, i.e., the interplay between sediment supply and mass (re)distribution with the full range of deep Earth to surface processes. However, the mechanisms that link exhumation, formation of topography, and sedimentation are still poorly understood because of a lack of insight into the variability of the rates and scales of the underlying processes. TOPO-EUROPE explores the dynamics of these processes and the role played by large-scale lithospheric stresses. To this end, lateral variations of tectonic and erosion/sedimentation evolution through time are incorporated into dynamic models of topography evolution by integrating deposition in sedimentary basins with topography formation and evolution in neighboring source areas. This will provide new opportunities to analyze and quantify the interplay between deep Earth and surface processes, which is critical for novel evaluation of geo-resources and natural hazards.

Scientifically, the role of topography in the Earth's system is as a dynamic, active permeable boundary layer between solid Earth processes occurring at different depths and atmospheric processes. Clearly, understanding the processes and hence predicting rates and signals of topographic change over the planet is a first-order challenge to the Earth Sciences.

Underpinning many of the pure and applied issues concerning resource and hazards is the basic question of which processes define present topographic change, and at what spatial and temporal scales they are acting. Processes such as so-called dynamic topography (e.g., Faccenna et al. 2014; Colli et al. 2018) driven by mantle flow, lithospheric partitioning of stress and strain, and the thermal structure of the mantle and overlying crust remain only partly understood.

The TOPO-EUROPE program has been designed to serve as a platform for integration of deep Earth and surface processes studies, taking the Europe continent and its margins as a natural laboratory. TOPO-EUROPE has focused on collaborative research projects in specific areas such as the Norwegian continental margin, the Pyrenees, the Alpine-Carpathian system, the western Mediterranean, the Anatolian Plateau, and Europe as a whole. Results of TOPO-EUROPE research have been published in a number of special topical volumes and publications therein (Cloetingh and Tibaldi 2012; Cloetingh et al. 2009, 2011, 2018). TOPO-EUROPE has been building on a rich database on the deep

crustal structure of key sectors of the European continent, and on data obtained from industrial and deep seismic reflection profiling programs (e.g., ECORS, CROP, NFP, DEKORP, and BIRPS), which were set up to characterize the structure and architecture of sedimentary basins and the crust (Roure et al. 2010; Laubscher 2010). Here we present a brief review of the rationale of TOPO-EUROPE as well as some examples of research approaches and research highlights.

Deep Earth

Plate reconstructions and absolute plate motions based on seismic tomography from research within the context of the TOPO-EUROPE project have led to a new reference frame to determine absolute plate motions from remnants of past subduction, as imaged by seismic tomography (Fig. 1). This novel approach is crucial for future understanding of the deep Earth controls on dynamic topography, formed in response to the interaction of the lithosphere and crust with thermal perturbations and convective movements in the Earth's mantle. Several studies (e.g., Faccenna et al. 2014) have explored dynamic topography of the Mediterranean area, demonstrating its sensitivity to adopted crustal models.

Formation of sedimentary basins is an intrinsic corollary to the Earth's planetary evolution, particularly of its lithosphere (Cloetingh et al. 2015). At present, knowledge on the evolution of the Earth's lithosphere is assembled in kinematic reconstructions at regional to global scales. The state-of-the-art in the fields of tectonic reconstructions and coupling deep Earth processes to surface evolution is of high international level. TOPO-EUROPE researchers have combined efforts in regional scale reconstruction with global reconstructions, utilizing Gplates (freeware, see www.gplates.org). These modern quantitative reconstructions provide an interface with thermo-mechanical modelling of plate tectonics coupled to the underlying mantle. Important advances have been made by integrating mantle structure, as a memory of Earth's dynamic evolution, with crust-lithosphere processes and tectonic reconstructions of complex plate boundary regions (Wortel and Spakman 2000) and with global tectonic reconstructions linked to mantle evolution (van der Meer et al. 2010). Crucial is the knowledge of precise mantle structure obtained from tomography. Tectonic transitions are considered to be of key importance in controlling, for instance, the preservation of hydrocarbon reservoirs and the formation of ore deposits as they lead to strong changes in the crustal stress-field, local thermal pulses from the asthenosphere, and mantle-driven crustal flow of mineral-rich fluids. In contrast to its importance, process-based understanding of basin and plate boundary deformation or tectonic

TOPO-EUROPE: From the Deep Earth to the Surface of Continental Europe and Its Margins, Fig. 1 Tomographic cross-sections for the upper mantle below Europe, illustrating heterogeneity in the upper mantle. Depth scale 600 km. Blue and red colours correspond to areas where seismic P-wave velocities are respectively higher and lower than the standard reference velocity model. The sections display distinct patterns of down-going slabs in convergent zones of Europe overlain

by lithosphere with reduced seismic velocities, corresponding with areas of high heat flow and high potential for geothermal energy exploration. The overall topography of Europe, depicted in the central panel, is characterised by elevated areas (including the Alps, Dinarides, Apennines, Carpathians, Pyrenees and the Anatolian Plateau) not only in the convergent settings, but also in intraplate settings such as Iberia and the southern Scandes. (Tomographic sections: Courtesy W. Spakman)

transitions is one of the weak links in current tectonic reconstructions.

Crucial for creating detailed process-based models of natural laboratories coupled to deep processes is the capability to embed regional modelling in a global dynamic

lithosphere-mantle framework. This provides the necessary (realistic) constraints on regional mantle flow and the stress field resulting from global plate-mantle interaction. Global and regional tomography models can now be used to estimate mantle composition, temperatures, and mantle flow, resolving

deep Earth structure in great detail and demonstrating the existence of side lobes of the Iceland Plume under intraplate areas in northwestern Europe with elevated topography (Fig. 2) (e.g., Rickers et al. 2013; Koptev et al. 2017). This potentially can be coupled to tectonic reconstructions in an absolute plate motion frame (Torsvik et al. 2010). To this aim, 3D numerical mantle modelling assimilating models of lithospheric age and thickness and incorporating evolving subduction systems, ocean spreading, and other plate boundary processes is required. The strategy of establishing a global dynamic reconstruction model is essential for predicting the impact of global plate-tectonic and mantle processes on the evolution of local subduction and other plate boundary systems as well as past tractions and temperatures at the base of lithosphere plates crucial for lithosphere-stress modelling.

Lithosphere Structure

On a completely different scale, new approaches have been developed to quantify plate rigidity on a full continental scale, resolving controversies regarding end-member rheological models for continental lithosphere (Tesauro et al. 2009). This work has also led to the insight that lower crustal flow in Europe's lithosphere and mechanical coupling between individual crustal layers is crucial for linking deep Earth processes and mantle-lithosphere interactions to surface deformation (Fig. 3) (Burov et al. 2007). Subsequent work has enabled a comparison of inferences for the effective elastic thickness of the lithosphere from admittance functions with spatial variations in integrated strength based on rock-mechanics data – on a global scale. The resulting strength maps display a robust pattern of variations in lithospheric strength, crucial for understanding localization of deformation in the interior of plates and basins, and for an assessment of stress propagation away from plate boundaries into these continental interiors.

In the context of TOPO-EUROPE, temporal changes in stress regime have also been investigated in terms of transient changes in tectonic regime in the Pyrenees (see also Erdős et al. 2014) and at the southern margin of the European continent where it interacts with the northern African margin (Faccenna et al. 2014). These models have demonstrated strong mechanical control on sedimentary basin systems and their intrinsically polyphase behavior. Stress and strain relationship and rheology are important ingredients in this context.

Mantle-Lithosphere Interactions

New fully consistent models of mantle-lithosphere interactions (Fig. 3) and stable and even unstable lithospheric

deformation (such as lithospheric folding) adopting realistic rheologies and integration into sedimentary basin studies (Cloetingh et al. 2015) have recently been developed. Advances in tectonic modelling and its integration with observational studies have allowed quantification of the time constants involved in the temporal succession of mantle/lithosphere interactions and of rifting and lithospheric folding by stress accumulation in intraplate continental crust and lithosphere. The results have been shown to be of critical importance for quantitatively assessing thermal regime, the record of differential vertical motions, and the faulting characteristics of super-deep basins created by the lithospheric folding and its interaction with phase changes in the crust. Key in this approach has been the integration of realistic models for Earth rheology in numerical studies of large-scale deformation and faulting and its role in intraplate structure and processes. Fully consistent 2D and 3D geodynamic numerical models incorporating thermomechanical, thermodynamic, and surface process (via implementation of free surface boundary or similar solutions) will play a key role in testing hypotheses on the topographic impact of deep processes and in separating tectonic components of deformation from dynamic topography. The latter task becomes extremely challenging since it is evident that tectonic and deep Earth processes are so interlinked that the notion of the dynamic topography will probably undergo significant changes in the nearest future.

Sedimentary Basins and Geo-Resources

By their nature, sedimentary basins develop and evolve in a plate tectonic setting, characterized by a strong mechanical coupling between plate boundaries and plate interiors. Of particular relevance in this context is the subduction factory, being the prime engine for build-up and release of stresses in the crust and lithosphere (Faccenna et al. 2014). Crucial in this context is the need to quantify the mechanisms for far-field stress propagation, away from plate boundaries and the localization of the resulting deformation in critical zones for resource formation in the interior of continents and their margins. At a regional scale, lithospheric and crustal stresses are responsible for the reactivation of preexisting faults and affect fluid transfers and reservoir characteristics, in particular across areas of contrasting strength and mechanical properties. The second so far underestimated factor significantly influencing subduction factories refers to the presence of structural heritage in the subducting and overriding plate (e.g., subduction of old terrains causing poly-phase subduction and metamorphic exhumation). The interplay between deep Earth and surface processes has distinct consequences for the record of vertical motions and sedimentary basin architecture (e.g., Cloetingh et al. 2015). As a result, the impact of these processes is a key for a quantitative

TOPO-EUROPE: From the Deep Earth to the Surface of Continental Europe and Its Margins, Fig. 2 (*top panel*) Horizontal cross-section through a high resolution S-velocity model of the North Atlantic region, derived from full-waveform tomography. Highlights of the model in the upper mantle include a well-resolved Mid-Atlantic Ridge and two distinguishable strong low-velocity regions (indicated by the red colors) beneath Iceland and beneath the Kolbeinsey Ridge west of Jan Mayen. A sub-lithospheric low-velocity layer is imaged beneath much of the oceanic lithosphere, consistent with the long-wavelength bathymetric high of the North Atlantic. The low-velocity layer extends locally

beneath the continental lithosphere of the southern Scandinavian Mountains, the Danish Basin, part of the British Isles and eastern Greenland. (After Rickers et al. 2013). (*bottom panel*) Tectonic setting of North Atlantic region and low velocity anomaly at 120 km-depth. The side lobes of the Iceland plume (*top panel*) and plume channeling through fracture zones explain the joint occurrence of Late Neogene uplift in the southern Scandes and northwestern part of the British Isles and compressional intraplate doming in the offshore part of the Northern Atlantic volcanic rifted margin system (Koptev et al. 2017)

TOPO-EUROPE: From the Deep Earth to the Surface of Continental Europe and Its Margins, Fig. 3 (top) Map of Europe with colour contours indicating the relative contribution of the crust to the rheological strength of the entire lithosphere (after Tesauro et al. 2009). Dark blue colours indicate that the strength distribution is dominated by the mantle lithosphere, whereas red and yellow colours indicate lithosphere where strength is primarily concentrated in the crust ("crème brûlée" model). Green and light blue coloured areas indicate a stratified

lithosphere with rheologically strong layers in both crust and upper mantle lithosphere ("jelly sandwich" model). (middle and bottom) Models that include a plate rheology and multilayer lithosphere structure predict a complex surface topography with several short-wavelengths generated by intraplate deformation, tectonic-style deformation at surface and strong lithosphere mantle erosion at depth. The short wavelengths are controlled by the thickness of the lithosphere and intra-lithospheric layers. (After Burov et al. 2007)

assessment of resource and storage potential (i.e., aquifers, ore deposits, geothermal energy, hydrocarbons, and greenhouse gases). Sedimentary fluxes are often characterized by episodic moments of rapid changes in tectonic, drainage network distribution, oceanic circulation, or connectivity between basins. The latter are, however, commonly studied in isolation and require constraints on their temporal evolution frequently beyond the resolution of existing dating methods. As a result of the current mismatch between their intrinsic temporal and spatial scales, incorporation of these elements in predictive models for geo-resources is far from complete.

Analogue Tectonic Modeling

European laboratory groups involved in the EU TOPOMOD international training network have all contributed at the international forefront of developments in their respective activities at the associated length scales. Using physical analogue, or scale model experiments, these researchers have delivered major contributions to understanding tectonic processes and faulting at the basin scale, providing a basis for unravelling geological and geophysical observations on basin and crustal structure, and for testing and improving numerical models of basin evolution (e.g., Cloetingh et al. 2015).

Novel tectonic concepts and their implementation in coupled numerical and analogue modelling have opened new approaches to study the thermomechanical behavior of the Earth's lithosphere and to assess the role and interaction of parameters such as intraplate stress, rock rheology, and lithosphere structure. Advanced numerical methods have been implemented for the quantitative analysis of dynamic models that address the link between lithosphere deformation processes and vertical and horizontal motions, including constraints from GPS data (see, e.g., Serpelloni et al. 2013) in space and time. Analogue modelling has been shown to be particularly useful in qualitative and quantitative studies of lithosphere deformation in settings with a complex 3D geometry, such as present in the European Alps where seismic tomography interpretations have yielded evidence for a flip in the polarity of the down-going slab (Fig. 4) (Luth et al. 2013). An extensive database compiled in the TOPO-EUROPE project for the Alpine uplift and erosion history is now available (Fig. 5) (Fox et al. 2015) to further test different models and scenarios proposed for Late Neogene tectonics and climate of this key mountain system.

Coupling of experimental predictions from analogue models into numerical models has led to a better

understanding of the interplay between the formation and evolution of sedimentary basins and of the mechanisms that control stress and strain distribution at crustal and lithospheric scale. This has resulted in novel predictions of depositional system behavior and hydrocarbon reservoir architecture.

It has been clearly demonstrated that sedimentary basin systems cannot be treated in isolation but should be treated by connecting their basin fill architecture to the evolution of adjacent basins and topographic highs, accounting for their hydrological connectivity (Matenco and Andriessen 2013). This research has allowed quantification of how different types of basin connectivity affect budgets and pathways of sedimentary fluxes, including source magnitudes and mechanisms of sediment depocenter shift across basins. Spatial variations in the rheology of the underlying crust appear to be key to basin connectivity and the sediment storage capacity of individual basins. These findings are also important for assessing the impact of differential vertical motions in highly populated areas affected by flooding events, regional landslides, and active seismicity (Matenco and Andriessen 2013).

Summary and Conclusions

Research on coupled deep Earth and surface processes has developed as a frontier in integrated solid Earth science. The European continent and its margins provide an excellent natural laboratory to test in particular process-oriented models, such as for instance the effects of spatial variations in lithosphere strength on the mode and surface expression of mantle-lithosphere interactions. This research is by its nature multiscale and requires a close integration of observations, monitoring, and modelling.

TOPO-EUROPE research has demonstrated, amongst others, an important control by side-lobes of the Iceland mantle plume on anomalous topography of the Southern Scandes of Norway and the offshore Northern Atlantic compressional domes. Slab detachment and slab tearing processes exert pronounced effects on the 4D evolution of the Mediterranean, such as for instance a polarity swap in subduction beneath the Alps. In Iberia, lithospheric folding is a key contributor to differential topography with an average anomalous elevation due to the interaction of intraplate deformation with plate edge driven thermal anomalous in the upper mantle. This research has important spin-offs in the domains of geo-hazards (i.e., volcanism, earthquakes, and landslides) and geo-resources, in particular the exploration and exploitation of geothermal energy, highly relevant for the present era of energy transition to a more sustainable world.

TOPO-EUROPE: From the Deep Earth to the Surface of Continental Europe and Its Margins, Fig. 4 (left) Tele-seismic tomographic cross-sections display along-strike variations in continental subduction polarity. Blue and red colors refer to relatively high and low P wave velocities, respectively. Top views show the major tectonic boundaries as black lines and the outline of the subducted slabs between 135 and 165 km depth in dashed red lines transposed on a DEM. (a) (bottom) Lower lithosphere transects through western Central Alps imaging in blue the SE-dip of subducted European lower lithosphere. Bold dashed line indicates lithosphere–asthenosphere boundary. (b) (middle) TRANSALP crustal section transposed on a deep tomographic transect

disclosing a steep dipping slab. (c) (top) Lower lithosphere transect through Eastern Alps imaging NE-dip of subducted Adriatic lower lithosphere. (right) Cross-sections located along white profile lines shown in top view inset. Within the cross-sections white material corresponds to mantle lithosphere, beige to strong lower crust, red to weak zone, and colored sand to upper crust. Black line represents Moho. White lines are interpreted faults, which are chronically numbered. A DEM overlies the cross-sections (both panels after Luth et al. 2013). See Laubscher (2010) and Roure et al. (2010) for constraints on crustal structure from deep seismic reflection programs across the Alps

TOPO-EUROPE: From the Deep Earth to the Surface of Continental Europe and Its Margins, Fig. 5 Alpine exhumation rates over the past 2 My, inferred by analysis of over 2500 thermo-chronometric ages. (After Fox et al. 2015)

Acknowledgments This review is based on the dedicated research efforts of the TOPO-EUROPE community. Funding by 23 national research councils in Europe and the European Community is gratefully acknowledged. ESF provided valuable coordination during the TOPO-EUROPE EUROCORES program. The International Lithosphere Program and the Academia Europaea are thanked for continuous support during various phases of the lifespan of TOPO-EUROPE. Constructive criticism by François Roure is greatly appreciated. Wim Spakman and Fred Beekman are acknowledged for suggestions and technical support.

Total Electron Content in Seismo-ionospheric Studies

J. K. Catherine and R. Rajesh
CSIR-NGRI, Hyderabad, India

Synonyms

Ionospheric seismology

Definition

Total electron content (TEC): It is a quantifiable parameter of Earth's ionosphere, which appear in five layers (D, E, Es, F1, and F2) between altitudes ~50–600 km. It represents integrated number of electrons between satellite and receiver along the ray path in a vertical column of unit cross section measured in multiples of the TEC unit defined as $1\text{TECU}=10^{16}\text{el/m}^2$. Although TEC accounts for integrated electron content along the ray path, it is mainly sensitive to the electron content of F2 layer of ionosphere, where the maximum ionization takes place.

Seismo-ionospheric: The processes involved in lithosphere–ionosphere relationship are believed to be associated with tectonic forces acting on the Earth's crust (e.g., seismic

activity/earthquakes and volcanic eruptions). The release of large amount of energy in such processes (acoustic/mechanical) disturb the ionospheric electron concentration. Persuasive correlations are observed between the seismic activities and the ionospheric disturbances preceding and during earthquakes (Davies and Baker 1965; Ryu et al. 2014).

Shock Acoustic Waves (SAW): Ionospheric Response of the Shock Wave

Co-seismic Ionospheric Disturbances (CID): Disturbance in the ionospheric electron content caused by the atmospheric pressure waves that propagate upward into the ionosphere due to co-seismic vertical motion of the ground during an earthquake.

Travelling Ionospheric Disturbances (TIDs): Manifestation of atmospheric waves excited by earthquakes, in the ionosphere.

Ionospheric Pierce Point (IPP) or Seismo-ionospheric Point: The point of intersection of the signal transmitted from satellite to the receiver with the thin ionospheric shell.

Sub-ionospheric Point (SIP): The footprint/projection of the seismo-ionospheric point on to the Earth's surface.

Slant TEC: Integrated TEC along the path connecting ground-based receiver to a GPS satellite

Vertical TEC: The vertical component of the slant TEC at the intercept of the slant path on the ionospheric surface

Plasma: An ionized gas of zero net electric charge comprising positively charged ions and free electrons that exist either at low pressure or high temperature conditions.

Geomagnetic Cyclotron Frequency: The frequency of a charged particle moving perpendicular to the direction of Earth's magnetic field.

Introduction

The ionosphere, a shell of ionized gas plasma, is a dispersive medium that delay GPS (Global Positioning System) signals. The ionospheric delay along the path from the GNSS (Global Navigation Satellite System) satellite to a GPS receiver is effectively eliminated by a dual-frequency GPS receiver ($f_1 = 1575.42$ MHz on the L1 band and $f_2 = 1227.60$ MHz on the L2 band). This delay is proportional to the TEC, which depends on the elevation angle, azimuth of the Line-of-Sight (LOS), altitude, local time, intensity of solar activity, season, and receiver position and helps to quantify ionospheric disturbances.

The atmospheric infrasonic waves excited by the natural (earthquakes, tsunamis, volcanic eruptions, polar aurora, convective storms) or artificial (rocket launches, powerful explosions) sources causing large vertical near-field displacement of the Earth's surface generate laterally and upward propagating acoustic and gravity oscillations with 10–15 min delay as Shock Acoustic Waves (SAW) away from the source with a velocity equal to the speed of sound (Blanc 1985) in the ionospheric F2layer (Fig. 1). The amplitude of the SAW is inversely proportional to the density which decreases exponentially with altitude and amplified by a factor of 10^4 at ionospheric heights, where the coupling between neutral and ionized atmosphere results in fluctuations of the ionospheric electron density (Calais and Minister 1995, 1998). In response to the large amplitude impulsive forcing by SAW, an N shaped waveform is generated in the ionospheric plasma (Zel'dovich and Raizer 1966) in which the compression is followed by the “recovery” of the medium through rarefaction

Total Electron Content in Seismo-ionospheric Studies,

Fig. 1 Schematic diagram illustrating vertical motion of seismic waves inducing atmospheric acoustic gravity waves

(Landau and Lifshitz 1995). Such disturbances in the ionosphere due to the mechanical coupling between the solid earth and the atmosphere are interpreted as Co-seismic Ionospheric Disturbances (CID) (Watada and Kanamori 1994).

It is generally perceived that dip-slip earthquakes of magnitude $M > 7$ occurring in subduction zones are expected to induce TEC fluctuations (Calais and Minister 1995; Heki and Ping 2005; Rolland et al. 2013). Although the static vertical crustal displacements in strike-slip earthquakes are rather small, still there are evidences of clear CIDs (Astafyeva et al. 2014; Catherine et al. 2015). Analyses of CIDs of earthquakes from different regions with magnitudes from 4.1 to 8.8 suggest that the earthquakes of magnitude $M_w \geq 6.5$ only elicit CIDs (Perevalova et al. 2014).

The expansion of regional and international GNSS networks of closely spaced GPS stations with continuous recordings with accurate phase measurements, generally at an interval of 30 s, provide an opportunity to investigate characteristics of ionospheric perturbation such as apparent propagation velocities, directionality, waveform, and initial motion of CID with high spatio-temporal resolution both near the epicenter and far away from it. Beginning from the great Alaskan earthquake (1964) (Davies and Baker 1965; Leonard and Barnes 1965), several studies have been carried out to detail CIDs due to natural and artificial sources (Bolt 1964; Row 1967; Yuen et al. 1969; Tanaka et al. 1984; Calais and Minister 1995, 1996; Calais et al. 1998; Afraimovich et al. 2002; Ducic et al. 2003; Liu et al. 2004; Artru et al. 2005; Heki and Ping 2005; Heki et al. 2006; Otsuka et al. 2006; Astafyeva et al. 2009, 2014; Ozeki and Heki 2010; Afraimovich et al. 2010; Astafyeva and Heki 2011; Rolland et al. 2010; Liu et al. 2010a, b; Galvan et al. 2011; Liu et al. 2011a; Heki and Enomoto 2013; Cahyadi and Heki 2013; Su et al. 2013; Rolland et al. 2013; Catherine et al. 2015, 2017; Zhang and Tang 2015; Reddy et al. 2016; Bagiya et al. 2018, etc.). These studies serve as a proxy to investigate the coupling and energy transfer processes in the Lithosphere, Atmosphere, and Ionosphere (LAI) coupled system and earthquake source mechanism characteristics. Analyses of period, velocity, and propagation direction of the CIDs help to distinguish the ionospheric disturbances linked with geomagnetic storms, solar flares, etc. Only those perturbations without significant solar and geomagnetic activity may be attributed to earthquakes. The general dynamics of the ionosphere can be studied from TEC Global maps and their computation algorithm is presented in Mannucci et al. (1998) and Schaer et al. (1998).

Methodology for Estimating Total Electron Content (TEC) from GPS Data

In case of electro-magnetic wave propagation in a plasma medium like ionosphere, the frequency of the wave is much

higher than both geomagnetic cyclotron frequency and Earth's ionospheric plasma frequency. The excess time delay due to propagation in the dispersive medium can be approximately expressed as

$$t_{ion} = \frac{e^3}{8\pi^2 m \epsilon_0 c f^2} \int_{\text{receiver}}^{\text{satellite}} N(z) dz \quad (1a)$$

where e and m are the charge and mass of electrons, ϵ_0 is the dielectric constant of vacuum, c is the speed of light, f is the radio wave frequency, and the integral of $N(z)dz$ is the Integrated electron content (IEC) in the propagation path (Sekido et al. 2003) between the satellite and the receiver. We can appropriately write the equation (1a) as follows

$$t_{ion} = \frac{40.3}{c f^2} * IEC \quad (1b)$$

Based on the equation 1, there are different approaches for TEC computation (Calais and Minister 1995; Afraimovich et al. 2001; Carrano and Groves 2009). Dual frequency measurements (1.2 and 1.5 GHz) from GPS satellites located ~20,000 km above the earth's surface provide integrated information of the ionosphere by computing the differential code and carrier phase measurements recorded by ground-based GPS receivers. These measurements compensate for the ionospheric delay by taking advantage of dispersive nature of the ionosphere.

The basic equation for the integrated electron content and its relation with phase ($\emptyset$) and code (p) measurements is given by

$$IEC_{\emptyset} = \frac{1}{40.3} \left[\frac{f_1^2 f_2^2}{f_1^2 - f_2^2} \right] (L_1 \lambda_1 - L_2 \lambda_2) + B \quad (2)$$

$$IEC_p = \frac{1}{40.3} \left[\frac{f_1^2 f_2^2}{f_1^2 - f_2^2} \right] (P_2 - P_1) + B \quad (3)$$

Here, L_1 and L_2 are the carrier phase measurements, P_1 and P_2 are code measurements, and λ_1 and λ_2 are signal wavelengths corresponding to the frequencies f_1 and f_2 . The product, $L_i \lambda_i$ (where 'i' takes the value 1 and 2, respectively, corresponding to f_1 and f_2) is the additional path of radio signal caused by the phase delay in the ionosphere and B is an unknown constant related to initial phase path caused by the cumulative result of indefinite number of phase rotations along the line of sight (Afraimovich et al. 2001; Carrano and Groves 2009). The relative IEC (IEC_R) can be obtained after removing the noise in CODE and ambiguity in the phase measurements by applying a phase leveling along the phase connected arc (Vijayan et al. 2013; Catherine et al. 2015).

$$IEC_R = IEC_{\emptyset} + \langle IEC_p - IEC_{\emptyset} \rangle_{arc} \quad (4)$$

Finally, the TEC can be obtained by scaling the IEC_R by elevation mapping function (emf_{θ}) as follows

$$TEC = \frac{IEC_R}{emf_{\theta}} \quad (5)$$

$$emf_{\theta} = \sec \left[\sin^{-1} \left(\frac{R}{R + h_{max}} \right) \cos \theta \right]. \quad (6)$$

$R \rightarrow$ radius of the Earth; $h_{max} \rightarrow$ height of maximum ionization.

This scaling helps to account for the discrepancy in the ray path length through the ionosphere as a function of GPS

satellite elevation angle θ during the course of an orbital pass. As the TEC represents the integrated electron content along the path, it is not possible to determine meaningfully the height of TEC anomaly. However, the TEC variations are mainly sensitive to the height (h_{max}) of the maximum ionization, that is, in F2 layer. The TEC represents a point of intersection of a line-of-sight within the thin F2 layer.

The CIDs are calculated from TEC by smoothing the noise of phase measurements and detrending the variations of regular ionosphere using band pass filtering of 1–10 min period. An example of raw slant TEC (Fig. 2a) time series recorded by commonly visible satellites for April 25, 2015, Gorkha earthquake, Nepal (Catherine et al. 2017) along with filtered TEC time series of sites in the near (Fig. 2b) and far (Fig. 2c) fields of the epicenter are shown in Fig. 2.

Total Electron Content in Seismo-ionospheric Studies, Fig. 2 (a) Time series of the raw slant TEC changes for the April 25, 2015, Gorkha earthquake, Nepal. Traces of band pass filtered (1–10 min) coseismic TEC variation (b) at sites close to the epicenter and (c) far from the

epicenter, as observed by GPS satellites at some of the stations. The vertical line indicates occurrence of the Mw 7.8 Gorkha earthquake (06:11 UT). Distance of the SIPS of GPS sites from the epicenter is indicated on the right side

Propagation Characteristics of CIDs

An anomalous signal is observed on TEC time series of sites that are both in the near and far fields of the source of disturbance, between 10 and 30 min after the earthquake. This signal shows time delays that increase with distance from the epicenter, consistent with the velocity of the propagating perturbation. Irrespective of the source (natural or artificial), the TEC anomalies show the character of a classical N-wave of period 180–360 s, for 30 min to 1 h with amplitude above the background variations under moderate geomagnetic conditions by a factor of 2–5 as a minimum. Such organized perturbation will be absent in the preceding and following days of the earthquake. The spatiotemporal characteristics of CIDs give some information about the source of disturbances.

Amplitudes of CID

The CID spreads out from the epicenter with a quasi-circular propagation pattern with a time lag equivalent to the time required for acoustic waves to reach IPP from the surface. The absolute and relative amplitude of CID increases with the increasing magnitude. The amplitude of acoustic mode of CID decreases quickly with time and distance of SIP's location and the epicenter up to 500 km. The surface wave mode of amplitudes increase from 500 to 1000 km (Fig. 2c). Multi-frequency anomalies are induced after the earthquake in the near and far fields (Fig. 2). Acoustic waves, Rayleigh waves (3–7 mHz) tsunami-generated gravity waves (<3 mHz) (Matsumura et al. 2011; Occhipinti et al. 2013), and also high frequencies signals (7–15 mHz) can be identified in the GPS TEC measurements. Negative or positive CID anomalies indicate either decrease or increase in TEC of ionospheric plasma medium by the rarefaction or compression induced by the acoustic wave front respectively for normal or reverse fault mechanisms. CIDs of negative anomalies are unstable and only visible for large earthquake (Astafyeva and Heki 2009). The polarities of ionospheric disturbance waveforms (Fig. 1b, c in Astafyeva and Heki 2009) are mostly consistent with the coseismic vertical ground motion and focal mechanism of earthquakes. The observed TEC response has N-wave and inverted N-wave for uplift and subsidence of the ground after the earthquake respectively. CID polarities are clear for a dip-slip earthquake, but in the case of strike-slip earthquake, visibility of the polarity depends on the magnitude of the vertical displacement generated by an earthquake.

However, discrepancies in the amplitude and waveforms of CIDs are plausible due to factors like complexity of rupture, distance from GPS station to epicenter, sampling interval, azimuth of the SIP, geometry of LOS, geomagnetic conditions (Afraimovich et al. 2001; Astafyeva and Heki 2009; Heki and Ping 2005) earthquake magnitude (Astafyeva et al. 2013a) attendant differences in the incidence

angles (shallow or deep) between the corresponding LOS and the wave front (Cahyadi and Heki 2013). Further, the difference in the apparent CID amplitudes at the same site for different satellites can also stem from the three-dimensional structure of the CID in the ionosphere of finite thickness (Heki and Ping 2005).

Generally, other than earthquakes, solar eclipses can cause an ionospheric anomaly of 0.15–15 TECU, tropical cyclone can perturb ionosphere at period 1–150 min with anomaly of ~2.5 TECU, geomagnetic storms can perturb ionosphere about 10–14% of its TEC, and rocket launching can cause nearly 0.2–2% change in ionospheric TEC at periods 3–8 min (Afraimovich et al. 2013). Studies suggest that the Earthquakes and tsunamis can cause 1.8–6% of TEC variation at 4–5 min period and 0.15TECU change around 9–14 min (Heki et al. 2006; Occhipinti et al. 2013; Astafyeva et al. 2014; Grawe and Makela 2015). Few examples of the earthquakes of different mechanism, Tsunamis, Solar Eclipse, rocket launch for which the CIDs were observed are charted in Table 1.

Propagation Speed of CIDs

The apparent velocity of CID can be obtained from the slope of the best fit line of travel time diagram, a plot between arrival times of CID at different subionospheric points versus the distances of these points from the center of crustal uplift along the great circle path.

The CIDs are classified into three types based on their characteristics and source of generation

- (i) The long period CIDs induced by large coseismic vertical crustal movement around the epicenter travels with speeds ~0.3 km/s (Bolt 1964) are the signatures of acoustic gravity waves (Davies 1990). They induce quasi-periodic ionosphere disturbances that are seen in the far-field of an earthquake without significant damping and changes of oscillation spectrum (Astafyeva and Afraimovich 2006; Liu et al. 2006b).
- (ii) The second type is the most general and obvious CIDs detected 10–15 min after strong earthquakes in the near fields caused by shock acoustic waves (SAW). They propagate with velocity 0.9–1.2 km/s from the earthquake location in a narrow cone of zenith angles (Calais and Minster 1995; Afraimovich et al. 2001; Heki and Ping 2005; Jung et al. 2006).
- (iii) The third type is short period CIDs induced by surface Rayleigh waves. They propagate along the Earth's surface with a velocity 2.6–3.6 km/s and recorded at the far-field stations (Yuen et al. 1969; Davies 1990; Ducic et al. 2003; Artru et al. 2004; Liu et al. 2006a, b).

Figure 3 shows the CID propagation patterns after the 11 April 2012 Indian ocean earthquake (Mw 8.6) induced

T: Thrust; SS: strike-slip; SSS: shallow strike-slip; ST: shallow thrust; SOR: shallow oblique reverse; CID-AT: CID arrival time after the event

by SAW at 1.2 km/s (Fig. 3a) and Rayleigh wave at 3.5 km/s (Fig. 3b) CID arrivals excited by Rayleigh waves are recorded at the far-field stations (Fig. 3c). The mainshock was followed by an aftershock of Mw 8.2 after 2 hours. The stations HYDE and PIMO seem to illustrate quasi-periodic TEC oscillations that continued for 60–75 min at epicentral distances of ~2000 km and 3500 km, respectively.

The first report on separation of CID into two modes was given by Astafyeva et al. (2009). The initial disturbance propagates with an apparent velocity equal to the speed of the sound at the height of ionosphere's F-layer, up to a distance of ~650 km from the epicenter. But from ~650 to 700 km away from the epicenter, the disturbance appears to split into two separate waves known as fast and slow components with velocities ~3 km/s and 600 m/s, generated by Rayleigh surface waves and vertical motion of the ground, respectively. Later this phenomenon was observed in other studies too (Catherine et al. 2015, 2017). Although it is not possible to discriminate these two components in the near-field, they can be seen in the TEC data after 600–700 km.

Further the fast component waves are clearly seen in the far-field due to their long wavelength and slow component gradually slows down and fades with increasing distance from the epicenter. The possible reasons for the appearance of the slow component could be due to multiple sources like distance from the epicenter as well as the LOS geometry and the azimuthal difference in energy emission of seismic waves (Calais et al. 1998). Two signals with different propagation velocities appear in the TEC time series near the epicenter (Fig. 3a, b) but only long wavelength signal is seen at far field sites which confirms the attenuation of shock acoustic waves at such distances (Fig. 3c). In some cases, Rayleigh wave signatures may not appear at all because of their small amplitudes coming from the prevailing geometric conditions (Cahyadi and Heki 2013) or absence of GPS points farther (>2000 km) from the epicenter.

Directivity of CID Propagation

Operation of dense regional and international GPS networks in a continuous mode enables the accurate mapping of

Total Electron Content in Seismo-ionospheric Studies, Fig. 3 Traveltime diagram of band pass-filtered TEC in the near field (a,b) and in the far-field (c) regions in response to the April 11, 2012, earthquake at the SIPs to the epicenter as recorded by the satellites PRN 6. Vertical thick lines indicate the time of the main shock and the

aftershock at 8:38UT and 10:43UT, respectively. The slanted black line shows the best fit of the CID arrival times denoting the propagation velocities of ionospheric TEC disturbance. The distances are great circle distances between SIPs and the epicenter

directivity of CID propagation. However, paucity of observations over a wide azimuth during the past earthquakes made estimates of CID directionality contentious. As the Lorentz force on the ionospheric charged particles in geomagnetic field hampers their motion perpendicular to geomagnetic field, the ambient magnetic field in the Northern hemisphere attenuates northward propagation of CID and favors southward propagation and allows the northward propagation in Southern hemisphere (Heki and Ping 2005). In the polar region, the ambient magnetic field which is vertical would attenuate the propagation of CID for all directions, whereas in the equatorial regions where the ambient magnetic field is horizontal, the CID would propagate in both north and south directions. Astafyeva et al. (2014) proposed equatorward propagation for much longer distances.

The directivity of CID propagation reported for the Southern Hemisphere 2007 Bengkulu earthquake (Cahyadi and Heki 2013) was in support of the above proposed model. However, azimuthal anisotropy of TEC variations also reported (Otsuka et al. 2006). Catherine et al. (2015) noticed the differences in Rayleigh wave radiation pattern as strong reason for the anisotropy than to the geomagnetic field effect. According to Calais et al. (1998), the ionospheric coupling factor (ICF) controls the ionospheric perturbation directivity. Attenuation of ionospheric coupled wave is less for regions with high ICF (Rolland et al. 2011). At midlatitudes, the CID propagating at angles larger than $\pm 10^\circ$ and $\pm 30^\circ$ with ambient magnetic field lines are attenuated by a factor of 0.5 and 0.25, respectively, and for CID propagating at $\sim \pm 45^\circ$ to the

magnetic field lines the amplitude is close to 0 (Rolland et al. 2013). Calais et al. (1998) suggested two possibilities for the north-south asymmetry in the ionospheric response: (i) the interaction with ambient geomagnetic field and (ii) azimuthal difference in energy emission in terms of seismic wave.

Observations on directivity of CIDs for some of the earthquakes occurring in different geographic regions are tabulated in Table 2. The source directivity-related effects appear to emerge as the potential driving mechanism to explain our observation. From future study of CIDs occurring in different geographical locations, directionality of CID propagation and the influencing factors would be better visualized.

Dip-slip Versus Strike-slip Earthquakes

In dip-slip earthquakes, vertical coseismic crustal displacement is the predominant characteristic that causes uplift or subsidence at the surface depending on reverse or normal motion of the faults, respectively. In strike-slip motion, horizontal motion is dominating with very small vertical motion. Piston like coseismic vertical motion in the earthquake zone plays a crucial role in generating perturbations in the ionosphere. In addition to the TEC fluctuations observed for dip-slip earthquakes ($M > 7$) occurring in subduction zones, strike-slip earthquakes also induce significant CIDs (Astafyeva et al. 2014; Catherine et al. 2015).

Although the CID amplitudes of strike-slip events are less than the dip-slip earthquakes, the characteristics are similar

Total Electron Content in Seismo-ionospheric Studies, Table 2 Details on directivity of CID for earthquakes occurring in different geographic regions

Earthquake	Region	Directionality of CID propagation	Rupture direction	References
Tokachi-Oki earthquake (Mw 8.0) September 26 2003	Northern Hemisphere	Northward CID smaller than the southward CID	NW	Yagi (2004)
Tohoku Earthquake (Mw 9.0) March 11 2011	Northern Hemisphere	Amplitude of northward CID (A_N) is smaller than the southward CID (A_S)	NW	Tsugawa et al. (2011)
Sumatra earthquake (Mw 9.3) Indian Ocean December 26 2004 and 2007 Bengkulu earthquake of Mw 8.5	Equatorial Region	Amplitude of northward CID is more than the southward CID, but could not be confirmed due to the absence of stations south of the epicenter	Northward	Otsuka et al. (2006) Cahyadi and Heki (2013)
Indian Ocean Earthquake (Mw 8.6) April 11 2012	Equatorial Region	CID propagates effectively to the north and south of the epicenter with different velocities A_N being larger than A_S	Rupture geometry is complex and propagated in all directions	Catherine et al. (2015)
Gorkha earthquake (Mw 7.8) April 25 2015	Mid latitude region	No northward propagation. Mostly CID propagated in south south east	South south east	Reddy and Seemala (2015) Catherine et al. (2017)
Illapel earthquake, Chile (Mw 8.3) September 26 2015	Southern Hemisphere	North direction with more north velocity with decreasing velocity toward south	North	Reddy et al. (2016)
Kaikoura earthquake, Newzealand (Mw 7.8) November 14 2016	Southern Hemisphere	North ward propagation of CID	Complex rupture in North East	Bagiya et al. (2018)

(Perevalova et al. 2014). The observed TEC response for dip-slip earthquakes has a precise N-shape and inverted N-shape waves over the regions of uplift and subsidence, respectively, whereas the CID polarities for uplift and subsidence are not clearly noticeable for strike slip events. However, the amplitude of ionospheric disturbance depends on many other factors as described in section “[Amplitudes of CID](#)”. Astafyeva et al. (2014) disclosed that the seismological parameters like magnitude of coseismic horizontal displacements, fault and slip dimensions, or a combination of them may play a role in generating large ionospheric perturbations in large strike-slip events with insignificant vertical ground motion.

Preseismic Ionospheric Anomalies

The study of the ionosphere state prior to the occurrence of large earthquakes has gained attention of the geophysicists, as the precursory studies, on success, may help to minimize the loss during great earthquakes. Availability of thousands of ground-based GPS receivers, on global to regional scale today, opened an opportunity to extensively study and validate the precursory seismo-ionospheric anomalies. It has been found that the ionospheric plasma critical frequency (f_oF_2) diminishes few days to few hours before some large earthquakes in the vicinity of an earthquake epicenter.

Interestingly, investigations of preseismic ionospheric disturbances are also gaining impetus (Liu et al. 2002, 2004; Pulinets et al. 2007; Dautermann et al. 2007; Zhao et al. 2008; Liu et al. 2009, 2010b, 2011b; Heki 2011; Kamogawa and Kakinami 2013; Heki and Enomoto 2015; Masci et al. 2015).

Wyss (1991) proposed that TEC enhancement prior to a large earthquake must satisfy the four requirements to be validated as an earthquake precursor. Le et al. (2011) noticed preseismic TEC anomalies tend to appear around the earthquake epicenter 1–4 days prior, particularly with a higher probability for large and shallow earthquakes. Positive TEC anomalies were noticed 60–40 min before the 2011 Tohoku-Oki, 2004 Sumatra Andaman and the 2010 Maule earthquakes (Heki 2011). The physical mechanism and the appearance of the preseismic TEC anomalies still remains unclear in spite of several new studies.

Besides the positive results on the seismo-ionospheric precursory studies for the short-term prediction, research on coining this information as precursors is underway and still remains as a matter of debate. However, in view of the socio-economical perspective, focused research on seismo-ionospheric precursors could be encouraged to develop accurate regional model that discriminates seismo-ionospheric precursory changes from the other natural and anthropogenic variations.

Influence of Equatorial Ionization Anomaly on CID

EIA (equatorial ionization anomaly) is a spatial variability in ionization density and TEC due to the “fountain effect” setup by the interaction of the diurnal variation of the zonal electric field with the horizontal geomagnetic field at the equatorial region causing uplift of the plasma by $E \times B$ drift (Anderson 1981; Walker et al. 1994). A well-formed EIA must be present in the equatorial region at the local noon time and may influence the spatial variability of TEC amplitude. This may be assessed by computing the percentage of relative TEC perturbation over the background TEC at each SIP during the time of observation.

$$\text{Relative dTEC} = (\text{dTEC}/\text{TEC}) * 100$$

Comparison between dTEC and relative dTEC will help to check the difference in the amplitude of the propagating CID from the background TEC and assess the influence of EIA.

Absence of CIDs

The co-seismic ionospheric perturbations are being captured by the growing GNSS network and its applications are gaining importance to investigate various coupled processes associated with the ionosphere. Nevertheless, Equatorial Plasma Bubble (EPBs), a stable and strong mode of ionospheric irregularities that develop during the postsunset period due to Rayleigh-Taylor (R-T) instability, diffract the signals from navigation and communication systems (Elgowainy and Ashgriz 1997). These EPBs obscure the signatures of CIDs due to the higher electron production rate of EPBs. Therefore, it appears difficult to capture CIDs in the GNSS signals (e.g., 2005, Nias earthquakes, Sumatra; 2017 Mexico earthquake). However, due to the lower production rate of EPBs at the high-latitudinal region, GNSS TEC measurements expose lucid CIDs even during night time (e.g., Iceland, Alaska) (Panda et al. 2019).

Applications of CIDs in Ionospheric Seismology

The various possibilities of GNSS ionospheric imaging are

- (i) As the location of initial TEC increase is associated with the crustal uplift, the first CID arrivals provide the seismic fault location and dimensions within few minutes after the earthquake (Astafyeva et al. 2011; Astafyeva and Shults 2019).
- (ii) The coupling of solid earth-ocean-atmosphere helps to estimate the earthquake source extent using CIDs observed from large GNSS continuous networks and Multi GNSS constellations.

- (iii) CID has a potential to provide information on rupture speed and relative magnitudes of multiple asperities (Heki et al. 2006; Astafyeva et al. 2013b)
- (iv) CID could serve as a new indicator of rupture on the fault with timescale up to 4–5 min in between seismic band (Broadband seismometers that are sensitive to periods longer than a few minutes) and tsunami band (data useful to constrain faulting as slow as a few tens of minutes) (Heki et al. 2006).
- (v) As the validation of tsunami risk in tsunamigenic earthquakes using sparsely located buoys around the ocean takes hours, the CIDs observed approximately ~8–9 min after the onset of earthquake can be utilized in the oceanic monitoring and tsunami warning system (Occhipinti et al. 2013)

Summary

Recent studies on co-seismic ionospheric disturbances are robust for understanding the coupling between lithosphere and ionosphere. Particularly, tremendous increase in the GNSS networks in the last decade, on the global scale, helped to improve the accuracy in estimates of propagation direction and velocity. The ionospheric perturbations imaged by dense GPS arrays act as a proxy to study energy transfer between the solid Earth and ionosphere (lower atmosphere) for distinguishing ionospheric signals of terrestrial versus extra-terrestrial origin. The spatio-temporal and dynamic features of CIDs due to natural and artificial sources and the factors influencing them have been extensively investigated within the last decade by using signals of Global Navigation Satellite Systems. The CID anomalies for different types of earthquake mechanism and tsunamis are analyzed to understand the scaling between anomaly strength and source parameter of the events. Physiognomies of ionospheric response to the earthquake are appropriate not only to decipher earthquake location, fault length, and other source characteristics but also help to assess the tsunamigenic risk. In addition, systematic analyses of pre-seismic ionospheric anomalies, if successful, will help to reduce the socio-economic losses associated with earthquakes.

Tracking Earth's Water in Motion from Satellite Gravity Observations

J. L. Chen

Center for Space Research, University of Texas, Austin, TX, USA

Introduction

The global water cycle (see Fig. 1), also known as the hydrological cycle, describes the continuous movement and redistribution of water within one or among different components of the climate system through the physical processes of evaporation, precipitation, surface runoff, subsurface flow, condensation, infiltration, etc., and variations of water storage in different reservoirs, such as soil moisture, groundwater, snow and ice, atmospheric water vapor, and water in the ocean (Dingman 1994). Monitoring and measuring these hydrological variables are critical for understanding the global water cycle and Earth climate and ecosystem. Accurate quantification of water mass variations associated with these hydrological processes at regional to global scales is difficult, due to the lack of adequate in situ observations of related hydrological variables. Predictions from hydrological models, also called land surface models (LSMs) have been a useful data resource for studying the global water cycle. However, large uncertainty is expected for model predicted hydrological variations (also due to the lack of adequate in situ observations to constrain the model predictions).

Since launched in March 2002, the Gravity Recovery and Climate Experiment (GRACE) satellite gravity mission has brought a new era to the studies of large-scale mass transport and redistribution within different components of the Earth system, including the atmosphere, hydrosphere, ocean, cryosphere, and solid Earth. The GRACE (decommissioned in November 2017) has accumulated over 15 years of time-variable satellite gravity measurements with unprecedented accuracy (Tapley et al. 2019). The GRACE Follow-On (GFO) mission was launched in 2018 to continue the endeavor of the GRACE mission. Time-variable gravity measurements from the GRACE and GFO (hereafter noted as GRACE) missions have been used in a wide range of investigations to quantify large-scale mass variations on the surface of the Earth, including ice mass change of polar ice sheets and mountain glaciers, terrestrial water storage change in river basins, regional groundwater depletion, global ocean mass change, and deformations of the solid Earth due to the Glacial Isostatic Adjustment (GIA) and large earthquakes. These studies have significantly improved our understanding of the Earth climate system and the global water cycle (e.g., Cazenave and Chen 2010; Rodell et al. 2018; Tapley et al. 2019).

Tracking Earth's Water in Motion from Satellite Gravity Observations, Fig. 1 Illustration of the global water cycle. (Modified from an original map from NASA)

GRACE Satellite Gravimetry

GRACE is a twin satellites gravity mission, jointly sponsored by US NASA and German Aerospace Center (DLR) (Tapley et al. 2004). The GRACE satellites were launched on 17 March 2002, with an initial altitude of approximately 500 km and a near-polar inclination of 89° . The satellites orbit one behind the other in the same orbit plane and are separated by approximately 220 km along their orbit track. GRACE utilizes a state-of-the-art technique to observe variations of Earth's gravity by tracking the inter-satellite range and range-rate (see Fig. 2) via a K-band ranging (KBR) system (Tapley et al. 2004). In addition, each satellite is equipped with a SuperSTAR Accelerometer, GPS receiver, Star Cameras, and Laser Retro Reflector to complete the complement of science instruments. The GRACE Science Data System uses the KBR range and range rate data, along with ancillary data, to estimate a new gravity field every month in the form of corrections to an a priori background gravity model used in the data processing procedure (Bettadpur 2012). The GFO mission is basically a duplicate of GRACE, with two satellites flying in the same polar orbit (as the GRACE satellites) and carrying the same science instruments with upgraded hardware. GFO also carries an experimental laser ranging interferometer (LRI) instrument that is assessed as a possible improvement for future GRACE-like missions.

Tracking Earth's Water in Motion from Satellite Gravity Observations, Fig. 2 GRACE includes twin satellites orbiting the Earth at an initial altitude of ~ 500 km in a near-polar orbit (89° inclination). GRACE was launched on March 17, 2002, and was decommissioned in November 2017. (Source: US NASA/UT CSR)

Monthly GRACE global gravity solutions are provided by three GRACE data processing centers forming the Science Data System, including the Center for Space Research (CSR) at the University of Texas at Austin, Geoforschungszentrum (GFZ) in Potsdam, and the NASA Jet Propulsion Laboratory (JPL). GRACE solutions are distributed by the NASA Physical Oceanography Distributed Active Archive Center (<https://podaac.jpl.nasa.gov/grace>) and GFZ Information System and Data Center (<http://isdc.gfz-potsdam.de/grace-isdc/>). GRACE monthly solutions are generally expressed in the form of fully normalized spherical harmonic (SH) coefficients, up to certain maximum degree and order (typically up to degree 60 or 96). Atmospheric and high frequency oceanic mass variations, and tidal effects are removed during GRACE de-aliasing process using atmospheric and oceanic model predictions (Bettadpur 2012). GRACE monthly mass concentration (mascon) solutions, as alternative GRACE mass change solutions with less noise and better spatial resolution are also generated by several data processing centers, including NASA JPL, UT CSR, and NASA Goddard Space Flight Center (GSFC) (Watkins et al. 2015; Save et al. 2016; Luthcke et al. 2013).

Quantifying Mass Change Using GRACE Gravity Solutions

When assuming that, at decadal or shorter time scales, GRACE observed time-variable gravity change represents contributions mainly from mass variations on the Earth surface in the Earth geophysical fluids envelope (atmosphere, ocean, hydrosphere, and cryosphere), GRACE monthly gravity SH coefficients C_{lm} and S_{lm} can be readily converted into surface mass load change as (Wahr et al. 1998),

$$\Delta\sigma(\theta, \lambda) = \frac{M_E}{4\pi a^2} \sum_{l=0}^N \sum_{m=0}^l \frac{2l+1}{1+k_l} W_l \tilde{P}_{lm}(\cos \theta) \times [\Delta C_{lm} \cos(m\lambda) + \Delta S_{lm} \sin(m\lambda)] \quad (1)$$

where θ and λ are the colatitude and east longitude, respectively; a is Earth mean radius (6.371×10^6 m); $\tilde{P}_{lm}$ are the fully normalized associated Legendre polynomials of degree l and order m ; M_E is the mass of the Earth (5.97219×10^{24} kg), $\Delta\sigma(\theta, \lambda)$ is mass load changes (in kg/m^2 or equivalent water height in mm) at a given point on the Earth surface, and k_l are load Love numbers of the solid Earth which account for mass redistribution of the Earth due to changing surface loads (see Table 1 in Wahr et al. 1998). W_l is a factor representing normalized Gaussian weighting (with maximum weight of 1), and reduces contributions from high degree and order SH coefficients. The computation of Gaussian weights as

functions of degree l and averaging radius (r) can be found in Wahr et al. (1998). GRACE high degree and order SH coefficients are affected by noise, especially the longitudinal stripes. The longitudinal stripes originate from the correlation between the even and odd degree pairs of GRACE SH coefficients of a given order, and can be removed through the proposed decorrelation filtering (Swenson and Wahr 2006). After decorrelation filtering, a degree of Gaussian smoothing is still needed to further suppress the residual noise, by applying the Gaussian weight W_l to SH coefficients of corresponding degree (l) in Eq. 1.

Monitoring Land Water Cycle Using GRACE

There are two major limitations of the GRACE gravity measurements. One is the coarse spatial resolution (of about a few to several hundred kilometers), which is influenced by several factors, including the truncation of GRACE SH solutions (e.g., at degree 60), and the need of spatial filtering due to the dominant spatial noise at high degrees and orders. Therefore, GRACE gravity measurements are mostly applied to study large regional or basin scale water mass changes. The other is the vertical separation. Over land region, when atmospheric effect is removed, GRACE observed time-variable gravity change represents integrated contribution from mass variations in different reservoirs of the water body, including soil moisture, snow, surface water (in lakes and rivers), and groundwater. GRACE itself cannot separate the different contributions. Independent estimates from other sources are needed when the focus is on a particular hydrological variable.

In any given region (or basin), the hydrological conservation equation can be expressed in terms of water fluxes, e.g., terrestrial water storage (TWS) change rate ($\frac{\Delta TWS}{\Delta t}$), precipitation (P), evapotranspiration (E), and surface and subsurface runoff (R) as,

$$\frac{\Delta TWS}{\Delta t} = P - E - R \quad (2)$$

The hydrological conservation equation can also be expressed in terms of water storage changes in different reservoirs of the water body, including soil moisture (ΔSM), snow water (ΔSN), surface water (ΔSW), and groundwater (ΔGW) as,

$$\Delta TWS = \Delta SM + \Delta SN + \Delta SW + \Delta GW \quad (3)$$

Based on the two hydrological conservation equations (Eqs. 2 and 3), it is theoretically possible to study any related components in the equations, as long as other components can be determined independently. For example, R can be

estimated from GRACE determined $\frac{\Delta TWS}{\Delta t}$ and climate model predicted P and E as,

$$R = \frac{\Delta TWS}{\Delta t} - (P - E) \quad (4)$$

And, groundwater storage change (ΔGW) can be estimated from GRACE determined ΔTWS and land surface model (LSM) predicted soil moisture, snow water, and surface water as

$$\Delta GW = \Delta TWS - (\Delta SM + \Delta SN + \Delta SW) \quad (5)$$

Some previous studies (e.g., Syed et al. 2005, 2009; Seo et al. 2009) combined GRACE observed ΔTWS with model predicted precipitation and evapotranspiration flux to quantify basin-scale river discharge using Eq. (2). Similarly, several other studies (Rodell et al. 2004, 2011; Ramillien et al. 2006; Cesanelli and Guarracino 2011) quantified basin-scale evapotranspiration flux using GRACE TWS change estimates with precipitation and river discharge data from model predictions and in situ observations. GRACE satellite gravity measurements have also been used to study large-scale TWS changes, especially those related to extreme climate events, such as severe floods and droughts (e.g., Papa et al. 2008; Chen et al. 2009, 2010), and groundwater depletions (e.g., Rodell et al. 2009; Famiglietti et al. 2011; Scanlon et al. 2012).

Groundwater plays a key role in connections between the global hydrological cycle and climate change, and is a vital resource in many parts of the world. Accurate quantification of groundwater storage change is difficult, and limited by in situ groundwater observations (Famiglietti et al. 2011). In developed countries (such as the U.S. and Australia) well networks may be relatively dense, but stacked aquifers can result in order of magnitude variations in storage coefficients, increasing uncertainty in converting groundwater level changes to groundwater storage (Rodell et al. 2007). Over the past decade, GRACE satellite gravity measurements have been successfully used to monitor and quantify major groundwater depletions in various regions over the world, including northwest and northern India (e.g., Rodell et al. 2009; Tiwari et al. 2009; Chen et al. 2014), the Middle East (Voss et al. 2013; Joodaki et al. 2014), California's Central Valley (Famiglietti et al. 2011; Scanlon et al. 2012), High Plains Aquifer in the USA (Strassberg et al. 2009), southern Murray Darling Basin in Australia (Leblanc et al. 2009; Chen et al. 2016), and North China Plain (Feng et al. 2013).

Monitoring Ice and Ocean Mass Change Using GRACE

Accurate quantification of polar ice sheet mass balance and its contribution to global sea level change has long been a

challenge, due to the lack of either in situ data or remote sensing measurements. Before the GRACE mission, for a long-time people were not certain whether the entire Antarctic ice sheet was losing or gaining ice. GRACE satellite gravimetry provides a unique and successful means for quantifying ice mass balance of polar ice sheets and mountain glaciers. Compared to other remote sensing techniques and in situ data, GRACE provides the first "direct" measurements of ice mass change on continental and large regional scales, although some uncertainty is expected in GRACE estimates due to the coarse spatial resolution of GRACE solutions, and errors in data calibration and other geophysical signals, e.g., the Global Isostatic Adjustment (GIA) effect, that need to be quantified and removed from GRACE. Over the past 15 years, GRACE satellite gravity measurements have been widely used to study ice mass change of the Antarctic and Greenland ice sheets (e.g., Velicogna and Wahr 2006; Chen et al. 2006), and mountain glaciers (e.g., Luthcke et al. 2008; Lenaerts et al. 2013). GRACE data shows that both Greenland and Antarctica are losing a significant amount of ice over the GRACE time span (April 2002–June 2017), with estimated rates of $\sim 258 \pm 26$ Gt/year and 137 ± 41 Gt/year, respectively (Tapley et al. 2019). The quantification of ice mass change of mountain glaciers is more challenging, limited by GRACE resolution. Optimal data processing methods, such as regional mascons or forward modeling, are needed to appropriately address the leakage issue when using GRACE SH solutions (e.g., Luthcke et al. 2013; Chen et al. 2015). Additional challenge comes from the needed separation of mountain glacier mass signal from surrounding TWS change, which mainly relies on model predicted TWS changes. Large uncertainty of model TWS estimates are expected, especially at interannual and long-term time scales.

Understanding the global sea level change and its driving forces is an important topic in climate change studies, and critical in interpreting and predicting the climate system. Global sea level change is driven by two major forces, water mass exchange between the ocean and land (including ice sheets) and sea water density change due to temperature and salinity change (the so-called steric sea level change). GRACE satellite gravimetry allows, for the first time, direct measure of oceanic mass contribution to global sea level change (e.g., Chambers et al. 2004; Chen et al. 2005). Since around 2005, the study of global sea level change has entered a completely new era, with the integration of observations from three independent modern techniques monitoring the global ocean from three different perspectives. Satellite radar altimeter has been measuring the global sea surface height (SSH) anomalies with unprecedented accuracy since 1992 when the TOPEX/Poseidon, the first of a series of the new generation of satellite altimeter missions, was launched (Fu and Davidson 1995). The ARGO float network is an international joint project designed to provide continuous

3-dimensional measurements of the temperature, salinity and other geophysical and chemical properties of the global ocean. The deployment of the Argo global floats array started in 2000 (Roemmich and Owens 2000; Argo 2000), and its global coverage has become relatively complete and homogeneous since around 2005. Combining satellite altimeter SSH, Argo ocean temperature and salinity, and GRACE gravity measurements offers the first opportunity to study the global sea level change and its different contributions using global-scale observations (e.g., Cazenave et al. 2009; Leuliette and Willis 2011; Chen et al. 2013; Chambers et al. 2017).

Summary

Over the past 15 plus years, GRACE time-variable gravity measurements have brought a new era to the study of large-scale water mass transport and redistribution within the Earth geophysical fluids system, including the atmosphere, hydrosphere, ocean, and cryosphere, and greatly enhanced our understanding and quantification of the global water cycle. GRACE is inarguably regarded as one of the most successful Earth science missions in the past several decades. GRACE offers the first opportunities for accurately quantifying large-scale TWS changes associated with the global water cycle, and monitor major floods and droughts on global basis. When combined with other independent data (e.g., measurements or model predictions), GRACE

can be used to study different components of the terrestrial water cycle, such as evapotranspiration, river discharge, groundwater, soil moisture, snow water, etc. on regional, basin, continental, and global scales. GRACE satellite gravimetry also provides a new means for quantifying ice mass changes of polar ice sheets and mountain glaciers with unprecedented accuracy. The integration of GRACE gravimetry, satellite altimeter, and Argo in situ ocean temperature and salinity measurements has offered the first opportunities to accurately quantify different driving forces of the global sea level change, which is critical for understanding and predicting the climate system.

GRACE time-variable gravity solutions have helped paint a much clearer picture of the global water cycle, in particular long-term water and ice mass changes in different components of the climate system and different parts of the world (see Fig. 3). After an extended period of data calibration and validation (Cal/Val), the GFO project has recently released its first year of gravity solutions in June 2019, with similar accuracy as the GRACE solutions. The GRACE and GFO missions are expected to provide more than two decades of time-variable gravity measurements, which will be a valuable resource for studying water mass transport in various components of the Earth climate system at broad time scales. Continuous improvements of GRACE data processing methods and background geophysical models are also expected, which will help improve the accuracy and spatial resolution of GRACE measurements and enable wider range of applications of satellite gravity observations.

Tracking Earth's Water in Motion from Satellite Gravity Observations, Fig. 3 Global mass change rates (in cm/year of equivalent water height) observed by GRACE during the period April 2002 and June

2017, based on CSR RL06 gravity solutions with 300 km Gaussian smoothing applied. Some major long-term mass signals from climate change or solid geophysical sources are labeled on the sides

Teisseyre-Tornquist Zone; Sorgenfrei-Tornquist Zone; Trans-European Suture Zone; Tornquist Fan

Definition

The Trans-European Suture Zone (TESZ) is the transition zone from the Precambrian East European Craton in the north and east to the younger Phanerozoic mobile belts to the south and west. It is the most prominent lithospheric tectonic feature of Europe.

The term Trans-European Suture Zone was only adapted around year 2000 during the Pan-European EUROPROBE program of the European Science Foundation. Until then, parts of the zone were termed Teisseyre-Tornquist Zone, Sorgenfrei-Tornquist Zone, Trans-European Fault, and Tornquist Fan.

Introduction

The Trans-European Suture Zone, TESZ, is associated with major geological differences, abrupt changes in crustal and lithospheric thicknesses, and major anomalies in all geophysical parameters (Fig. 1). Historically, it was discovered as a geological-geophysical lineament around 1900 from geological observations by W. Teisseyre despite the presence of a thick sedimentary cover, and observation by A.J.H. Tornquist of a pronounced, linear magnetic anomaly extending from the Black Sea to the Baltic Sea. The craton to mobile belt transition was, therefore, originally named the Teisseyre-Tornquist Zone (TTZ) in central Europe. The term TESZ was introduced in the late 1990s to emphasize that the transition is represented by a suture zone, rather than a lineament, between Precambrian cratons in the north and east and younger Europe in the south and west, which is composed of a series of terranes that were amalgamated to proto-Europe in the Palaeozoic (Winchester and PACE Network Team 2002).

Another geological lineament across southern Sweden and Denmark into the North Sea, the Sorgenfrei-Tornquist Zone (STZ, Fig. 1b), was for long understood as the NW continuation of the TTZ from a dog-leg offset in the Baltic Sea. It was believed to represent the SW transition between the original Baltica Plate and younger terranes. However, radiometric dating and interpretation of deep crustal seismic data has shown that the STZ is not the edge of the craton but instead a tectonic feature inside the original Baltica Plate in its tectonically reworked SW corner (EUGENO-S Working Group 1988). Interpretation of a large amount of seismic reflection profiles from industry has shown that STZ is a pronounced tectonic inversion zone in the sedimentary cover (Thybo 1997). The TTZ is co-located with a similar inversion zone in Poland, and in this regard, the two zones are similar. Deep seismic profiling has demonstrated that the inversion affected basement and even created the basement horst at the island Bornholm in the transition between TTZ and STZ, where the inversion likely was accompanied by crustal thickening in a

Trans-European Suture Zone, Fig. 1 Location of the Trans-European Suture Zone (TESZ). (a) Hypsometric map around TESZ indicating four characteristic areas. The exact limits of TESZ are undefined, and the zone largely covers the four rhombuses. For orientation the Teisseyre-Tornquist Zone (TTZ) and Sorgenfrei-Tornquist Zone (STZ) are shown by a thick red line, and by a thick black line in all other maps. The map includes the location of seismic profiles in the region (thin

straight lines) and the location of the generalized seismic profile in Fig. 2 (black curved line). (b) Tectonic map of the region around TESZ. Abbreviations: TTZ – Teisseyre-Tornquist Zone, STZ – Sorgenfrei-Tornquist Zone, TF – Tornquist Fan, TEF – Trans-European Fault. (c) Map of Europe showing the TESZ region. (Figure after Artemieva and Thybo (2013))

complex “crocodile tectonic structure” or by “subversion” (BABEL Working Group 1993).

The STZ occurs within the Tornquist Fan, which is defined by a series of transtensional fault zones that were active in the late Palaeozoic, accompanied by intensive volcanic and magmatic activity throughout the area (Thybo 1997). The transtensional displacement was introduced by dextral strike-slip on the TTZ in the triangular area of the TF area of the Baltic Shield. The northeastern termination of the Tornquist Fan largely coincides with the inversion zone STZ and the

southwestern termination has been named the Trans-European Fault in northernmost Germany close to Denmark (Berthelsen 1992).

To the south of Poland, the structures of the TTZ have partly been overprinted by the structures related to the Carpathian Mountains, and its termination in the Black Sea has, so far, not been imaged.

Much new knowledge on TESZ was obtained during the EGT (European GeoTraverse) and EUROPROBE pan-European large-scale geoscientific programs in the 1980s

and 1990s. These programs included projects for integrated geophysical-tectonic-geological studies of the TESZ, usually centered around major acquisition of new deep seismic, wide-angle reflection and refraction, as well as normal-incidence reflection seismic data in the northwestern part of the TESZ, such as in the EUGENO-S, BABEL, and POLONAISE projects, as well as the TOR broadband seismological project. Other projects applied similar approach, including the major CELEBRATION2000 refraction (region 2 and 3 in Fig. 1a, Guterch et al. 2003) and MONA LISA high resolution reflection/refraction (region 1 in Fig. 1a) seismic projects, as well as the PANCAKE and VRANCEA seismic projects in region 3 and the DOBRE 4 and 5 projects in region 4.

Geologic-Tectonic Overview

The East European Craton (EEC) includes the sediment-covered East European Platform and the Baltic and Ukrainian Shields, where basement rocks outcrop. The Trans-European Suture Zone (TESZ) forms the transition zone between cratonic Europe and the tectonically younger western Europe, which formed by amalgamation of a series of terranes onto proto-Europe during the Phanerozoic. The main periods in the evolution of TESZ include the Caledonian (mid Palaeozoic) and Hercynian (late Palaeozoic) orogenies as well as activity in relation to the Africa-Europe collision, affecting the Carpathians and creating inversion tectonics along most of TESZ.

TESZ at the edge of the EEC includes four distinct zones (Fig. 1), which each show unique geophysical properties and structure that attests to a complex evolution and relation between deep and shallow Earth processes topography:

1. The Tornquist Fan around the Danish area, where the craton to non-craton transition splits into a 60° wide fan of fault zones that were active in a dextral transtensional environment in the late Palaeozoic (Thybo 1997). The transtension created a series of deep graben structures. This development was associated with major volcanic and magmatic activity that created huge mafic batholiths in the crust. Their solidification and cooling may have caused the formation of the up-to 5 km deep, late Palaeozoic to early Mesozoic, broad Danish-Norwegian sedimentary basin in the region. The upper mantle shows pronounced variation and contrasts in seismic velocity over a depth interval of >150 km which is not manifested in the gravity signal. The Tornquist Fan shows significant short-wavelength variation in crustal thickness and average seismic velocity. The inversion zone, STZ, formed at the NE edge of the Tornquist Fan, where the strong and thick crust of the Baltic Shield may have acted as a back-stop to Alpine compression (EUGENO-S Working Group 1988).
2. The cratonic margin in central Europe is coincident with the more than 20 km deep Polish basin. The processes that formed this deep basin are not well understood, and probably include transtension as in the Tornquist Fan. TESZ is generally characterized by major crustal thinning from the >45 km thick cratonic crust to the <35 km Caledonian/Variscan crust. However, the crustal thickness and velocity structure within the TTZ part of TESZ is variable along strike between generally thin crust in the NW and thick crust in the SE (Guterch et al. 2003). It was recognized in the 1980s that the TTZ was underlain by a Moho keel in parts of Poland, similar to the basement horst at Bornholm at the transition between TTZ and STZ. Lithosphere thickness changes abruptly across TESZ from <60 km in the SW to >150 km in the NE. Palaeozoic subduction along the entire central European Tornquist Zone has been proposed but not documented. The Alpine-related inversion also created a tectonic inversion zone within the TTZ in Poland. The magnetic lineament of TTZ and the inversion zone generally are co-located, probably because the craton edge also here acts as a backstop to compression.
3. The TESZ has been overprinted by structure related to the formation of the Carpathian Mountains in zone 3. The geometry of the bends of the Carpathian Mountains suggests a strong effect of the craton edge on the deformation processes in the adjacent younger lithosphere. The recent PANCAKE seismic project has documented a strong change in crustal thickness and velocity across TESZ from the ca. 50 km thick crust with high average velocity in the craton, across an up-to 25 km deep basin as in Poland, but here overthrust by the Carpathians, to the young Pannonian Basin with low average velocity crust thinner than 25 km (Starostenko et al. 2013a).
4. The southeastern end of the TESZ around the Danube Delta at the Black Sea may have been significantly affected by Devonian rifting, which also affected large parts of the EEC. The resulting crustal structure shows very little variation in depth to Moho and average velocity between the EEC and Phanerozoic Europe (Starostenko et al. 2013b). This region may have been affected by the closure of the Tethyan Oceans and the formation of the deep Black Sea. One may speculate if the processes associated with closure of the Palaeo-Tethys ocean may have formed background for the rifting that initiated subsidence, which may still be ongoing.

Geophysical Signature of TESZ

TESZ has been covered by a dense network of deep seismic profiles since the international profiling in Eastern Europe in the 1960–1970s and boosted by a series of pan-European programs up to the turn of the millennium (Fig. 1a).

Crustal Profile

The crustal structure displays short-wavelength variation in both seismic velocity and thickness, cf. the generalized seismic profile in Fig. 2. The crust on the western side of TESZ is almost everywhere less than 35 km thick and has very small average velocity in the terranes that were accreted to proto-Europe during the Phanerozoic. On the contrary, the cratonic crust on the eastern side of TESZ is generally more than 45 km thick and has high average velocity. Some localized sedimentary basins (aulacogens that probably formed as rift zones) have slightly thinner crust, although the major aulacogen, the Dniepr-Donetsk Rift, today shows no crustal thinning, but instead is underlain by a thick high-velocity crustal layer. This observation may be explained by magma-compensated crustal thinning as recently observed at many active and extinct rift zones (Thybo and Nielsen 2009).

TESZ is characterized by abrupt change in average velocity and crustal thickness (Artemieva and Thybo 2013). It includes deep sedimentary basins in all subregions. It appears that the abrupt change in lithosphere structure across TESZ has made it a favorable location for formation of extensional and transtensional/strike-slip basins. It is characteristic that the Carpathian Mountains were thrust over the sedimentary basins and that their formation did not cause crustal thickening.

Gravity and Magnetic Signature

A characteristic lineament in the magnetic anomaly field (Fig. 3a) was one of the original observations of TTZ in central Europe (region 2 and 3). Here, the magnetic anomalies change abruptly from very high amplitude with short-wavelength variation in the cratonic regions to smooth, low-amplitude anomalies in the west. These differences relate to

the crustal composition and cannot be solely explained by the presence of the sedimentary cover in the west, which is evident from the observation that the sharp, abrupt change in several places occurs inside the thick sedimentary basins in TTZ and STZ.

The magnetic transition occurs gradually in the regions at the ends of TESZ (regions 1 and 4). This is particularly clear across the Tornquist Fan, which shows strong amplitudes despite the crust is relatively thin and hot. The high amplitudes have been explained and modeled by the presence of major volcanic and magmatic bodies within the sedimentary sequences and crystalline crust superimposed on the highly magnetic original Baltica crust (Thybo 1997).

The Bouguer gravity anomaly across the TESZ (Fig. 3b) is surprisingly constant despite the abrupt change in crustal thickness. Likewise, the free air gravity anomaly (Fig. 3c) shows relatively little change across the TESZ from generally 0 mGal in the east to +10 to +20 mGal in the west, apart from the Carpathian and SW Norwegian mountain ranges, indicating general isostatic equilibrium of the lithosphere which, however, may not necessarily indicate crustal isostasy.

The largest negative Bouguer anomalies are observed in a linear belt along TTZ in region 3 to 4, including the Carpathian Mountains and the Moesian platform. Deep seismic profiles indicate that the crust has low velocity in this area, which together with the presence of a thick sedimentary cover may explain the observed negative gravity anomaly, although the thin crust would indicate positive anomalies. Likewise, the deep sedimentary basin in region 2 has negative Bouguer gravity anomalies which also may be explained by the presence of the sedimentary cover together with relatively low density crust as indicated by low seismic velocity.

Trans-European Suture Zone, Fig. 2 Generalized profile across TESZ along 49° (for location see Fig. 1b) based on the EUNASEIS database (Artemieva and Thybo 2013). Overall, the crustal thickness increases from Phanerozoic Europe in the west to cratonic Europe in the

east, accompanied by a general increase in velocity from west to east. Notice the strong short-wavelength variation in crustal thickness and velocity

Trans-European Suture Zone, Fig. 3 Maps of total magnetic field (a), Bouguer gravity (b), and free air gravity (c) anomalies in the TESZ region. Notice the sharp change in the magnetic field from the strongly magnetized crust in cratonic Europe in the east to the weakly magnetized

crust in Phanerozoic Europe in the west. The Bouguer gravity field is relatively stable across the TESZ despite the substantial change in crustal thickness. Free air gravity anomalies within ± 30 mGal indicate that the region is generally in isostatic equilibrium

The Tornquist Fan (region 1) generally includes large positive Bouguer anomalies (>50 mGal). These anomalies are interpreted by the presence of huge mafic magmatic batholiths within the crust (Thybo 1997), as identified from high-seismic velocities.

Crustal Structure from Seismic Data

The deepest sedimentary basins around TESZ occur in its northwestern end along the linear TTZ in Poland and within the Tornquist Fan, in particular along the Trans-European Fault Zone (Fig. 4a). Here the basins attain thicknesses of more than 20 km. Similar deep sedimentary basins extend all along the TTZ almost to the Black Sea coast.

Due to the dense coverage by seismic profiles in the whole TESZ region, it is possible to contour a detailed

map of depth to Moho (Fig. 4b; Artemieva and Thybo 2013). Generally, Moho is deep (>45 km) in the cratonic regions and shallow (<35 km) in younger Europe. The almost abrupt transition between these two regions occurs along the TTZ and, more transitional, in the Tornquist Fan region. The Moho depth change is also transitional in the SE end of TESZ. Very thin crust is observed in the rifted North Sea region to the NW of TESZ and in the region around the Black Sea, which may include crust of oceanic origin.

The crystalline crust (Fig. 4c) shows similar thickness variation with cratonic crust being >45 km thick and the crust in younger Europe being <30 km thick. Below the thick sedimentary basins, the crystalline crust is exceptionally thin in most of the Tornquist Fan region.

Trans-European Suture Zone, Fig. 4 (continued)

The differences in Moho depth and thickness of the crystalline crust between east and west is mainly due to the presence of a lower-crustal layer with very high seismic velocity (>6.8 km/s) in the eastern cratonic regions, which we interpret as a layer of mafic composition (Fig. 4d). Such layers are usually observed in cratonic regions, and its thickness may have to some degree increased by localized underplating since the initial formation of the cratonic crust. This may in particular be the case in the Tornquist Fan during its extensive magmatic-volcanic evolution in the late Paleozoic.

It is remarkable that no high-velocity lower crustal layer is observed in Caledonian and Variscan Europe. Such layer appears absent throughout this region, despite several of the docking terranes are believed to originate from the Gondwana supercontinent, and therefore expectedly would include such lower crustal layer. It has been proposed that a mafic layer originally was present in these terranes up to the Gondwana-Laurentia collision, and that crustal thickening and the formation of a crustal root during the Variscan orogeny may have led to pressure induced metamorphic reactions that formed eclogite facies rocks from the original mafic lower crust.

Trans-European Suture Zone, Fig. 4 Maps showing seismic properties of the crust around TESZ. (a) Thickness of the sedimentary cover, showing a series of very deep sedimentary basins concentrated in TESZ along the TTZ and around the TF area. (b) Moho depth showing a strong change from thick crust in cratonic Europe to the east to thin crust in Phanerozoic Europe in the west. (c) Thickness of the crystalline crust

showing an even more pronounced change than for the crustal thickness. (d) Thickness of the lower (mafic) crust, showing that the difference in thickness of the crystalline crust mainly is caused by the lack of mafic lower crust in Phanerozoic Europe in the west. (Figure after Artemieva and Thybo (2013))

Trans-European Suture Zone, Fig. 5 Mantle properties in the TESZ region. **(a)** Lithosphere thickness (from Artemieva, 2019), showing the generally very thick lithosphere in cratonic Europe and thin lithosphere in Phanerozoic Europe in the west. **(b)** S-wave velocity anomalies at 100 km depth, showing a change from high velocity in the east to low

velocity in the west for the lithospheric mantle. **(c)** Residual mantle gravity anomalies calculated by subtracting the crustal contribution from the observed gravity field, showing that TESZ marks a transition from high density in the east to low-density in the west for the lithospheric mantle

Some authors have proposed that the formation of such dense lower crustal layer could have led to its delamination. The existence of the presently very thin lithosphere in this region may provide some support to this model, although an alternative interpretation would be that the eclogitic rocks are still present below the seismic Moho with seismic velocities and densities similar to peridotitic upper mantle.

Lithospheric Mantle in TESZ

The lithosphere thickness variation in the TESZ region generally shows similar variation as the crustal thickness. Although the lateral resolution is lower than for the crustal thickness, it appears that the variation occurs over a narrow zone between the very thick (>250 km) lithosphere below the cratons and the very thin (<60 km) lithosphere in Caledonian/Variscan Europe (Fig. 5a; Artemieva et al. 2006). The thin lithosphere in southern Norway (NW part of the map in Fig. 5a) indicates that the extensional tectonics and magmatism within the Tornquist Fan affected the whole lithosphere.

A map of S-wave anomaly at a depth of 100 km in the TESZ region shows a very distinct and abrupt change at the TTZ between very high velocities in the cratonic regions and very small velocities in younger Europe (Fig. 5b). This change in velocity may be partly due to a temperature change between craton and platform, but studies have shown that a substantial part of the change is caused by compositional change. It is remarkable that the Tornquist Fan area has intermediate S-wave velocity at 100 km depth.

This interpretation is supported by calculated residual mantle gravity anomalies (Fig. 5c), which show a similar abrupt change across the TTZ between large positive values in the cratonic regions and negative values in younger Europe. The variation in values (300 to –200 mGal) is pronounced, not least considering that neither Bouguer nor free air anomalies show any significant anomalies (generally less than 40 mGal in total, Fig. 3). Also the mantle gravity values in the Tornquist Fan are similar to the values for young Europe despite the crustal structure and the age of the basement rocks suggest a cratonic origin.

Conclusions

The NW-SE trending Trans-European Suture Zone (TESZ) forms the most pronounced geophysical- tectonic-geological transition zone in Europe affecting the whole lithosphere. It marks the transition between the Precambrian cratonic regions in the northeast and younger Europe, formed by amalgamation of a series of generally Gondwana-derived terranes, in the southwest.

TESZ was originally observed from a clear lineament in magnetic anomalies between high-amplitude, low-wavelength

anomalies in the east, and low-amplitude, long-wavelength anomalies in the west. It is observable by lithospheric anomalies in all geophysical parameters. Seismic velocities and densities are large on the cratonic side and small on the western side, both in the crust and lithospheric mantle. The crust and lithosphere are thick on the cratonic side and thin on the western side. Some of the very deepest sedimentary basins in Europe are located within TESZ and a major late-Palaeozoic volcanic-magmatic region is observed in the Tornquist Fan region in northwestern TESZ.

Traveltime Tomography Using Controlled-Source Seismic Data

Colin A. Zelt

Department of Earth Science, Rice University, Houston, TX, USA

Synonyms

Active-source data; Traveltime inversion

Definition

Controlled-source seismology	Determination of earth structure using seismic waves generated by artificial sources such as chemical explosives, mechanical vibrators, weight drops, gun shots, etc.
Tomography	Determination of model structure by back projection of the data along a path connecting a source and a receiver.
Traveltime	The total time for a particular wave to travel from a source to a receiver.

Background

Traveltime tomography is the main method by which the Earth's seismic velocity structure is determined on all scales, from the upper few meters to the whole mantle. It was adapted from algorithms used in medical imaging in the 1970s (Dziewonski and Anderson 1984). In seismology, the term tomography refers to the back projection of data along a path connecting a source and receiver using a mathematical inverse method. Ideally, the traveltimes of seismic arrivals corresponding to many criss-crossing rays are used to construct a two-dimensional (2D) or 3D image of the Earth's seismic velocity variations. Tomography is a type of inverse problem, although the terms traveltime inversion and traveltime tomography are used in the seismological community without a well-defined distinction. The latter usually implies a uniform, fine grid model parameterization, in which a smooth model is sought. Any departure from this approach is usually referred to as traveltime inversion, although the distinction is somewhat arbitrary (Levander et al. 2007); this article will discuss both approaches. This article concerns traveltime tomography using controlled-source data and does not discuss other types of tomography that use seismic amplitudes, phases, or waveforms as input data, nor earthquake or surface-wave data.

Data from earthquakes and artificial (controlled) sources are used in traveltime tomography, the former usually for crustal or mantle structure, the latter usually for crustal or near-surface structure. Much of the theory and practice of traveltime tomography is the same or similar for controlled-source and earthquake data. However, earthquake tomography usually uses delay times and includes a determination of the source locations (hypocenters), whereas controlled-source tomography usually uses total times and the source locations are known very accurately. Also, the degree of lateral velocity heterogeneity in the crust, and in particular the near-surface, can be much greater than in the mantle, so there is often no sense of a reference model in controlled-source seismology as there is in earthquake seismology, and this in turn means that a nonlinear tomographic method must be applied to controlled-source data in which the rays must be determined along with the unknown velocity structure as part of the inverse problem. Finally, controlled-source data are often acquired using sources and receivers distributed along a straight or nearly straight line, yielding a so-called 2D dataset. In this case, 2D modeling is used in which lateral homogeneity perpendicular to the line is assumed. Earthquake tomography is almost always 3D given the typical distribution of earthquakes and stations. Today, 3D controlled-source data is not uncommon, but it is expensive to acquire, especially for crustal-scale studies. In some studies, both earthquake and controlled-source data have been inverted simultaneously (e.g., Ramachandran et al. 2005).

Controlled-source seismology can be divided into two main approaches: (1) near-vertical reflection methods, and (2) refraction/wide-angle reflection methods. Traveltime tomography is applied to data from both experiments, although it is more common for refraction data. The most common applications of traveltime tomography using controlled-source data are (1) tectonic studies of the crust and uppermost mantle, (2) earthquake risk studies for upper crustal fault and basin geometries, (3) petroleum exploration in crosswell studies, model building to facilitate migration, and for refraction statics, and (4) environmental/engineering studies of the near surface (as shallow as a few meters). The traveltimes utilized are often limited to those of the first arrivals corresponding to direct, refracted (turning) or diffracted waves. Sometimes the traveltimes of primary reflections are included, for example, from the basement overlying sediments or the crust-mantle (Moho) boundary, necessitating the need for layers or interfaces in the model parameterization. Only rarely are later refracted arrivals, multiples or conversions utilized. Traveltimes are picked from the seismograms usually either interactively by eye, or using a semi-automated scheme whereby a few picks are made interactively, and the intervening picks are determined automatically using a cross-correlation scheme (Zelt 1999). Usually

only very high quality, spatially-dense data can be picked using fully automated schemes.

Most controlled-source tomography uses only P-wave traveltimes to constrain the compressional wave-velocity structure because P wave are easiest to generate and therefore the P wave arrivals are usually the strongest and easiest to pick. However, S wave experiments are quite common in environmental/engineering studies (e.g., Chambers et al. 2009). Theoretically, traveltime tomography is the same for P- and S-wave data, and if both data are available in the same study, Poisson's ratio can be estimated. The forward modeling component of traveltime tomography is almost always based on ray theory, an infinite-frequency approximation of wave propagation, although recently a finite-frequency approach

for controlled-source data has been proposed (Zelt 2009). Almost all applications of traveltime tomography assume isotropic media because it is rarely necessary to invoke anisotropy to model the observed data. Exceptions to this are mainly for crosswell data and in studies of the oceanic crust (e.g., Pratt and Chapman 1992; Dunn et al. 2000). Traveltime tomography is applied to land and marine data, as well as onshore-offshore data, using the same tomographic methodology. Arrays of airguns are the most common marine source, while on land chemical explosives, mechanical vibrators, weight drops, hammers, shotguns and rifles are common sources.

The ideal dataset for traveltime tomography is one with as dense a spacing of sources and receivers as possible, along a

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 1 Shallow crustal example from the South Portuguese Zone fold-and-thrust belt of first-arrival tomography by Schmelzbach et al. (2008) using the smoothing-regularized Zelt and Barton (1998) algorithm to seek a minimum-structure model. There were 99 shots (grey stars) along the crooked line. (a) Velocity model obtained by projecting all the data onto a straight line and performing a 2D inversion. (b) Velocity model

obtained by performing a 2.5D inversion that preserves the true positions of all shots and receivers. (c) Rays projected into the horizontal plane for the 2.5D modeling to illustrate the extreme crookedness of the experiment. Model regions not sampled by rays are grey. The models in (a) and (b) are very similar, confirming the appropriateness of 2D modeling of traveltime data, even in the case of extreme crooked lines

line for a 2D experiment, or areally distributed for a 3D experiment. As a result, a subsurface point will be sampled by rays at as many different angles as possible, which in turn will yield the best possible spatial model resolution as discussed later. There is usually very little processing of seismic data before traveltime picking, only that required to “clean up” the data to make it easier for picking. This may include bandpass filtering, trace editing, velocity filtering, trace mixing or binning, or deconvolution. Picks should not be interpolated to provide uniform spatial coverage if there are significant trace gaps, since this will provide an incorrect sense of model constraint (Zelt 1999). Uncertainties should be assigned to the pick times to avoid over- or under-fitting the data, and to allow the appropriate up- and down-weighting of less noisy and more noisy data, respectively (Zelt 1999). Elevation or bathymetric corrections should be avoided as they depend on the unknown velocity structure. Instead, the known surface topography or bathymetry should be incorporated into the 2D or 3D model. For a 2D experiment in which the shot and receiver locations deviate significantly from a straight line, it may be necessary to perform 2.5D modeling, i.e., using a 3D model and 3D ray tracing, and the known topographic or bathymetric surfaces, but keeping the velocity model homogeneous in a direction perpendicular to the main trend of the profile (e.g., Van Avendonk et al. 2004). Given the spatial resolution of most velocity models derived from traveltime tomography, the degree of profile “crookedness” must be substantial to warrant 2.5D modeling (Schmelzbach et al. 2008; Fig. 1).

There are several review papers relevant to this article. Nowack and Braile (1993) review traveltime tomography methods in 1D and 2D media. Zelt (1999) focuses on 2D traveltime tomography and inversion, as well as model assessment methods. Rawlinson and Sambridge (2003a) present an overview of traveltime tomography for 2D and 3D structure. Levander et al. (2007) review all aspects of crustal-scale controlled-source seismology, including traveltime tomography.

Forward Modeling

In the 1970s, ray theory, an infinite-frequency approximation of wave propagation, for laterally heterogeneous media was developed (Cerveny et al. 1977; McMechan and Mooney 1980). This allows earth models of arbitrary 2D and 3D complexity to be considered, provided the tenants of ray theory are honored, that is, the velocity field varies slowly with respect to the seismic wavelengths. Sharp velocity changes are modeled as velocity discontinuities (layer boundaries) using Snell’s law. As a result, ray theory models are typically composed of one or a few layers, bounded by smoothly varying interfaces, within which the velocity varies

smoothly. Ray theory forms the basis for the forward modeling used today in almost all traveltime tomography algorithms. There are two main types of infinite-frequency modeling: ray tracing and wavefront tracking.

Two end-member approaches to ray tracing are used: numerical and analytical. In the former case, the velocity field is specified by a regular (e.g., McMechan and Mooney 1980) or irregular (e.g., Zelt and Ellis 1988) grid of nodes, together with a scheme for interpolation between nodes, and a ray is traced by specifying a take-off angle from a point source and solving a set of ordinary differential equations, the ray tracing equations (Cerveny et al. 1977). In the analytic case, the velocity field is specified by a regular (e.g., Chapman and Drummond 1982; White 1989; Rawlinson et al. 2001) or irregular (e.g., Spence et al. 1984) grid of nodes, but with a form of interpolation, for example linear, such that the rays can be calculated analytically within each cell of the grid. In practice, the numerical and analytical techniques may be about equally efficient if the analytical method uses a fine grid of nodes to represent a sufficiently smooth velocity field as required by ray theory, and if the numerical scheme adjusts the step length according to the velocity gradient (Zelt and Ellis 1988).

For an arbitrary 2D velocity model, a non-trivial consideration is the determination of ray take-off angle from the source such that an arbitrary receiver location is reached, or such that a particular layer or interface in the model is reached. Today, most 2D ray tracing algorithms offer an automatic determination of take-off angles by shooting trial rays followed by a bisection scheme to sufficiently refine the take-off angles so that the receivers are hit (e.g., Zelt and Smith 1992). The robustness of the shooting method is crucial because the data from receivers for which it is not possible to find rays will not be used in the inverse step. Also, it is important to be sure that an inability to find rays is because of the velocity model, e.g., a shadow zone, as opposed to a shortcoming of the ray tracing algorithm.

To avoid the limitations of shooting/bisection algorithms, particularly for 3D models, ray bending methods were developed (Um and Thurber 1987). In this approach, a ray connecting a source and receiver is estimated, typically using a 1D reference model, and the ray’s path is iteratively updated using Fermat’s principle until the minimum time path is determined. In practice, shooting methods are more efficient and sufficiently robust for 2D models, whereas bending methods are favored for 3D models.

In the late 1980s, a new infinite-frequency forward modeling approach was introduced in which first-arrival traveltimes are calculated on a fine grid using a finite-difference solution of the eikonal equation (Vidale 1988, 1990; Podvin and Lecomte 1991). Rays are obtained by following the gradient of the time field. These methods are known as wavefront tracking algorithms. Reflected rays can be calculated in a

two-step procedure by calculating downgoing and upgoing wavefronts (Hole and Zelt 1995). Hole and Zelt (1995) also presented a modification to Vidale's approach which otherwise breaks down for velocity contrast of more than ~40%. The advantage of wavefront tracking methods is that they find the ray between any two points with the shortest traveltime, including the diffracted path in the case of a geometrical shadow zone, and they can be very efficient, especially for 3D models. The disadvantages are that they are computationally cumbersome for calculating later arrivals, and they can be inaccurate and/or computationally intensive for high-contrast media. Another type of wavefront tracking scheme that solves the eikonal equation is the fast-marching method, which is computationally efficient and unconditionally stable (Sethian and Popovici 1999).

Nakanishi and Yamaguchi (1986) and Moser (1991) introduced the shortest path ray-tracing method based on Fermat's principle which uses a fine network of nodes and graph theory. It is capable of handling arbitrarily heterogeneous media and calculating first arrivals, reflections, and multiples. Its advantages over other methods are robustness and the fact that the grid does not have to be rectangular or regular. However, its memory and computation requirements are greater. Van Avendonk et al. (2001) developed a hybrid of the shortest path and ray bending methods that uses the shortest path algorithm to find an initial ray, and then refines it using a bending method. The result is an efficient and robust algorithm to calculate accurate traveltimes and rays for refractions and reflections in 2D and 3D media.

Traveltime Tomography and Inversion

The traveltime t between a source and receiver along a ray L is given in integral form for a velocity field $v(\mathbf{r})$ as

$$t = \int_L \frac{1}{v(\mathbf{r})} dL$$

where $\mathbf{r}$ is the position vector in 2D or 3D media. This is a nonlinear inverse problem given the relationship between the measured data (traveltimes) and the unknown model parameters (the velocity field). However, by transforming variables to use slowness $s(\mathbf{r})$, the reciprocal of velocity, instead of velocity as the unknown, a seemingly linear inversion problem is created:

$$t = \int_L s(\mathbf{r}) dL.$$

However, the ray L is also dependent on the velocity (or slowness) model, thus making the inverse problem

nonlinear regardless of what form of model variable or parameterization is used. In global seismology, a 1D (radially-symmetric) earth model is often used to predict the rays given the relatively small velocity heterogeneities in the mantle, and thereby converting the inverse problem into a linear one. In controlled-source seismology, there is no concept of a reference model that is sufficiently accurate to predict the rays in advance given the relatively large velocity heterogeneities that are typically encountered in the crust. This means the controlled-source tomography or inverse problem is always treated as a nonlinear one. This also means the model can be parameterized any number of ways using velocity or slowness, and cells, nodes, or splines, since the problem's nonlinearity must be dealt with regardless of the parameterization. Most often a linearized gradient approach is applied in which a starting model is used and both the model and rays are updated over a series of iterations with the hope that there will be convergence to an acceptable model (the final model).

The model is almost always discretized using cells, nodes, splines, or other interpolating functions; in the latter two cases, the discrete model parameters are the coefficients of the interpolating functions. In the simplest formulation of the tomography problem, the model is parameterized using constant-slowness cells, in which case the equation for the i th data becomes

$$t_i = \sum_j l_{ij} s_j$$

where l_{ij} is the length of the i th ray in the j th model cell and s_j is the slowness in the j th cell. In vector-matrix form this is

$$\mathbf{t} = \mathbf{L}\mathbf{s}.$$

Applying a Taylor series expansion to this equation keeping only the linear term and assuming the rays are independent of slowness yields the perturbation equation

$$\delta\mathbf{t} = \mathbf{G}\delta\mathbf{s}$$

where $\delta\mathbf{t}$ is the data misfit vector equal to the difference between the observed traveltimes and those predicted by a prior model, and $\delta\mathbf{s}$ is the difference between the unknown slowness model and the prior slowness model; the unknown model is also called the estimated model. The partial derivative matrix, $\mathbf{G}$, contains the elements $g_{ij} = \partial t_i / \partial s_j$, and for the constant-slowness cell parameterization, $g_{ij} = l_{ij}$, or $\mathbf{G} = \mathbf{L}$. In the general case, the elements of the partial derivative matrix are $g_{ij} = \partial t_i / \partial m_j$ where m_j is the j th model parameter, which could be the velocity at a node or the coefficient of an interpolating function, or the position of an interface within

the velocity model (e.g., Zelt and Smith 1992). In the general case, the perturbation equation becomes

$$\delta \mathbf{t} = \mathbf{G} \delta \mathbf{m}.$$

The elements of the partial derivative matrix $\mathbf{G}$ are usually calculated analytically to avoid the potential inaccuracy of numerical differencing and the extra computation needed to trace additional rays. The approximations involved in the analytic partial derivatives, e.g., the stationary ray assumption, are typically not a problem since the resultant gradient direction in model space will be improved over a series of iterations.

The perturbation equation is not solved directly because the unknown model parameters are typically under- or mixed-determined (Menke 1989), depending on the model parameterization; with relatively few model parameters, it is possible for the problem to be overdetermined, but even in this case the perturbation equation is not solved directly because it is wise to constrain the magnitude of the model perturbation to avoid violating the linearization assumption. Thus, model constraints, in addition to the observed data, are usually included to stabilize the solution. Also, all observed data contain noise and to avoid over-fitting noisy data, additional model constraints are required to select one model from an infinite number that will statistically predict the observed data at the equivalent desired misfit according to the estimated noise level. This issue points out the non-uniqueness of all inverse problems involving real data, regardless of whether the system of equations is overdetermined or underdetermined.

The additional model constraint is called regularization (e.g., Scales et al. 1990), and in addition to stabilizing a

solution, it is an effective way of steering the solution towards models with desirable pre-defined characteristics. The regularization is most often in the form of the zero-, first- or second-order spatial derivatives of the estimated model parameters, or their perturbation from a background model. This is because it is often desirable to seek an estimated model that is as close as possible to another model, and/or a model that has a minimum structure as measured by its spatial derivatives in keeping with Occam's principle (Constable et al. 1987). Regularization is always arbitrary, and the specific form of regularization that is best for a particular problem depends on the model parameterization, the data, including its coverage and noise level, and the experimental objectives.

The most common forms of regularization in traveltime problems are the minimization of the model's perturbation from a background model, and/or the minimization of the second-order spatial derivative of either the model, or its perturbation from a background model. A model with minimum perturbation is called the smallest model; a model with minimum second-order derivative is called the smoothest model. Any combination of model constraints may be included as a part of the regularization to form the objective function, $\Phi(\mathbf{m})$, where $\mathbf{m}$ is the vector containing the estimated model parameters. The objective function usually measures the square of the data misfit vector and the square of the perturbation or spatial derivative operators comprising the regularization so that minimizing the objective function leads to a linear system of equations that is amenable to efficient algorithms for their exact or approximate solution. One example of an objective function for the traveltime problem is

$$\Phi(\mathbf{m}) = \delta \mathbf{t}^T \mathbf{C}_d^{-1} \delta \mathbf{t} + \lambda \{ \beta [\alpha (\mathbf{v}^T \mathbf{W}_h^T \mathbf{W}_h \mathbf{v} + s_z \mathbf{v}^T \mathbf{W}_v^T \mathbf{W}_v \mathbf{v}) + (1 - \alpha) \Delta \mathbf{v}^T \mathbf{W}_p^T \mathbf{W}_p \Delta \mathbf{v}] + (1 - \beta) [\mathbf{z}^T \mathbf{W}_z^T \mathbf{W}_z \mathbf{z}] \}$$

where $\mathbf{m} = \mathbf{v} + \mathbf{z}$; $\mathbf{v}$ and $\mathbf{z}$ are vectors containing the estimated model parameters defining the velocity (or slowness) field and the interfaces (if any); $\Delta \mathbf{v}$ is the velocity perturbation vector equal to $\mathbf{v} - \mathbf{v}_0$, and $\mathbf{v}_0$ is the background velocity model vector. $\mathbf{C}_d$ is the data covariance matrix containing the estimated pick uncertainties providing the appropriate up-weighting and downweighting of the low-noise and high-noise data, respectively. $\mathbf{W}_h$ and $\mathbf{W}_v$ are the horizontal and vertical roughness matrices containing the second-order spatial finite-difference operators that measure the roughness of the velocity field in the horizontal and vertical directions, respectively; $\mathbf{W}_p$ is the velocity perturbation weighting matrix which is a diagonal matrix containing the weights applied to the perturbation between each estimated and background velocity model parameter; $\mathbf{W}_z$ is the interface roughness

matrix containing the second-order spatial finite-difference operators that measure the roughness of the interfaces. When applying spatial derivative operators to the velocity field, it is common to use different operators to measure the horizontal and vertical structure, and weight these differently, since one would normally expect the earth to contain more heterogeneity vertically compared to horizontally. Any or all of these operators may be normalized by the reference model values so that relative quantities are penalized as opposed to absolute values (e.g., Toomey et al. 1994). In addition, the operators can be weighted according to their spatial position in the model, e.g., penalize model structure more in the deep portion of the model versus the shallow portion since one would generally expect decreasing resolution with depth.

There are four free parameters in this example objective function to control the relative weight of each term. λ determines the overall amount of regularization, that is, the trade-off between fitting the data and constraining the model; β determines the trade-off between velocity and interface regularization; α determines the trade-off between second derivative and perturbation regularization of the velocity parameters; and s_z specifies the relative weight of vertical versus horizontal smoothing regularization of the velocity parameters. In some algorithms, λ is not a free parameter because it is reduced automatically by the algorithm at each iteration from a free-parameter starting value, λ_o (e.g., Zelt and Barton 1998). The reduction of λ stabilizes the inversion by constraining the long-wavelength structure in the initial iterations and allowing progressively finer model structure to enter in later iterations.

Minimizing the objective function with respect to the unknown model parameters ($\mathbf{v}$ and $\mathbf{z}$) leads to a linear system of equations that may be relatively small or very large, depending on the number of data and model parameters. If the linear system is large, it will also typically be very sparse (at least 99.9%), in which case there are efficient algorithms for their solution (e.g., Paige and Saunders 1982; Rawlinson et al. 2001). If the linear system is relatively small, it can be solved directly using standard matrix inversion routines, such as LU decomposition (Press et al. 1992).

The objective function presented is designed to illustrate in a single example the different types of regularization that are most commonly applied. In practice, the objective function will typically be simpler depending on the data, model parameterization, and experimental goal. This objective function can be simplified or modified to correspond to those used in most of the popular traveltime inversion and tomography algorithms used today. For example, the Zelt and Smith (1992) inverse method includes only perturbation constraint on the velocity and interface parameters with respect to the model from the previous iteration; the Zelt and Barton (1998) tomographic method includes only smoothness constraints on the velocity field. Thus, together with their very different model parameterizations to be discussed in the next section, these two algorithms can be viewed as end-members of the same regularized inverse approach, and most algorithms in use today fall somewhere in between. In fact, the main differences between the algorithms discussed in the next section lies not in the details of the objective function, but more so in the form of model parameterization, forward calculation, and the types of arrivals considered.

For layered models, including both velocity and interface parameters in a single inversion scheme, as opposed to solving for each parameter separately, either one after the other, or by alternating between the two, makes the problem significantly more challenging. There will be more model non-uniqueness because of trade-offs between the two parameter

types, and more prior information will be required to deal with the increased ambiguity. Also, more testing will be required to ensure that the tradeoffs are fully understood. But solving for both parameter types simultaneously allows one to explore the trade-offs more thoroughly and is the only way to ensure the overall minimum-structure model is obtained, if that is the objective.

Assuming uncorrelated, Gaussian picking errors, and a model parameterization that does not limit the degree to which the predicted data can match the variability of the observed data, a final model should be chosen that provides a normalized misfit, χ^2 , of one (Bevington 1969).

$$\chi^2 = \frac{1}{N} [\delta \mathbf{t}^T \mathbf{C}_d^{-1} \delta \mathbf{t}]$$

where N is the number of data. A model that provides a χ^2 value less than one means the observed data are being over-fit, and therefore to some extent, the noise in the data is also being fit. Although the χ^2 criterion is a good rule of thumb, there are several instances in which it should not be followed. First, traveltime picking errors are likely not uncorrelated. Second, for spatially sparse data from a region with strong lateral heterogeneities, it may be necessary to use so many independent model parameters in order to achieve $\chi^2 = 1$ that the constraint on some parameters is unacceptably small, in which case fewer parameters may be preferable and a χ^2 value greater than one is allowed (Zelt 1999). An inability to achieve $\chi^2 = 1$ may be because of inconsistent picking, for example for reciprocal pairs, in which case the inconsistencies should either be corrected or used as the basis for assigning the pick uncertainties in the first place (e.g., Zelt et al. 2006a).

Algorithms

This section describes many of the algorithms available today, each with its own capabilities and limitations. Some of the earliest 2D traveltime tomography and inversion algorithms were presented by Firbas (1981) and White (1989) which used regular parameterizations and only first arrivals, and Spence et al. (1985) which allowed an irregular model grid and later arrivals. Lutter and Nowack (1990) and Lutter et al. (1990) developed a 2D inversion algorithm using a regular grid of nodes and numerical ray tracing that allows for the independent inversion of first arrivals and reflections for velocity and interface geometry, respectively. The Zelt and Smith (1992) 2D algorithm is the opposite in many respects. An irregular grid of velocity and interface nodes can be used, and any type of refracted or reflected arrival can be inverted simultaneously for velocity and interface geometry. In addition, unique to the Zelt and Smith (1992) algorithm, it allows any subset of the total set of model parameters to be inverted

for, holding all others fixed, facilitating an automated forward modeling approach and making it straightforward to incorporate prior information. Clowes et al. (1995) used the Zelt and Smith (1992) algorithm to simultaneously invert refraction and reflection times from a network of 2D profiles such that the model parameters at the intersection points were linked to ensure consistency. This approach can be used to infer 3D structure from 2D data, or develop a starting model for full 3D inversion if offline data is available in addition to inline data (e.g., Zelt et al. 1999).

Hole (1992) developed a 3D first-arrival tomography algorithm using the Vidale (1990) forward modeling scheme and back projection to solve for a smooth velocity field. Hammer et al. (1994) developed a 3D first-arrival tomography algorithm specially suited to sparse data using a spectral, continuous function model parameterization. Toomey et al. (1994) developed a 3D first-arrival tomography algorithm to obtain a smooth velocity field in which the velocity grid is “draped” from an irregular bathymetric surface by vertically shearing the columns of nodes to accurately model seafloor relief. Vertically sheared grids are particularly important for marine data, especially at mid-ocean ridges, where a large velocity discontinuity may exist. Other algorithms with sheared grids have been developed by Van Avendonk et al. (1998) and Korenaga et al. (2000), although they are limited to 2D models, but include reflections. The main difference between these two algorithms is the former uses first arrivals that can turn above or below a reflecting interface at which there is no velocity discontinuity, whereas the latter only uses first arrivals that turn above a reflecting interface.

Lailly and Sinoquet (1996) developed a 2D algorithm for inverting reflection times to estimate a smooth velocity model for pre-stack depth migration of reflection data using the wavefront tracking method of Podvin and Lecomte (1991) for the forward calculation (Fig. 2). Zelt and Barton (1998) developed a 3D first-arrival tomography algorithm using smoothing regularization and compared the results with those from the back-projection method of Hole (1992) (Fig. 3). The results showed that for the same level of fit to the data, regularized inversion can provide a simpler model. Zelt et al. (2006b) applied 3D simultaneous refraction and reflection tomography to solve for smooth velocities and multiple interfaces using a sparse crustal-scale 3D dataset (Fig. 4). McCaughey and Singh (1997) and Hobro et al. (2003) developed related 2D and 3D simultaneous refraction and reflection tomography algorithms that solve for smooth velocities and interfaces with the allowance for discontinuities across the layer boundaries (Fig. 5).

Most of the algorithms described above are general purpose in nature and follow more or less from the objective function presented in the previous section. However, more specialized algorithms have been developed and a few are described here to give a sense of what is possible. Hole et al. (1992) developed an algorithm for determining a 3D interface using first arrivals with known velocities above and below the interface. Zhang et al. (1998) inverted traveltime curves instead of points, specifically average slowness and apparent slowness. They claim this balances the contribution from short and long rays, and enhances resolution and convergence speed. Rawlinson and Sambridge (2003b) developed an algorithm for the inversion of refraction and reflection times using

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 2 Synthetic example of reflection tomography for a smooth velocity model by Lailly and Sinoquet (1996) based on real data from a passive margin with a salt structure and a listric fault. (a) True model. The reflectors (white curves) are embedded in the smooth velocity field

and are allowed to cross each other. (b) Estimated model using reflections from the continuous portions of the reflectors (white curves); the parts of the reflectors represented by dashed lines are not illuminated by rays

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 3 Example of 3D first-arrival tomography applied to ocean-bottom-seismometer (OBS) data from the Faeroe Basin to find the minimum-structure model (Zelt and Barton 1998). (a) Model obtained using smoothing-regularized tomography. (b) Model obtained using back-projection tomography method of Hole (1992). Horizontal slices of velocity perturbations with respect to a 1D starting model are shown at

the depths labeled from 2 to 10 km. The OBS locations and shot lines are overlaid on the $z = 2$ km slice. Regions not sampled by rays are blank. Contour interval is 0.1 km/s. Both models provide the same level of fit to the data, but the model from back-projection contains more structure overall. The high-velocity anomaly at $z = 10$ km likely indicates a basement high

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 4 Example of simultaneous 3D first-arrival and reflection tomography of sparse crustal data across the Tintina strike-slip fault in the northern Canadian Cordillera (Zelt et al. 2006b). Left panel shows the lower crustal velocity averaged vertically between 1 and 15 km above the Moho. Center panel shows depth to Moho; dots show reflection

points. Right panel shows the upper mantle velocity averaged vertically between 1 and 15 km below the Moho. Stars are shot locations. The straight lines labeled 21 and 22 indicated the best-fit lines of the crooked profiles containing the receivers locations. Regions not sampled by rays are blank. Dashed line is the surface location of the fault. There is a 0.3–0.4 km/s change in upper mantle velocity across the fault

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 5 Example of simultaneous 3D refraction and reflection tomography of OBS data and coincident single channel reflection profiles over a gas hydrate stability zone offshore Vancouver Island (Hobro et al. 2005). (a) Seafloor depth. (b) Bottom simulating reflector (BSR) depth. (c) BSR depth below the seafloor. (d) Slices through the velocity model at the

seafloor, at 50-m intervals through the hydrate stability zone and immediately above the BSR. Labeled contours indicate velocities (km/s) and color scale marks formal uncertainty estimates. Ten OBS positions and ODP site 889 are marked. Refracted arrivals from above and below the BSR were inverted along with wide-angle and normal-incidence reflections from the BSR

a 3D multi-layered model parameterization. Interfaces are defined by a non-uniform node distribution and velocities vary linearly with depth so rays are calculated analytically as piece-wise circular arcs using a shooting method. Trinks et al. (2005) presented a method for simultaneous refraction and reflection inversion using a 2D layered model parameterization which adapts to non-uniform ray coverage such that the cell size is inversely proportional to the local ray density.

Refraction/wide-angle reflection traveltimes can be jointly inverted with coincident near-vertical reflection times in several ways (Zelt 1999). Arrivals in pre-stack reflection data can be picked and inverted jointly with the wide-angle data, but it is often difficult to pick weak events in pre-stack data. The most common approach is to pick reflections from a stacked reflection section and invert these data simultaneously with the wide-angle data by modeling zero-offset reflections (e.g., McCaughey and Singh 1997; Zelt et al. 2003). One potential

pitfall when using coincident reflection data is incorrectly correlating the near-vertical reflection event with the corresponding wide-angle event or layer boundary; Jaiswal et al. (2006) present a way to avoid this problem. As an alternative to joint inversion, the reflector geometries and interval velocities from stacked data can be used as prior information in the regularization to constrain a layered velocity model (e.g., Bosch et al. 2005).

The close relationship between seismic velocity and density (Brocher 2005) lends gravity data to a joint inversion with traveltime data. Nielsen and Jacobsen (2000) used the Zelt and Smith (1992) algorithm as the basis for a simultaneous inversion of refraction and reflection times with gravity data to derive a layered 2D crustal model. Korenaga et al. (2001) carried out a joint inversion of traveltime and gravity data in which error propagation from the velocity model to the predicted gravity anomalies was taken into account.

Model Assessment

Once a model to explain a particular set of data is developed, model assessment should be used to explore the non-uniqueness, resolution, and errors associated with the model. This is an attempt to quantify the robustness of the model, a process that is not straightforward for nonlinear inverse problems, and different assessment techniques will be appropriate depending on the data, model parameterization, geologic target, and objectives of the experiment. There are two classes of assessment methods: linear and nonlinear. The former methods assume it is valid to consider only a local neighborhood of the final model within which the model-data relationship is linear. The latter methods involve additional nonlinear inversions of the real data or synthetic data using the true source-receiver geometry of the experiment. Linear methods are quick and easy to apply, although potentially less reliable depending on the nonlinearity of the problem. Nonlinear methods are computational intensive, often more so than what was needed to derive the final model, and may require a specialized inversion algorithm. However, nonlinear methods are the only way to properly estimate the final model's robustness. Zelt (1999) and Rawlinson and Sambridge (2003a) describe many of the assessment techniques in use today, while Zelt et al. (2006a) apply several different techniques to the same 3D dataset (Fig. 6).

The simplest form of model assessment is to examine the ray coverage in the model using ray plots or "hit counts" (the number of rays sampling each model parameter). These can be misleading since a limited distribution of ray angles may provide less independent model constraint than expected from the number of rays alone. For example, rays in the uppermost mantle will tend to be sub-horizontal, and therefore capable of providing little lateral resolution. Toomey et al. (1994) used a measure called derivative weight sum (DWS) that equals the sum of the partial derivatives for each model parameter. This is somewhat more meaningful than hit count since it weights the contribution from each ray according to the parameter's sensitivity to that ray. However, it also fails to account for the degree of independence within the ray set. Other common linear assessment measures include an examination of the diagonals of the posterior resolution and covariance matrices (e.g., Zelt and Smith 1992). These are more precise measures since they account for the independence of the ray set, but they are best used in a relative as opposed to absolute sense, since they do not account for the nonlinearity of the problem. Rows of the resolution matrix, known as resolution kernels, provide a spatial sense of the averaging of the true structure by the model (Zelt 1999). Probably the most precise linear assessment method uses singular value decomposition (SVD) since it is able to quantify the nature and degree of model constraint through construction of an orthogonal set of basis vectors that

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 6 Example of model assessment for near-surface 3D first-arrival tomography at a groundwater contamination site (Zelt et al. 2006a) using the Zelt and Barton (1998) regularized inversion algorithm seeking a minimum-structure model. Target of the surface was a low-velocity paleochannel cut into a clay layer running roughly north-south through the center of the survey area. The depth to the clay layer was known from extensive well data in the area; depth-to-clay contours (green) from 7 to 11 m overlay the depth slices at 10 m for this comparison of nine different models. Models displayed as perturbations relative to a 1D starting model; the starting velocity at this depth is 1150 ms/s. The preferred final model is in the center. The other models were obtained by trying two different starting models, different values for five free parameters that control the inversion, and by fixing the model above 3 m at the starting model values. Overall, the preferred model has minimum structure; the model in the lower left appears simpler in this depth slice, but it is rougher vertically

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 7 Example of 2D first-arrival checkerboard test for crustal data from an onshore-offshore experiment across the South American-Caribbean plate boundary at 67°W (Magnani et al. 2009). There were shots and receivers both onshore and offshore. (a–e) show recovered checkerboard anomalies for sizes from 25×2.5 km to 150×15 km. (f)

Estimated lateral resolution of the velocity model using a 2D version of the method presented by Zelt (1998). Regions with better than 25 km resolution are black; regions with worse than 150 km resolution are white. Pink line indicates the land surface and bathymetry. The coast line is at ~160 km. Black line indicates the Moho from the preferred final model

span model space, each with a specified weight in the model reconstruction (e.g., White 1989; Scales et al. 1990).

A nonlinear assessment of the spatial resolution or uncertainty of a single model parameter, or set of parameters, is possible in which the real data and synthetic data are inverted in the same way that the final model was derived, allowing the full nonlinearity of the problem to be accounted for, including trade-offs between model parameters (Zelt and White 1995;

Zelt 1999; Christeson et al. 1999). For spatial resolution, the value of a model parameter is perturbed enough to yield a significant traveltime anomaly with respect to the pick uncertainties. Rays are traced through the perturbed model to calculate a set of perturbed traveltimes. The perturbed data are then inverted using the final model as the starting model. The spatial resolution about the selected parameter will be indicated by the amount that the values of adjacent parameters

differ from their corresponding value in the original final model. If the model is poorly resolved about the selected parameter, then the parameter's perturbation will be smeared into adjacent parameters, perhaps both velocities and interface depths if both parameter types are involved, and the extent of the smearing indicates the spatial resolution. Both positive and negative parameter perturbations should be tested, and it will likely be sufficient to examine only one or two representative velocity and interface parameters for each layer or region of the model.

A parameter-selective algorithm such as the Zelt and Smith (1992) approach allows for a nonlinear estimate of a single parameter's absolute uncertainty (Zelt 1999). The value of the model parameter is slightly perturbed from its value in the final model and held fixed while inverting the observed data involving all other model parameters. The size of the perturbation is increased until the recovered model is unable to fit the observed data as well as the preferred final model based on

an F test comparing the traveltime fits of the preferred and perturbed final models. The maximum parameter perturbation that allows a comparable fit to the observed data is an estimate of its absolute uncertainty. Again, both positive and negative parameter perturbations should be tested, and it will likely be sufficient to examine only one or two representative velocity and interface nodes for each layer or region of the model. A fine grid tomographic approach can also be used to perform tests like these. For example, Zelt and Barton (1998) examined one region of a model where there was significant lateral structure even though the constraint from the ray coverage was known to be low in this area. They added regularization to the inversion to force that region to remain laterally homogeneous and thereby establish the required trade-offs elsewhere in the model.

One of the most common forms of nonlinear model assessment to estimate spatial model resolution is the checkerboard test (e.g., Magnani et al. 2009; Fig. 7). In these tests an

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 8 Example from central India across the Narmada-Son lineament of applying two different traveltime inversion algorithms to the same refraction/wide-angle reflection data (Zelt et al. 2003) to compare the “geological” model with the minimum-structure model. (a) Layered model parameterization using the Zelt and Smith (1992) algorithm; there are 43 velocity nodes (blue dots) and 21 interface nodes (red squares). (b) Velocity model corresponding to parameterization in (a); both first arrivals and reflections from the top of the third layer were used.

(c) Fine-grid model parameterization using the Zelt and Barton (1998) algorithm to seek a smooth minimum-structure model; there are 7018 slowness cells. (d) Velocity model corresponding to parameterization in (c); only first arrivals were used. Only those portions of the models sampled by rays are shown. Isovelocity contours of 5.0 km/s (black) and 6.0 and 6.1 km/s (white) indicated. Shot point locations (black dots) and geologic features labeled above the models. An interpretation of the main features of the geological model in (b) is supported by the minimum-structure model in (d) since it contains the same features

Traveltime Tomography Using Controlled-Source Seismic Data

Seismic Data, Fig. 9 Example of model assessment using a nonlinear Monte Carlo procedure to estimate model variance (Korenaga et al. 2000). (a)

Velocity model for the southeast Greenland continental margin obtained by joint traveltime inversion of first arrivals and wide-angle Moho reflections recorded at 18 OBS's and eight land stations (white circles). This model was obtained by averaging 100 Monte Carlo ensembles. (b) Corresponding standard deviation for velocity and depth nodes; the standard deviation of the Moho is indicated by the width of the grey zone at the base of the crust

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 10 Example of near-surface 3D first-arrival tomography at a groundwater contamination site (Zelt et al. 2006a) using the Zelt and Barton (1998) regularized inversion seeking a minimum-structure model. The Horizontal depth slices from 6 to 14 m displayed as perturbations relative to a 1D starting model. Black contour interval is 100 m/s. Target of the surface was a low-velocity paleochannel cut into a clay

layer running roughly north-south through the center of the survey area. The depth to the clay layer was known from extensive well data in the area; depth-to-clay contours (green) from 7 to 11 m overlay the 8 and 10 m depth slices. This experiment consisted of ~600 shots recorded by ~600 receivers yielding ~360,000 traces, providing 187,877 useable picks for the inversion

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 11 Example of near-surface first-arrival tomography over a buried waste disposal site seeking a smooth model (Lanz et al. 1998). (a) Estimated standard deviation of velocities computed using

200 randomized datasets. (b) Mean velocity model from 200 randomized datasets. (c) Preferred final model from inversion of original picked data. Open circles are shot locations. Arrows indicate landfill borders defined by several other geophysical techniques

alternating pattern of high and low anomalies is superimposed on the starting model from the inversion of the real data. Synthetic data are calculated for the “checkerboard” model, and then inverted using the same starting model and source-receiver geometry as the real data. The recovered model will closely resemble the checkerboard pattern in regions of good constraint, but will otherwise not resemble the checkerboard model. The resolution at different length scales can be estimated by testing anomaly patterns of different sizes. Anomaly patterns with different polarity, registration, and orientation should be tested to average out the effects of changing ray coverage due to the nonlinearity of the problem (Zelt 1998).

Other nonlinear assessment techniques include trying different starting models, different values of the free parameters in the objective function, and exclusion of subsets of the data considered less reliable (e.g., Zelt et al. 2006a; Fig. 6). Using

different model parameterizations and different inversion algorithms can be effective, especially when one inversion algorithm seeks a model that satisfies all notions of what is geological reasonable, and one algorithm seeks the minimum-structure model (Fig. 8; Zelt et al. 2003). In this way, it is possible to determine what model structure is consistent with the data to facilitate hypothesis testing, while at the same time establishing what model structure is required by the data.

Perhaps the most complete and computationally intensive form of model assessment involves a nonlinear Monte Carlo procedure. Many inversions are performed in which randomized data and/or randomized starting models are used. The resulting models are used to compute posterior model covariance and resolution estimates. Zhang et al. (1998) and Korenaga et al. (2000) applied this approach to 2D inversions of first arrivals and reflections (Fig. 9).

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 12 Example of crosswell tomography in which transverse isotropy is assumed and regularization was used to seek a smooth model (Pratt and Chapman 1992). The velocity and anisotropic parameters were solved for simultaneously. (a) Comparison of isotropic velocity model

and horizontal velocity model from anisotropic inversion. The model is 20 m across and 60 m deep. (b) Anisotropy parameters. The amount of anisotropy generally increases with depth, reaching nearly 20%. (c) Symmetry axis orientation. The length of the markers is proportional to one of the anisotropy parameters (epsilon)

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 13 Example of imaging the near-surface weathering layer (i.e. the refraction statics problem) using smoothing regularization (Scales et al. 1990). Shots were placed at either end of the model and there were 100 receivers between them. (a) True model. Refractor velocity is

5000 ft/s. (b) Starting model with blocky thickness variations in the weathering layer. Refractor velocity is 4000 ft/s. (c) Final model. Refractor velocity is 5001 ft/s. The inversion solved simultaneously for a laterally-varying weathering-layer velocity and refractor, and a constant refractor velocity

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 14 Example of first-arrival tomography across the San Andreas Fault comparing models from two different algorithms (Hole et al. 2006). There were 63 shots (red stars) and 912 receivers (Thick black line). (a) Velocity model from application of the Hole (1992) back-projection method. (b) Velocity model from application of Zelt and Barton (1998) smoothing-regularized method. Both models provide roughly the same level of fit to the picks. Regions without ray coverage

are white. Well-log observations at SAFOD (San Andreas Fault Observatory at Depth) are white for granite and black for sedimentary rock. Note how high velocities (>5 km/s) better match the known position of granite in the well for the model in (b) compared to the model in (a), suggesting that some of the additional structure in the model in (b) may be true. (c) Geology and fault interpretation overlaid on the model in (a). Black lines are top of basement; red lines are faults

More Examples

The examples in Figs. 1, 2, 3, 4, 5, 6, 7, 8, and 9 demonstrate the types of models that can result from a wide range of controlled-source experiments. The remaining examples presented in this section are intended to round out the range of applications to which traveltime tomography and inversion are applied in controlled-source studies, and the types of model structure that can result. The main purpose of the examples is to show what is possible in terms of tomographic imaging of different kinds of geologic features in the near-surface, upper crust, lower crust, and uppermost mantle using traveltime data. All examples shown in this article use only P-wave traveltime data.

Zelt et al. (2006a) applied the regularized 3D first-arrival tomography algorithm of Zelt and Barton (1998) to a dense

3D dataset from a groundwater contamination site (Fig. 10). Lanz et al. (1998) applied 2D first-arrival tomography and a Monte Carlo scheme to estimate a smooth model with standard deviations for a buried waste disposal site (Fig. 11). Pratt and Chapman (1992) applied 2D first-arrival tomography to crosswell data to simultaneously determine velocity and anisotropy parameters (Fig. 12). Scales et al. (1990) imaged a nearsurface weathering layer using 2D first-arrival times, solving simultaneously for lateral variations in the velocity and thickness of the layer (Fig. 13). Hole et al. (2006) applied 2D first-arrival tomography to data recorded across the San Andreas Fault using two different algorithms (Fig. 14). Dunn et al. (2000) applied 3D refraction and reflection tomography incorporating anisotropy to data from the East Pacific Rise (Fig. 15). Van Avendonk et al. (1998) inverted refraction and reflection times for a smooth 2D velocity model and an

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 15 Example of 3D refraction and reflection tomography across the East Pacific Rise at 9°30'N for crust and uppermost mantle structure (Dunn et al. 2000). There were 15 OBS's and 480 explosive sources. Refracted arrivals from the crust and upper mantle and reflections from the Moho were simultaneously inverted. Anisotropy of 4% in the crust and 7% in the upper mantle was included in the modeling. Final velocity model as perturbations relative to a 1D model are shown and are contoured at 0.2 km/s intervals. (a) vertical section through the center of the model. (b–g) Depth slices from 1.2–8.0 km beneath the seafloor. The low-velocity body is interpreted to represent melt distribution within a magmatic system

assumed flat Moho across the Clipperton transform fault (Fig. 16). Clark et al. (2008) inverted refractions and reflections from an onshore-offshore survey across the South American-Caribbean plate boundary using a smooth tomography approach for the upper crust, and a layer-based inversion for the lower crust, Moho, and upper mantle (Fig. 17). Zelt et al. (2003) compared layer-based simultaneous refraction and reflection inversion with independent smooth refraction and reflection tomography for three different 2D crustal datasets (Fig. 18).

Future

Full 3D seismic experiments are likely to become more commonplace, necessitating the need for some of the popular 2D tomography and inversion algorithms to be extended to 3D. It is likely that three-component, S-wave, and converted-wave studies will become more widespread, especially for near-surface environmental and engineering studies, necessitating the need for algorithms that can perform coupled P-wave, S-wave, or Poisson's ratio inversions. The desire to incorporate or determine anisotropy will likely become more commonplace in the future, and there are currently only a few traveltime algorithms that include any form of anisotropy (e.g., Dunn et al. 2000).

For all scales of seismic experiments, the need for flexible, general-purpose traveltime tomography and inversion algorithms will remain, both as the primary modeling tool and to provide long-wavelength starting models for higher-resolution full waveform inversion techniques (e.g., Brenders and Pratt 2007). The Zelt and Smith (1992) traveltime inversion algorithm has been widely used for many years for several reasons: (1) an irregular, layered model parameterization adaptable to the data coverage and geologic structures, (2) parameter-selective inversion, (3) any type of body-wave data can be modeled, and (4) it is easy to incorporate prior information. As such it stands apart from most other popular algorithms that use a uniform, fine grid parameterization, and consider only first arrivals, and in some cases reflections. However, the Zelt and Smith (1992) algorithm was primarily intended for relatively sparse 2D data. There will likely be a niche for a new version of the Zelt and Smith algorithm if it maintains all of its current advantages, but is extended to 3D and includes regularization to handle dense data, namely second-order derivatives to seek a smooth, minimum-structure model.

About 10 years ago, a theory for traveltime tomography was developed in global seismology to take into account the finite-frequency nature of seismic data (Dahlen et al. 2000). This method is known as finite-frequency traveltime tomography and it yields what are popularly known as banana-doughnut sensitivity kernels. By taking finite-frequency effects into account, this form of traveltime tomography should, theoretically, yield a more accurate estimation of velocity anomalies in terms of their magnitude and spatial resolution because the physics of wave propagation is treated more accurately. The theory developed for global seismology uses as input data delay times relative to a reference Earth model, and as such the theory is generally not applicable to controlled-source data. This is because for controlled-source data there is no requisite reference velocity model known in advance that is capable of yielding realistic synthetic waveforms that are close enough to the recorded seismograms to yield a meaningful delay time through cross correlation of the

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 16 Example of 2D tomography across the Clipperton transform fault (Van Avendonk et al. 1998). There were only five OBS's. Crust and upper mantle refracted arrivals and Moho reflections were inverted

simultaneously for a smooth velocity model. A flat Moho at 8.6 km depth was assumed. The model shows reduced velocities in the upper crust as far as 10 km south and 18 km north of the transform fault (CFZ)

Traveltime Tomography Using Controlled-Source Seismic Data, Fig. 17 Example of crustal velocity model from onshore-offshore survey across the South American-Caribbean plate boundary at 64°W (Clark et al. 2008). There were airguns offshore, two shots on land (green dots), OBS's offshore (yellow dots), and seismometers on land (red dots). The model above the dashed white line was obtained by first-arrival tomography using the Zelt and Barton (1998) smoothing-

regularized tomography algorithm; the model below the dashed line was derived using the Zelt and Smith (1992) layer-based inversion using upper mantle refractions and Moho reflections to determine a sharp velocity contrast for the Moho. The strike-slip system near the coastline at ~150 km accommodates relative motion between the two plates and from this model is interpreted to extend near vertically through the entire crust and offset the Moho

waveforms because the crust and near-surface are much more laterally heterogeneous than the mantle. As a result, a non-linear inverse method must be used, requiring a starting model, an iterative method and recalculated travel paths at each iteration. In addition, the method must be capable of calculating a frequency-dependent traveltime along the total

path, as opposed to a delay time. Zelt (2009) presented a finite-frequency traveltime tomography method specifically designed for controlled-source data, that is, a nonlinear inversion of total traveltimes, with frequency taken into account for both the forward calculation of traveltimes, and in the inverse step by calculating the appropriate frequency-dependent

Traveltime Tomography Using Controlled-Source Seismic Data,

Fig. 18 A comparison of three sets of 2D crustal velocity models obtained using two different inversion algorithms (Zelt et al. 2003). The study areas are southeastern British Columbia, the Iberia margin and the Chilean margin. The top row of “geologic” models were obtained using the Zelt and Smith (1992) layer-based algorithm simultaneously inverting crust and upper mantle refractions and Moho reflections. The bottom row of “minimum-structure” models were obtained using the Zelt and Barton (1998) smoothing-regularized first-arrival tomography algorithm. Open circles are shot locations; yellow circles

are OBS’s. Black contours in the crust have an interval of 0.5 km/s; white contours representing the Moho in the smooth tomographic models have an interval of 0.1 km/s from 7.0–7.6 km/s. Pink lines are the Mohos from the layered models overlain on the tomographic models for comparison. Yellow lines are the Mohos from independent reflection tomography in which the tomographic velocity models were held fixed. Interpretations of the main features of the geological models are supported by the corresponding minimum-structure models since they contain the same features

sensitivity kernels. The results show it is possible to achieve more accurate velocity estimation than in the equivalent infinite-frequency-derived models. And in addition, applications without any regularization are possible, and therefore finite-frequency traveltime tomography has the potential to allow the data alone to determine the model structure in a robust manner. These characteristics of finite-frequency traveltime tomography suggest that it will play an important role in the future. This is especially true for near-surface studies where infinite-frequency (ray) theory is least likely to be valid because the length scales of heterogeneities are often comparable or smaller than the seismic wavelengths.

Tsunami

Steven N. Ward

Institute of Geophysics and Planetary Physics, University of California at Santa Cruz, Santa Cruz, CA, USA

Definition

Dispersive	Characteristic of waves whose velocity of propagation depends on wave frequency. The shape of a dispersive wave packet changes as it moves along.
Eigenfunction	Functional shape of the horizontal and vertical components of wave motion versus depth in the ocean for a specific wave frequency.
Geometrical spreading	Process of amplitude reduction resulting from the progressive expansion of a wave from its source.
Run-up	Final phase of tsunami life starting when the wave shoals to a size equal to the water depth and begins to break, and ending when

the water runs over land and reaches its highest level.

Shoal

Process of waves coming into shallow water. Shoaling waves slow, shorten their wavelength, and grow in size.

Wavenumber

Wavenumber k equals 2π divided by wavelength λ . Large wavenumbers associate with short waves and small wavenumbers associate with long waves.

Tsunami are gravity-driven water waves. They belong to the same family as common sea waves that we see every day; however, tsunami are distinct in their mode of generation and in their physical traits. Unlike common sea waves that evolve from persistent winds, most tsunami spring from sudden shifts of the ocean floor. These sudden shifts can originate from undersea landslides and volcanoes, but mostly, submarine earthquakes parent tsunami. Compared to wind-driven waves, tsunami waves have periods, velocities, and wavelengths ten or a hundred times larger and present profoundly different shoreline consequences than do their common cousins.

Tsunami = Killer Wave?

In the years since the 2004 Sumatra earthquake, everyone has seen disturbing videos of tsunami-caused destruction. Certainly the prospect of a “killer wave” born from some far off earthquake is frightening. More so is the thought that after traveling with stealth great distances, that wave might suddenly rise up without warning at your own doorstep. Could it be me desperately floating by in the next tsunami video?

Understandably, worst-case scenarios of natural hazards come to mind, but it is important to keep perspective. Tsunami over 2 m high are not common. It takes a submarine earthquake greater than magnitude M8 to source a wave of this size. On a global average, only one M8+ earthquake occurs per year. Of these, maybe one in five strikes under the ocean with an orientation favorable for tsunami excitation. True, tsunami decay in transit and have shorter run-up at distant shores, so wave damage tends to localize within 1,000 km of that one in five quakes. On these accounts, tsunami that induce widespread damage and casualties number only about one per decade. Even at that modest recurrence rate, your personal risk is mitigated increasingly through education and technology. Today, ocean bottom pressure sensors detect stealthy tsunami of a few centimeters height in the open sea. Moreover, with advances in understanding, communication, and implementation since the 2004 Sumatra earthquake, scientists are better, quicker, and more specific at prediction than they were just a decade past. There is a good chance now that you will be warned and take action even if that rare wave does come your way.

Tsunami Characteristics

Tsunami Period, Velocity, and Wavelength

When discussing tsunami, I like to contrast them with something that we all have experienced – waves at the beach. Tsunami belong to the same family as these ordinary ocean waves but with major distinctions: principally tsunami period, tsunami velocity, and tsunami wavelength.

Tsunami period. The period (T) of a wave equals the time elapsed between one passing crest and the next. Common beach waves have a period of about 10 s (darkened column right side Fig. 1). The period of tsunami depends upon what creates it (earthquake, landslide, asteroid impact), but I can tell you that tsunami have far greater periods than beach waves. The “tsunami window” in Fig. 1 covers waves of 70, 200, 500, or even 2,000 s periods. Unlike “splash and dash” beach waves, tsunami arrive and may continue to flow in for several minutes. I like the description – “The ocean turns into a river.” Anyone who has seen those 2004 Sumatra videos can testify that tsunami act more flood-like than wave-like.

Tsunami velocity. Under classical theory, the phase $c(\omega)$, and group $u(\omega)$ velocity of surface gravity waves on a flat ocean of uniform depth h are:

$$c(\omega) = \sqrt{\frac{gh \tanh[k(\omega)h]}{k(\omega)h}} \quad (1)$$

and

$$u(\omega) = c(\omega) \left[\frac{1}{2} + \frac{k(\omega)h}{\sinh[2k(\omega)h]} \right]. \quad (2)$$

Here, g is the acceleration of gravity (9.8 m/s^2) and $k(\omega)$ is the *wavenumber* associated with a sea wave of frequency $\omega = 2\pi/T$. Wavenumber connects to wavelength as $\lambda(\omega) = 2\pi/k(\omega)$ and to phase velocity as $c(\omega) = \omega/k(\omega)$. Wavenumber also satisfies the relation:

$$\omega^2 = gk(\omega) \tanh[k(\omega)h]. \quad (3)$$

For surface gravity waves spanning 1–50,000 s period, Fig. 1 (*top*) plots $c(\omega)$ and $u(\omega)$. These velocities vary widely and increase for waves of longer periods in deeper water. The speed of ordinary sea waves is about 15 m/s (50 km/h) – the speed of a moped. Because of their longer period, waves in the tsunami window travel much more rapidly, reaching 160–250 m/s (600–900 km/h) in the open ocean. It is said that deep-water tsunami travel at the speed of a jet airliner. While true, be aware that wave energy is the quantity that runs ahead at jet speeds. The physical bits of water in a deep-water tsunami move less than a meter per second (see next section). Waves whose velocity varies with frequency are called *dispersive*. During propagation, dispersion “pulls apart”

Tsunami, Fig. 1 Phase velocity $c(\omega)$ (solid lines) and group velocity $u(\omega)$ (dashed lines) of tsunami waves on a flat earth covered by oceans of 100 m to 6 km depth (*top*). Wavelength associated with each wave period. The “tsunami window” is marked (*bottom*)

originally pulse-like waves into their component frequencies. Dispersion is strongest for waves whose period falls on the steepest slopes of the group velocity curves in Fig. 1.

Tsunami wavelength. Wavelength measures the distance between one wave crest and the next. Wavelength equals the product of wave period times phase velocity $\lambda(\omega) = Tc(\omega)$. Common beach waves have a wavelength of about 100 m – the length of a football field (Fig. 1, *bottom*). Tsunami, with their longer period and higher velocity, have much longer wavelengths than beach waves. In the deep ocean, tsunami span 10, 30, even 100 km between crests. If you could stand on one tsunami crest, the next one might be over the horizon. With wavelengths this large, tsunami slopes are very small even if the wave has large amplitude. For ships at sea, tsunami pass completely unnoticed.

Short wave versus long wave: Discussions of waves of length λ , in oceans of depth h sometimes include two simplifications: a long wave approximation ($\lambda \gg h$, $1/k \gg h$) and a short wave approximation ($\lambda \ll h$, $1/k \ll h$). Under a long wave approximation [$kh \rightarrow 0$, $\tanh(kh) \rightarrow kh$, $\sinh(2kh) \rightarrow 2kh$] Eqs. 1, 2, and 3 predict nondispersive wave propagation with $c(\omega) = u(\omega) = \sqrt{gh}$. Long wave theory holds for the flat part of the curves in Fig. 1 (*top*). Under a short wave approximation, [$kh \rightarrow \infty$, $\tanh(kh) \rightarrow 1$, $\sinh(kh) \rightarrow \infty$] the equations predict dispersive propagation with $c(\omega) = 2u(\omega) = gT/2\pi$. Short wave theory holds to the right in Fig. 1 (*top*) where all the curves lie atop each other. Waves in the tsunami window have intermediate character, behaving like shallow water waves at their longest periods and like deep-water waves at their shortest periods. Neither the long nor the short wave simplification serves

adequately in tsunami studies. A rigorous treatment requires an approach that works for waves of all lengths.

Tsunami Eigenfunctions

Tsunami also differ from waves at the beach in the way they move the ocean. Tsunami *eigenfunctions* describe wave motion in a tsunami mode of a particular frequency. Consider coordinate system (x, y, z) where $\hat{x}$ points north, $\hat{y}$ east, and $\hat{z}$ down. Vertical (u_z) and horizontal (u_x) components of tsunami eigenfunctions normalized to vertical amplitude A_z at the sea surface are:

$$\begin{aligned} u_z(\omega, z) &= A_z \frac{k(\omega)g}{\omega^2} \frac{\sinh[k(\omega)(h-z)]}{\cosh[k(\omega)h]} e^{i[k(\omega)x - \omega t]} \\ u_x(\omega, z) &= A_z \frac{-ik(\omega)g}{\omega^2} \frac{\cosh[k(\omega)(h-z)]}{\cosh[k(\omega)h]} e^{i[k(\omega)x - \omega t]} \end{aligned} \quad (4)$$

Figure 2 plots tsunami eigenfunctions versus depth in a 4-km deep ocean at long (1,500 s), intermediate (150 s), and short (50 s) periods. The ellipses trace the path of a water particle as a wave of frequency ω passes. At 50-s period (Fig. 2, *right*), ordinary ocean waves have deep-water behavior. Water particles move in circles that decay exponentially from the surface. Sensibly, because the eigenfunctions of short waves do not reach to the seafloor, their velocity is independent of ocean depth [$c(\omega) = 2u(\omega) = gT/2\pi$, Fig. 1, *top right*]. The failure of short waves to “feel” the seafloor also means that they cannot be excited by deformations of it. The only means to excite ordinary ocean waves is to disturb the surface.

Tsunami, Fig. 2 Tsunami eigenfunctions in a 4-km deep ocean at periods 1,500, 150, and 50 s. Vertical displacements at the ocean surface has been normalized to $A_z = 1$ m in each case

At 1,500 s period (Fig. 2, *left*), the tsunami has a wavelength of $\lambda = 297$ km and it acts like a long wave. Although vertical displacement peaks at the ocean surface and drops to zero at the seafloor, horizontal displacement persists undiminished through the ocean column. Unlike ordinary waves that are confined near the sea surface, the energy of a tsunami spreads through the entire depth of the sea. You cannot out dive a tsunami. This fact explains why tsunami can be detected by pressure sensors on the seafloor. A second distinction of tsunami versus ordinary sea waves is that their horizontal motion far exceeds their vertical motion. Every meter of up and down in a 1,500-s tsunami involves ≈ 10 m of back and forth. If you were to build a shore-based or space-based “tsunami detector,” the large horizontal motions might make a better target than the vertical motions. Applications of Doppler radar come to mind.

Toward the short period side of the tsunami window at 150 s (Fig. 2, *middle*), λ decreases to 26 km. For these tsunami waves, long wave characteristics begin to break down, and horizontal and vertical motions more closely agree in amplitude.

From (4), it is easy to deduce the peak velocity of surface water in waves of amplitude A_z as:

$$|v_x^{\max}(\omega, z=0)| = \frac{A_z k(\omega) g}{\omega} = \frac{A_z g}{c(\omega)}. \quad (5)$$

For long waves $c(\omega)$ equals $\sqrt{gh}$, and peak surface water velocity in a 1-m amplitude tsunami in 4,000 m of water would be just 4.9 cm/s. Peak water velocity at the sea floor

$$\begin{aligned} |v_x^{\max}(\omega, z=h)| &= \frac{A_z k(\omega) g}{\omega \cosh[k(\omega)h]} \\ &= \frac{A_z g}{c(\omega) \cosh[k(\omega)h]} \end{aligned} \quad (6)$$

is even less. As mentioned, although tsunami travel at several hundred meters per second, the water itself moves at a tiny fraction of this.

Tsunami Excitation

Tsunami get started in many ways. Suppose that the seafloor at positions $\mathbf{r}_0$ uplift instantaneously by an amount $u_z^{\text{bot}}(\mathbf{r}_0)$ at time $\tau(\mathbf{r}_0)$. Under classical tsunami theory in a uniform ocean of depth h , this sea bottom disturbance produces surface tsunami waveforms (vertical component) at observation point $\mathbf{r} = x\hat{\mathbf{x}} + y\hat{\mathbf{y}}$ and time t of

$$u_z^{\text{surf}}(\mathbf{r}, t) = \text{Re} \int_{\mathbf{k}} d\mathbf{k} \frac{e^{i[\mathbf{k} \cdot \mathbf{r} - \omega(k)t]}}{4\pi^2 \cosh(kh)} F(\mathbf{k}). \quad (7a)$$

with

$$F(\mathbf{k}) = \int_{\mathbf{r}_0} d\mathbf{r}_0 u_z^{\text{bot}}(\mathbf{r}_0) e^{-i[\mathbf{k} \cdot \mathbf{r}_0 - \omega(k)\tau(\mathbf{r}_0)]} \quad (7b)$$

$k = |\mathbf{k}|$, and $\omega^2(k) = gk \tanh(kh)$. The integrals in (7a and 7b) cover all wavenumber space and locations $\mathbf{r}_0$ where the seafloor disturbance $u_z^{\text{bot}}(\mathbf{r}_0) \neq 0$.

Equation 7a looks scary but it has three identifiable pieces:

- The $F(\mathbf{k})$ term is the wavenumber spectrum of the seafloor uplift. This number relates to the amplitude, spatial and time distribution of the uplift. Tsunami trains are dominated by wavenumbers in the span where $F(\mathbf{k})$ is the greatest. The peak of $F(\mathbf{k})$ corresponds to the characteristic dimension of the uplift. Large-dimensioned uplifts produce longer wavelength, lower frequency tsunami than small-dimensioned sources.
- The $1/\cosh(kh)$ term comes from the tsunami eigenfunction shapes (4) and it acts to low-pass filter the source spectrum $F(\mathbf{k})$. Because $1/\cosh(kh) \rightarrow 1$ when $kh \rightarrow 0$, and $1/\cosh(kh) \rightarrow 0$ when $kh \rightarrow \infty$, the filter favors long waves. Due to the low-pass filter effect of the ocean layer, only wavelengths of the uplift that exceed three times the ocean depth (i.e., $kh = 2\pi h/\lambda < \approx 2$) contribute much to tsunami.
- The exponential term in (7a) contains all of the propagation information including travel time, *geometrical spreading*, and frequency dispersion.

By rearranging Eqs. 7a and 7b, vertical tsunami motions at $\mathbf{r}$ can also be written as:

$$u_z^{\text{surf}}(\mathbf{r}, t) = \text{Re} \int_0^\infty \frac{k dk e^{-i\omega(k)t}}{2\pi \cosh(kh)} \sum_{n=-\infty}^\infty J_n(kr) e^{in\theta} F_n(k)$$

with

$$F_n(k) = \int_{\mathbf{r}_0} d\mathbf{r}_0 u_z^{\text{bot}}(\mathbf{r}_0) J_n(kr_0) e^{i(\omega(k)\tau(\mathbf{r}_0) - n\theta_0)} \quad (8)$$

Here θ marks azimuth from north (the $\hat{\mathbf{x}}$ direction) of the observation point $\mathbf{r}$ from the coordinate origin. The $J_n(x)$ are cylindrical Bessel functions. For simply distributed uplift sources, (8) might be easier to evaluate than (7a and 7b).

Tsunami Excitation by Earthquakes

Earthquakes produce 80–90% of tsunami. Not surprisingly, earthquake features determine many sea wave characteristics. Earthquakes result from slip on faults and three primary parameters describe the process – moment, mechanism, and depth.

Moment measures earthquake strength. Moment M_0 is the product of rigidity μ of the source region's rocks, fault area A , and average fault slip Δu . Earthquake moment and earthquake magnitude tie through a number of empirical formulae. One formula defines moment magnitude M_w as $M_w = (2/3)(\log M_0 - 9.05)$. Earthquake moment varies by 2×10^4 within the magnitude range $6.5 \leq M_w \leq 9.5$ (Table 1). Even without a detailed understanding of tsunami generation, it is safe to suppose that the larger the earthquake moment, the larger the tsunami, all else fixed.

Mechanism specifies the orientation of the earthquake fault and the direction of slip on it. Usually, faults are idealized as plane rectangles with normal $\hat{\mathbf{n}}$. Three angles then, summarize earthquake mechanisms – the strike and dip of the fault and the angle of slip vector $\hat{\mathbf{a}}$ measured from the horizontal in the plane of the fault. (Seismologists call this angle the “rake.”) The role of fault mechanism on tsunami production is not as obvious as the influence of moment; however, one might suspect that earthquakes that affect large vertical displacements of the seafloor would be more effective than faults that make large horizontal displacements.

Earthquake *depth* needs no explanation. Because seafloor shifts cause tsunami, the distance of the fault from the seafloor should be important. Presumably, deep earthquakes produce less potent tsunami than similar shallow earthquakes.

Numerical, or synthetic waveforms quantify the roles of earthquake parameters on tsunami generation. For illustration, insert into (7a and 7b) the surface uplift pattern $u_z^{\text{bot}}(\mathbf{r}_0)$ of a small earthquake fault (point source really) placed at depth d in a halfspace. Further assume that the uplift occurs instantly with $\tau(\mathbf{r}_0) = 0$. (Actually, real earthquakes uplift the seafloor over several, or several tens of, seconds. This distinction is not a big issue because tsunami waves have periods of many hundreds of seconds. Uplifts taking a few dozen seconds to develop look “instantaneous” to tsunamis.) Equations 7a and 7b becomes

$$u_z^{\text{surf}}(\mathbf{r}, t) = \int_0^\infty k dk \frac{\cos \omega(k)t}{2\pi \cosh(kh)} [A \Delta u \mathbf{M}_{ij} \epsilon_{ij}], \quad (9)$$

where

$$\begin{aligned} \epsilon_{xx} &= -\frac{1}{4} \left(\frac{\mu}{\lambda + \mu} - kd \right) [J_0(kr) - J_2(kr) \cos 2\theta] e^{-kd} \\ \epsilon_{yy} &= -\frac{1}{4} \left(\frac{\mu}{\lambda + \mu} - kd \right) [J_0(kr) + J_2(kr) \cos 2\theta] e^{-kd} \\ \epsilon_{xy} &= \epsilon_{yx} = \frac{1}{4} \left(\frac{\mu}{\lambda + \mu} - kd \right) [J_2(kr) \sin 2\theta] e^{-kd} \\ \epsilon_{zz} &= -\frac{1}{2} \left(\frac{\mu}{\lambda + \mu} + kd \right) [J_0(kr)] e^{-kd} \\ \epsilon_{xz} &= \epsilon_{zx} = \frac{kd}{2} [J_1(kr) \cos \theta] e^{-kd} \\ \epsilon_{yz} &= \epsilon_{zy} = \frac{kd}{2} [J_1(kr) \sin \theta] e^{-kd} \end{aligned} \quad (10)$$

The six elements of symmetric tensor

$$M_{jk} = (\hat{a}_j \hat{n}_k + \hat{n}_j \hat{a}_k) \quad (11)$$

capsulize the mechanism of the earthquake. In (11), $\hat{\mathbf{n}}$, $\hat{\mathbf{a}}$ are the fault normal and slip vectors introduced above. A pure dip slip earthquake on a vertical north–south trending fault for instance, has $\hat{\mathbf{n}} = \hat{\mathbf{y}}$ and $\hat{\mathbf{a}} = \hat{\mathbf{z}}$, so $M_{yz} = M_{zy} = 1$ and $M_{xx} = M_{yy} = M_{zz} = M_{xz} = M_{zx} = M_{xy} = M_{yx} = 0$.

The bracketed terms in (9) contain all of the relationships between earthquake parameters and tsunami features. Some relationships are easy to spot: tsunami amplitudes from earthquakes are proportional to the product of fault area and average slip ($A \Delta u$); tsunami amplitudes decrease with earthquake depth via the e^{-kd} terms. The ϵ_{ij} provide the dependence of tsunami amplitude and azimuthal radiation pattern on source type. Equation 10 says that tsunami from point sources radiate in azimuthal patterns no more intricate than $\sin 2\theta$ or $\cos 2\theta$.

Figure 3 shows 5 h of tsunami waveforms calculated from (9) at distances of $r = 200, 500, 1,000, 2,000$ km from dip slip ($M_{yz} = M_{zy} = 1$) and strike slip ($M_{xy} = M_{yx} = 1$) point sources of magnitude $M_w = 7.5$ ($\Delta u A = 3.98 \times 10^6 \text{ m}^3$. See Table 1) buried at 10 km depth. Sea waves from these sources have

Tsunami, Table 1 Relationship between earthquake magnitude and moment with values of fault area, length, and mean slip for typical tsunami-generating earthquakes. This paper assumes $\log(L) = 0.5 M_w - 1.8$, $\Delta u = 2 \times 10^{-5} L$, and $\lambda = \mu = 5 \times 10^{10} \text{ Pa}$

Magnitude M_w	Moment M_0 (Nm)	Area A (km ²)	Length L (km)	Width W (km)	Slip Δu (m)
6.5	6.3×10^{18}	224	28	8	0.56
7.0	3.5×10^{19}	708	50	14	1.00
7.5	2.0×10^{20}	2,239	89	25	1.78
8.0	1.1×10^{21}	7,079	158	45	3.17
8.5	6.3×10^{21}	22,387	282	79	5.66
9.0	3.5×10^{22}	70,794	501	141	10.0
9.5	2.0×10^{23}	223,872	891	251	17.8

radiation patterns of $\sin\theta$ and $\sin 2\theta$, respectively. I compute the waveforms in Fig. 3 at the azimuth of maximum strength, $\theta = 90^\circ$ and $\theta = 45^\circ$. Frequency dispersion, with the long periods arriving first, is the most conspicuous feature of the waveforms. Tsunami onset rapidly. They reach maximum height in the first few cycles and then decay slowly over an hour or more. Even for this large earthquake, tsunami beyond 500 km distance reach just a few centimeters – hardly killer waves. Note that if the observation direction was west versus east (Fig. 3, *top*), or northwest versus northeast (Fig. 3, *bottom*), the tsunami waveforms would be inverted. Whether tsunami onset in a withdrawal or an inundation at a particular shoreline strictly depends on the style of faulting and the relative positions of the shore and the fault.

Figure 3 demonstrates that for point sources, dip slip earthquakes produce three or four times larger tsunami than strike slip earthquakes of equal moment. The differences in generation efficiency are understood most easily by considering directly the seafloor deformation patterns $u_z^{\text{bot}}(\mathbf{r}_0)$. I find these by setting $t = 0$ and $h = 0$ in (9) so $\cos\omega(k)t/\cosh(kh) = 1$. Figure 4 pictures the uplift patterns for the two faults of Fig. 3

Tsunami, Fig. 3 Synthetic record sections of vertical tsunami motions at distances of 200, 500, 1,000, and 2,000 km from point dip slip (*top*) and strike slip (*bottom*) earthquakes of magnitude $M_w = 7.5$ and depth 10 km. Time runs for 5 h and the peak amplitude of each trace is given in centimeters at the right. The lower half of the focal sphere and azimuth of observation θ are shown toward the right. For other directions, the waveforms should be scaled by $\sin\theta$ and $\sin 2\theta$, respectively

where two ($\sin\theta$) and four-lobed ($\sin 2\theta$) deformations spread over a region 40 km wide. The most striking contrast in the fields is maximum vertical displacement – 1.4 m for the strike slip versus 5.4 m for the dip slip. It is no coincidence that the ratio of maximum uplift for these two faults replicates the ratio of tsunami heights in Fig. 3. After all, vertical seafloor deformation drives tsunami and vertical deformation is controlled largely by the rake of the slip vector $\hat{\mathbf{a}}$. Strike slip faults have a rake of 0° or 180° . Dip slip faults have rake equal $\pm 90^\circ$. Further simulations show that, excepting very shallow, nearly horizontal faults, dip is not a terribly significant factor in tsunami production.

The sea surface cross sections in Fig. 5 (*left* and *middle*) chronicle the birth and early life of a sea wave spawned by M7.5 thrust earthquakes on 45° dipping planes. In these figures, I replace the idealized point sources of Fig. 3 with faults of typical dimension ($L = 89$ km, $W = 25$ km, and $\Delta u = 1.78$ m; see Table 1). In Fig. 5 (*left*) the fault reaches to the sea floor. In Fig. 5 (*middle*) the fault stops 30 km down. Soon after the earthquake, the sea surface forms “dimples” similar to those on the deformed sea floor. The sea surface dimples, however, are smoother and a bit lower in amplitude because of the $1/\cosh(kh)$ low-pass filtering effect of the ocean layer. After a time roughly equal to the dimension of the uplift divided by tsunami speed $\sqrt{gh}$, the leading edges of the wave organize and begin to propagate outward as expanding rings (Fig. 5, *right*). Early on, the wave appears as a single pulse. Characteristic tsunami dispersion begins to be seen only after 10 or 20 min. Consequently, for shorelines close to tsunami sources, seismic sea waves arrive mostly as a single pulse. For distant shorelines, sea waves arrive with many oscillations, dispersion having spread out the initial pulse.

The e^{-kd} terms in the tsunami excitation functions (10) let shallow earthquakes excite higher frequency tsunami than deep earthquakes (compare Fig. 5 *left*, with Fig. 5 *middle*). Higher frequency waves travel more slowly than longer period waves, so high frequency waves contribute to peak tsunami height only while it propagates as a single pulse. After a few hundred kilometers of travel, high frequency waves drift to the back of the wave train (Fig. 5, *left*) and no longer add to the tsunami maximum. At 200 km distance, the shallow earthquake generates a wave about three times larger than the 30-km deep event. If you track the waves out to 2,000 km, however, you would find that the extra high frequencies in the shallow event will have fallen behind and that the maximum wave heights for the two events would be nearly equal. Beyond 2,000 km distance, any earthquake depth less than 30 km appears to be equally efficient in tsunami genesis.

Faults of finite size, like those in Fig. 5, radiate tsunami in distributions more complex than the $\sin\theta$ and $\sin 2\theta$ patterns from point sources. The largest earthquakes have fault lengths of several hundred kilometers. Simulations show that long

Tsunami, Fig. 4 Static vertical displacements of the seafloor for the dip slip (*top*) and strike slip (*bottom*) earthquake point sources that generated the tsunami of Fig. 3. Maximum excursions of the seafloor are 5.4 and 1.4 m, respectively

earthquake faults preferentially emit tsunami in a tight beam perpendicular to the fault strike, regardless of the focal mechanism. This preferential beaming simplifies tsunami forecasting because it tells us which direction to look for the biggest waves.

Tsunami Excitation from Submarine Landslides

Earthquakes parent most tsunami, but other things do too. For instance, earthquake shaking often triggers landslides. If the slide happens under the sea, then tsunami may form. Consider a seafloor landslide confined in a rectangle of length L and width W . Let a constant uplift u_0 start along one width of the rectangle and run down its length ($\hat{x}$ direction, say) at velocity v_r , that is, $\tau(\mathbf{r}_0) = x/v_r$. Placing this $u_z^{\text{bot}}(\mathbf{r}_0)$ and $\tau(\mathbf{r}_0)$ into (7a and 7b), I find the tsunami from this uplift source at observation point $\mathbf{r}$ and time t to be

$$u_z^{\text{surf}}(\mathbf{r}, t) = \frac{u_0 L W}{4\pi^2} \operatorname{Re} \int_k \frac{e^{i(\mathbf{k} \cdot \mathbf{r} - \omega(k)t)} e^{-iX(\mathbf{k})}}{\cosh(kh)} \frac{\sin X(\mathbf{k})}{X(\mathbf{k})} \frac{\sin Y(\mathbf{k})}{Y(\mathbf{k})} d\mathbf{k} \quad (12)$$

where

$$X(\mathbf{k}) = \frac{kL}{2} (\hat{\mathbf{k}} \cdot \hat{\mathbf{x}} - c(k)/v_r) \quad \text{and} \quad Y(\mathbf{k}) = \frac{kW}{2} (\hat{\mathbf{k}} \cdot \hat{\mathbf{y}}).$$

The $X(\mathbf{k})$ and $Y(\mathbf{k})$ factors, because they depend on the relative positions of the observation point and the landslide source, instill radiation patterns to the tsunami much like the ε_{ij} do for earthquakes.

By adding a trailing excavation source to the uplift source (12), I simulate tsunami from a sliding submarine block. Figure 6 pictures in cross section the waves stirred from a 2-km wide block, 10-m thick sliding at 49 m/s for 6 km along the bottom of an ocean 500 m deep. As the block moves, the water must go around the obstruction. Water gets pushed up in front and drawn down behind the slide block. Experiments reveal that, depending on the aspect ratio of the block and the ratio of slide velocity to the tsunami phase velocity, significant beaming and amplification of the tsunami are possible. In particular, when the slide velocity v_r approaches the tsunami speed $c(k) \approx \sqrt{gh}$, $X(\mathbf{k})$ is nearly zero for waves traveling in

Tsunami, Fig. 5 *Left.* Cross sections of expanding tsunami rings from a M7.5 thrust earthquake. The fault strikes north-south (into the page) and the sections are taken east-west. Elapsed time in minutes and maximum amplitude in centimeters are given at the left and right sides. *Middle.* Cross sections of expanding tsunami rings from the same M7.5 thrust earthquake now buried 30 km. Deeper earthquakes make smaller and

longer wavelength tsunami. *Right.* Views of the expanding tsunami rings from the shallow earthquake case at $t = 6$ and 12 min. The dashed rectangle in the center traces the surface projection of the fault. For large earthquakes, nearly all tsunami energy beams perpendicular to the strike of the fault (toward the left and right in this picture)

Tsunami, Fig. 6 Tsunami produced by a submarine landslide. The slide block is 10 m thick and 2 km wide. The slide starts to the left and runs to the right at 49 m/s. Note the amplification of the wave in the slide direction

Tsunami, Fig. 7 Map view of a tsunami from a landslide block similar to Fig. 6. Note the dipole form of the wave in its early stages and the beaming in the southeast direction of the slide

the slide direction. In this direction, the waves from different parts of the landslide arrive nearly “in phase” and constructively build. Figures 6 and 7 highlight the beaming and amplification effects. In both cases, witness the large tsunami pulse sent off in the direction of the slide. (Quicktime movies of Figs. 6 and 7 and many other Figures in this paper are available for viewing; see Table 2.) Submarine landslides are prime suspects in the creation of “surprise tsunami” from small or distant quakes. Surprise landslide tsunami might initiate well outside of the earthquake uplift area or be far larger than expected given the magnitude of the quake. Historical examples of surprise landslide tsunami include the 1929 Grand Banks and the 1998 Papua New Guinea waves.

Tsunami Excitation from Impacts

In addition to tsunami from earthquakes and landslides, another class holds interest – those generated from surface detonations, explosive volcanoes, and asteroid strikes. I call waves from these sources “impact tsunami.” Imagine that the initial stage of cratering by an impact excavates a radially symmetric, parabolic cavity of depth D_C , and radius R_C :

$$u_z^{\text{impact}}(\mathbf{r}) = D_C(1 - r^2/R_C^2) \quad r \leq \sqrt{2}R_C = R_D$$

$$u_z^{\text{impact}}(\mathbf{r}) = 0 \quad r > \sqrt{2}R_C = R_D$$

Based on Eq. 8, the impact tsunami at observation point $\mathbf{r}$ and time t is

$$u_z^{\text{surf}}(\mathbf{r}, t) = \int_0^\infty \frac{k dk}{2\pi} \cos[\omega(k)t] J_0(kr) F_0(k), \quad (13)$$

where

$$\begin{aligned} F_0(k) &= \int_{r_0} r d\mathbf{r}_0 u_z^{\text{impact}}(\mathbf{r}_0) J_0(kr_0) \\ &= \frac{2\pi D_C R_D}{k} J_3(kR_D). \end{aligned}$$

The principal distinction between (8) and (13) is the absence in the latter of the $1/\cosh(kh)$ low-pass ocean filter. Impacts crater the surface of the ocean not the sea floor, so this filter does not come into play.

If we restrict ourselves to asteroid-induced tsunami and suppose that the depth of the impact cavities equals $1/3$ their diameter $d_c = 2R_C$, then D_C relates scales with the density, velocity, and radius of the impacting asteroid as

$$D_C = d_c/3 = (8\varepsilon\rho_1 V_1^2/9\rho_w g)^{1/4} R_1^{3/4} \quad (14)$$

In (14), ε is the fraction of the kinetic energy of the asteroid that goes into the tsunami wave. High velocity impact experiments suggest that $\varepsilon \approx 0.15$. With $\rho_1 = 3 \text{ gm/cm}^3$, $\rho_w = 1 \text{ gm/cm}^3$, and $V_1 = 20 \text{ km/s}$, (14) returns crater depths of 1,195, 2,010, and 4,000 m for asteroids of radius $R_1 = 50, 100$, and 250 m.

Figure 8 plots cross sections of the expanding rings of tsunami waves induced by the impact of a 200-m diameter asteroid at 20 km/s as computed by Eq. 13. Within 100 km of ground zero, tsunami from moderate size (100–250 m) asteroids have heights of many hundreds of meters and dwarf the largest (10–15 m) waves parented by earthquakes. Fortunately, impact tsunami fall on the steep-sloped part of the group velocity curve (Fig. 1) so they decay faster with

distance than earthquake tsunami (more like r^{-1} vs. $r^{-3/4}$ for earthquake tsunami). Figure 9 illustrates how dispersion quickly pulls apart the initial impulse into dozens of waves. At 1,000 and 3,000 km, the tsunami in Fig. 8 would decay to 6 and 2 m amplitude, respectively – still a concern, but not catastrophic. For perspective, asteroids with diameters $>200 \text{ m}$ impact Earth about every 10,000 years, far less frequently than great M9 earthquakes that strike the planet once in 25 years or so.

Tsunami Propagation

In uniform depth oceans, tsunami propagate out from their source in circular rings (e.g., Fig. 9) with ray paths that look like spokes on a wheel. In real oceans, tsunami speeds vary place to place (even at a fixed frequency) so tsunami ray paths refract and become bent. Consequently, in real oceans, both tsunami travel time and amplitude have to be adjusted relative to their values in uniform depth ones. To propagate tsunami in real oceans, I find it best to keep tsunami “mode-like” versus depth but “ray-like” horizontally. I first transform the various integrals over wavenumber (7, 8, 9, etc.) to integrals over frequency because wave frequency, not wave number, is conserved throughout. Using the relations $u(\omega) = d\omega/dk$ and $c(\omega) = \omega/k(\omega)$, I find that tsunami vertical motions from (13) for instance, are to a good approximation:

$$u_z^{\text{surf}}(\mathbf{r}, t) = \int_0^\infty \frac{\cos(\omega t) d\omega}{2\pi k(\omega) u(\omega)} J_0(\omega T(\mathbf{r}, \omega)) F_0(k(\omega)) \cdot \quad (15)$$

$$G(\mathbf{r}) S_L(\omega, \mathbf{r})$$

In (15) the travel time of waves of frequency ω has been changed from $r/c(\omega)$ to

$$T(\mathbf{r}, \omega) = \int_{\text{ray path}} dr/c(\omega, h(\mathbf{r})), \quad (16)$$

where the integral path traces the tsunami ray from the source to the observation point. Equation 15 also incorporates a new shoaling factor $S_L(\omega, \mathbf{r})$ that accounts for wave height changes due to water depth and new ray geometrical spreading factor $G(\mathbf{r}) \leq 1$ that takes into consideration the reduction of wave amplitudes into shadow zones.

Real geometrical rays for tsunami can be very messy (*top left*, Fig. 10). Rather, I employ “network rays” that are simply minimum time paths between source and receiver (*top right*, Fig. 10). Unlike geometrical rays, network rays possess

neither caustics nor shadow zones. To compute the ray geometrical spreading factor $G(\mathbf{r})$, I replace the curvature of the wave front with curvature of the ray in the path integral (Fig. 10, bottom row):

$$G(\mathbf{r}) = \exp \left[-\frac{1}{2} \int_{\text{raypath}} \frac{\partial \alpha(s)}{\partial w} ds \right] \quad (17)$$

$$\Rightarrow \exp \left[-\frac{1}{2} \int_{\text{raypath}} \left[\frac{\partial \theta(s)}{\partial s} \right] ds \right].$$

In this approach the distinction between wave refraction and diffraction blurs.

Tsunami Shoaling and Run-up

Shoaling. Toward shore, real oceans shallow and the waves carried on them amplify in a process called *shoaling*. Shoaling is easy to understand. The tsunami velocity depends on the ocean depth so as water shallows, tsunami waves slow down. Because their frequency is fixed, the wavelength of a slowing tsunami decreases (Fig. 11, inset) and its energy compresses horizontally. Secondly, because a tsunami occupies the entire water column, as it enters shallow water its energy also gets compressed vertically. The only way for the compressing wave to maintain the same energy flux is for it to grow in amplitude. For the shoaling factor in (15), linear theory gives:

$$S_L(\omega, \mathbf{r}) = \sqrt{\frac{u(\omega, h_0)}{u(\omega, h(\mathbf{r}))}}. \quad (18)$$

Tsunami, Fig. 8 Computed tsunami induced by the impact of a 200-m diameter asteroid at 20 km/s. The waveforms (shown at 10 s intervals) trace the surface of the ocean over a 30 km cross section that cuts rings of

tsunami waves expanding from the impact site at $x = 0$. Maximum amplitude in meters is listed to the left

Tsunami, Fig. 9 Expanding rings of an impact tsunami in a 3D-like style. Note the strong wave spreading due to dispersion

Shoaling amplification depends on the ratio of group velocity at the nucleation-site and the coast-site (ocean depths h_0 and $h(r)$, respectively). As does $G(r)$, S_L reverts to one in oceans of uniform depth.

Figure 11 pictures a shoaling tsunami wave of 150 s period. Initially, a unit height wave comes ashore from 4,000 m of water at the left. As the water shallows, the velocity of the wave decreases and the wave grows in amplitude. By the time it reaches 125 m depth it has slowed from 137 m/s group velocity to 35 m/s and grown in height by a factor of 2. Figure 12 plots (18) as a function of coast-site

depth for sea-wave periods from 10 s, and ocean depths of 2, 4, and 6 km. Because their energy does not occupy the entire water column, beach waves at 10 s period do not amplify much (perhaps 50%) in shoaling. Tsunami waves (100–2,000 s period) experience much stronger shoaling amplification – about 3–6 over a wide range of conditions. For waves of period greater than 250 s, $u(\omega, h_0) = (gh_0)^{1/2}$, $u(\omega, h(r)) = (gh(r))^{1/2}$, and the shoaling factor reduces to Green's Law, $S_L = (h_0/h(r))^{1/4}$ (dashed red line in Fig. 12).

Run-Up. Run-up is the final phase of tsunami life. The run-up phase begins when the approaching tsunami shoals to an

Tsunami, Fig. 10 Real tsunami rays (*top left*) versus network rays (*top, right*). I track the curvature of the ray (*right, bottom*) rather than the curvature of the wave front (*left, bottom*) to account for wave size losses as tsunami propagate around obstacles

amplitude roughly equal to the water depth and the wave begins to break. Run-up also covers the inundation phase where the water runs over land and reaches its maximum excursion above sea level. Run-up is the most complicated phase of tsunami life; nevertheless, “Will I get wet?” is the question everyone wants answered, so tsunami scientists have to take their best shot at carrying the waves to the last mile.

One approach to run-up is wave tank or computer experiments like Figs. 13 and 14, where waves of various sizes and periods are sent onto model beaches. These experiments reveal a wide range of behaviors depending on wave period, wave size, wave direction, number of waves, beach slope, and beach friction. In real-world situations, this information is not known well, so the direct applications of the experimental results are limited. I follow an alternative approach that takes a broad brush view of run-up, but allows for considerable random uncertainty in the outcome. Using the methods above, I propagate tsunami to a position close to shore in shallow water where it can be considered a long wave, but not so shallow that its amplitude $A(h)$ exceeds water depth h there. I estimate run-up height η , on shore by:

$$\eta = A(h)^{4/5} h^{1/5} \quad (19)$$

Because $A(h) < h$, run-up always exceeds the offshore wave amplitude. Considering the large uncertainties involved, I view run-up at any field site to be a random variable drawn from a distribution function with (19) being its mean and its spread ranging from 1/2 to 2 times the mean. It does not matter at which depth h is used to evaluate (19), provided the water is shallow enough for the tsunami to act like a long wave. According to Green’s Law, a long wave with amplitude $A(h_1)$ in water of depth h_1 , has an amplitude $A(h_2) = A(h_1) (h_1/h_2)^{1/4}$ in water of depth h_2 . Run-up estimate at η_2 at depth h_2

$$\begin{aligned} \eta_2 &= A(h_2)^{4/5} h_2^{1/5} = \left(A(h_1) \left[\frac{h_1}{h_2} \right]^{1/4} \right)^{4/5} h_2^{1/5} \\ &= A^{4/5}(h_1) h_1^{1/5} = \eta_1 \end{aligned}$$

equals estimate η_1 at depth h_1 .

Tsunami, Fig. 11 Effect of shoaling on tsunami eigenfunctions. The shallowing ocean near shore concentrates wave energy into smaller and smaller volumes and tsunami grow in response

Tsunami, Fig. 12 Shoaling amplification factor for ocean waves of various frequencies and source depths. The dashed red line is Green's Law

Tsunami Samples

Sumatra earthquake 12/26/2004. Figure 15 snapshots a simulation of the 2004 Sumatra tsunami. As modeled by several rectangular patches, the megathrust fault that sourced the wave trends north–south for several 100 km (Fig. 15 top left). As the example in Fig. 5 predicted, nearly all of the wave energy in the 2004 tsunami emits perpendicular to the fault – Sumatra and Thailand toward the east, and India and Sri Lanka toward the west. Not surprisingly, these locations suffered the lion's share of tsunami damage. I believe that the very large run-up near Banda Aceh was due to concentrated slip on a thrust ramp splaying up from the megathrust just offshore at that latitude.

La Palma landslide tsunami. Like its fellows in the Canary Island chain, the volcanic Island of La Palma has experienced cycles of growth and partial collapse. Its flank last failed 550,000 years ago. Since then, new Cumbre Vieja volcano has filled the vacant scar. For the last 125,000 years this volcano grew steadily but in the last 7,000, its structure changed. It now mainly erupts along a north–south trending rift that splits the mountain in half. Moreover, during an eruption in 1949 a fault broke surface along the crest of the volcano and part of its western side slid 5 m down and toward the ocean. The volcano again may be showing initial stages of instability. While certainly collapse is not imminent and it

Tsunami, Fig. 13 Run-up and inundation of a 20 m high, 1,200 s duration wave on a steep 0.5° slope. On steep beaches breaking has little time to operate so run-up amplifications are large

may take many eruptive cycles over the next few thousand years to give it that final shove, the volcano will collapse so it is sensible to consider the consequences (Fig. 16). If 500 km³ of its flank falls into the sea like it did last time, a La Palma collapse will spawn a mega tsunami hundreds of meters high locally that will buffet all coasts of the Atlantic with 10–30 m waves.

Gulf of Guinea impact tsunami. In a 2008 training exercise, the US Air Force considered the consequences of, and response to, an impact of a small comet into the Atlantic Ocean off the coast of Guinea. In this scenario, pictured in Fig. 17, tsunami run-ups exceed 10 m along a 1,200 km stretch of coastline. This wave would knock out coastal shipping and oil production facilities for many months and trigger major ripple effects in

Tsunami, Fig. 14 Simulation of 2 m tsunami wave beaching at Galveston Texas. Red area blankets the predicted inundation zone. Note the multiple wave reflections and wave interference that contribute to run-up complexity and randomness

the global economy. Unlike those Hollywood movies, currently there is no defense against an asteroid impact.

Tsunami Forecasting

Official approach: Perhaps the ultimate goal of tsunami research is forecasting. A forecast predicts the size of a particular tsunami given the knowledge that a potentially dangerous earthquake has occurred already. Tsunami travel

at jet speeds, but for many places there may be several hours between the earthquake and the arrival of the sea waves. This time can be spent analyzing seismograms, estimating earthquake parameters, and forecasting the expected height of the oncoming wave with the aid of computer models and initial field reports. This is precisely the mission of the various warning centers like NOAA's Pacific Tsunami Warning Center (PTWC). The past decade has witnessed considerable progress in tsunami forecasting coupled with faster and more geographically selective warnings. By and large, the

Tsunami, Fig. 15 Simulation of the Sumatra Earthquake Tsunami of December 2004. Note the large wave directed toward the northern tip of Sumatra due to the small thrust ramp offshore there

Tsunami, Fig. 16 (Top row) First 12 min of the La Palma Tsunami. Initial wave heights exceed 500 m. (Bottom row) Landslide and tsunami in cross section. Just like the simple example in Fig. 6, water gets pushed up in front of the slide and drawn down behind

Tsunami, Fig. 17 Guinea Impact Tsunami. Four-hour sequence of waves from the impact of a 270 m diameter icy bolide off the west coast of Africa

current tsunami prediction system functions well. Figure 18 pictures a nearly real-time prediction of tsunami run-up from the M8.1 Samoa Earthquake of September 29, 2009. Based on rapid calculations like these, the PTWC issued accurate advanced warnings and watches for this tsunami – at least for locations greater than 2,000 km distance from the quake where sufficient delay time existed.

The biggest uncertainty in the current procedures lay in fixing earthquake parameters quickly. For instance, in the first hours after a quake, it is not uncommon for estimates of earthquake magnitude to vary 0.3 or 0.4 units as more extensive seismic data arrive. Because earthquake magnitude or earthquake moment is the prime driver for tsunami (Eq. 9), a 0.4 unit uncertainty makes for a factor of 2 or 3 uncertainty in tsunami height all else aside. Partly on this concern, the DART buoy network that provides real-time measurements of passing tsunami was expanded from 6 to 24 sites after the Sumatra earthquake. Information from the DART sensors provides a real-time “reality check” on computer simulations run rapidly on uncertain earthquake parameters.

Do-it-yourself approach: Apart from official predictions, readers of this article have enough information to produce a Do-It-Yourself tsunami forecast. The three step recipe needs: earthquake magnitude M , the ocean depth at source H_o , distance to the quake R , and mean ocean depth $\bar{H}$ between the earthquake and you.

Step 1 – Find Initial Tsunami Amplitude A_0

Let us approximate initial tsunami height by:

$$A_0 = \frac{\alpha \Delta u(M)}{\cosh \left[\frac{4\pi H_o}{W(M)+L(M)} \right]}, \quad (20)$$

where α is the fraction of earthquake slip that transforms into tsunami-making uplift:

$$\alpha = (1 - \theta/180) \sin \theta \mid \sin \phi \mid,$$

with θ and ϕ being the fault dip and rake angles in degrees. Fault slip $\Delta u(M)$, width $W(M)$, and length $L(M)$ are functions of magnitude and can be read from Table 1 or computed from the formulas in its caption. You recognize the $1/\cosh$ as the low-pass filter due to the ocean layer. Unlike Eqs. 9 and 20 makes no assumption about radiation pattern, so in this sense it represents the worst case. The most efficient mechanism (surface breaking, pure dip slip on planes dipping near 45°) for tsunami generation gives $\alpha = 0.55$.

Step 2 – Correct for Propagation Loss P

Tsunami waves decay as they travel due to geometrical spreading and frequency dispersion. For an ocean of constant depth $\bar{H}$, the propagation loss is roughly.

Tsunami, Fig. 18 Nearly real-time prediction of run-up height from the 9/29/09 M8.1 Samoa Earthquake. Colors correspond to run-up heights: *Brown* 10–25 cm; *Yellow* 25–50 cm; *Orange* 50–100 cm; *Red* 1–2 m; *Pink* > 2 m

$$P = \left(1 + \frac{2R}{L(M)}\right)^{-\psi}, \quad (21)$$

where

$$\psi = 0.5 + 0.575 \exp\left(-0.0175 \frac{L(M)}{\bar{H}}\right). \quad (22)$$

The first term in exponent (22) accounts for square root of distance losses due to geometrical spreading. The second term in (22) accounts for additional losses due to frequency dispersion with larger dimensioned tsunami decaying more slowly. Peak deep-water tsunami amplitude $A_d(R)$ at distance R is

$$\begin{aligned} A_d(R) &= A_0 P \\ &= \frac{\alpha \Delta u(M)}{\cosh[4\pi H_0 / (W(M) + L(M))]} \left(1 + \frac{2R}{L(M)}\right)^{-\psi} \end{aligned} \quad (23)$$

Propagation loss (23) supposes an unobstructed wave path to the observation location. If the waves pass around headlands, squeeze through narrows, or cut into shadow zones, then (23) again overestimates tsunami size.

Step 3 – Correct for Shoaling and Run-Up

For long waves, the shoaling correction S_L (18) reduces to Green's Law $S_L = (H_0/H)^{1/4}$ and the shoaled tsunami amplitude $A_S(R)$ at distance R is

$$\begin{aligned} A_S(R) &= A_0 P S_L \\ &= \frac{\alpha \Delta u(M)}{\cosh\left[\frac{4\pi H_0}{W(M) + L(M)}\right]} \left(1 + \frac{2R}{L(M)}\right)^{-\psi} \left[\frac{H_0}{H}\right]^{1/4}. \end{aligned} \quad (24)$$

Applying (19) on (24) returns peak wave run-up height $\eta(R)$

$$\begin{aligned} \eta(R) &= [A_0 P S_L]^{4/5} H^{1/5} \\ &= \left[\frac{\alpha \Delta u(M)}{\cosh\left[\frac{4\pi H_0}{W(M) + L(M)}\right]} \left(1 + \frac{2R}{L(M)}\right)^{-\psi} \right]^{4/5} H_0^{1/5}. \end{aligned} \quad (25)$$

Figure 19 plots Do-It-Yourself prediction (25) for earthquake magnitudes 6.5–9.5, at distances R to 10,000 km, for $\bar{H}$ between 1,000 and 4,000 m, and $H_0 = 1,000$ m (*top panel*) and $H_0 = 4,000$ m (*bottom panel*). Because several steps above selected extreme assumptions, these curves represent a mean worst case. The worst worst case might be twice as large still. For $M = 8$, $H_0 = \bar{H} = 4,000$ m, Fig. 19 (*bottom*) predicts run-ups of 3 m at 300 km distance, 2 m at 600 km distance, 1 m at 2,000 km distance, and 0.5 m at 5,000 km distance. These numbers compare well with the more rigorous calculations in Fig. 18.

Tsunami, Fig. 19 Mean worst-case tsunami run-up height versus distance from earthquakes of magnitude 6.5–9.5. The blue areas include an allowance for mean ocean depth between 1,000 (*upper limit*) and 4,000 m (*lower limit*). Top and Bottom panels assume 1,000 and 4,000 m water depth at the source

Summary

Tsunami are gravity-driven water waves caused mostly by undersea earthquakes, but sometimes they are sourced by submarine landslides, surface detonations, explosive volcanoes, and asteroid strikes. Tsunami differ from ordinary beach waves in that they have longer period, larger wavelength, and higher velocity. Because of shoaling effects, these characteristics make tsunami especially damaging because they grow in height proportionally more in approaching shore than do ordinary waves of equal size. This article provides mathematical expressions for tsunami excitation, propagation, and simplified steps to compute wave run-up height from tsunamigenic earthquakes.

Definition

Tsunami. Japanese word literally meaning harbor wave (tsu + nami). Tsunamis are series of ocean gravity waves caused mainly due to undersea earthquakes and undersea volcanic activity, rarely due to submarine landslides and very infrequently due to meteor impacts.

Tsunamigenic earthquake. Large earthquake occurring mostly in subduction zones capable of generating tsunami.

National Tsunami Warning Center (NTWC). A center officially designated by the government for collating and disseminating tsunami warnings/advisories and other related information within its country according to established national Standard Operating Procedure (SOPs).

Tsunami Service Provider (TSP). A center that monitors seismic and sea level activity and issues timely tsunami forecast information within an Intergovernmental Coordination Group (ICG) framework to NTWCs/TWFPs and other TSPs operating within an ocean basin. TSPs may also act as NTWCs providing tsunami warnings for their own countries.

Tsunami Warning Focal Point (TWFP). A 24 × 7 point of contact (office, operational unit or position, not a person) officially designated by the NTWC or the government to

Srinivasa Kumar Tummala is responsible for the choice and the presentation of the facts contained in the publication and for the opinions expressed therein, which are not necessarily those of UNESCO and do not commit the Organization

receive and disseminate tsunami information from a TSP according to established national SOPs.

Tsunami National Contact (TNC). The person designated by a Member State to an ICG to represent his/her country in the coordination of international tsunami warning and mitigation activities.

Tsunami Bulletin. A real-time situation report of the event.

Service Level. Level of operational capability in accurately advising/warning target populace.

Introduction

The 2004 Sumatra-Andaman earthquake and subsequent tsunami in the Indian Ocean were a grim reminder of nature's fury. The event prompted many countries to set up tsunami warning centers (TWC), which were further integrated into a collaborative network of regional tsunami warning systems in the Indian Ocean and Caribbean and Mediterranean Seas by the Intergovernmental Oceanographic Commission (IOC) of the United Nations Educational, Scientific and Cultural Organization (UNESCO). These regional systems, along with the Pacific Tsunami Warning System (PTWS), form a globally integrated system, built on three pillars: tsunami risk assessment and mitigation; tsunami detection, warning, and dissemination; and tsunami awareness and response.

An important fact that is well known about tsunami is that they travel very fast in open ocean (velocity of the order of several hundreds of kilometers per hour) and cannot be discernible easily by wave heights (of the order of a few centimeters), but slow down as they approach the coast (of the order of several tens of kilometers per hour) with wave heights increasing to disastrous proportions (of the order of several meters). Historically, coastal populations would depend on traditional knowledge and natural signs such as ground shaking or water withdrawing from the beach to identify an impending tsunami. While rapid increase in coastal population has increased risk in terms of loss of lives and economic damages (socioeconomic parameters) many fold, advancement of science has made it possible to mitigate the impacts through forewarning. With appropriate sensor networks, modeling, geospatial technologies, and communication infrastructure, such forewarning systems can detect and monitor tsunamis and provide timely advice to coastal populace at risk. Such a scientific establishment is known as Tsunami Warning Center (TWC). The mission of a TWC is to provide early warnings on potentially destructive tsunamis to emergency/disaster management officials, and as appropriate, directly to the public to prevent loss of life and property. This entry briefly describes TWC, its components, the products that are generated, and level of operational service that these centers are designed for.

A typical TWC comprises observational networks (seismic and sea level) for detection of earthquakes and evaluation of potential for tsunami; modeling for generation, propagation of tsunami wave and inundation; database of bathymetry and coastal topography; computational and communication facilities for data acquisition in real time, analysis, and modeling; decision support systems (DSS) based on standard operating procedure (SOP) for generation and dissemination of tsunami advisories (Nayak and Kumar 2011). Based on the capability and the Area of Service, a TWC can be categorized as a National Tsunami Warning Center (NTWC) or a Tsunami Service Provider (TSP). Within India, the Indian Tsunami Early Warning Centre (ITEWC) was established in 2007 at the Earth System Science Organization (ESSO) – Indian National Centre for Ocean Information Services (INCOIS), Hyderabad (Gupta 2005; Nayak and Kumar 2008a). Along with similar centers in Australia and Indonesia, the ITEWC also serves as one of the tsunami services providers (TSP) in the IOC-coordinated Indian Ocean Tsunami Warning and Mitigation System (IOTWMS).

Types of Tsunamis

Several terms are in use for describing tsunamis: historical tsunami, local tsunami, maremoto, meteorological tsunami (meteotsunami), microtsunami, ocean-wide tsunami, paleotsunami, regional tsunami, and teletsunami (distant tsunami) (UNESCO-IOC 2019). However, from the early warning perspective, three types are considered most relevant, based on the distance from the source and the tsunami travel time. They are the following.

1. Local tsunami originates from a nearby source for which its destructive effects are confined to coasts less than 1 h tsunami travel time, or typically within about 200 km from its source. A local tsunami is usually generated by an earthquake, but can also be caused by a landslide or a pyroclastic flow from a volcanic eruption. Over history, 90% of tsunami casualties have been caused by local tsunamis. These can often be the most dangerous because there is often little warning between the causing event and the arrival of the tsunami.
2. Regional tsunami is capable of creating destruction in a particular geographic region, generally within 1000 km or 1–3 h tsunami travel time from its source.
3. Distant tsunami (also called an ocean-wide, distant, tele, or far-field tsunami) is a tsunami that originates from a far-away source, which is generally more than 1000 km away from the area of interest or more than 3 h tsunami travel time from its source. A distant tsunami is capable of causing widespread destruction, not only in the immediate

region of its generation but across an entire ocean. All known ocean-wide tsunamis have been generated by major earthquakes in the subduction regions.

Regional Tsunami Warning Systems

There are four major tsunami warning systems operating today. They are Pacific Tsunami Warning Mitigating System (PTWS); Indian Ocean Tsunami Early Warning and Mitigation System (IOTWMS); Tsunami Early Warning and Mitigation System in the North-Eastern Atlantic, Mediterranean and Connected Seas (NEAMTWS); and Tsunami and other Coastal Hazards Warning System for the Caribbean and Adjacent Regions (CARIBE-EWS). These regional systems operate as “system-of-systems” through their respective Intergovernmental Coordination Groups (ICGs) that are governed by IOC-UNESCO.

The core regional tsunami warning framework comprises a network of NTWCs or Focal Points that receive tsunami forecast information from one of more TSPs. It is the NTWCs/TWFPs, operating within the legal framework of the sovereign nation in which they reside and serve, that provide warnings, watches, and advisories to their citizens. These warnings are based either on the NTWC’s own analysis of the situation, or on the forecast information received from TSPs, or on a combination of all. The TSPs operating within an ocean basin are interoperable not only within themselves but also with other ocean basin TSPs, by using common and agreed formats and procedures. For instance, the IOTWMS comprises NTWCs/TWFPs in 28 countries bordering the Indian Ocean with three centers acting as the TSPs – Indian Tsunami Early Warning Centre (ITEWC), Indonesian Tsunami Early Warning System (InaTEWS), and Joint Australian Tsunami Warning Centre (JATWC). Other TSPs in the IOC-UNESCO framework operating in other ocean basins include French National Tsunami Warning Centre (CENALT), Institute of Geodynamics, National Observatory of Athens, Kandilli Observatory and Earthquake Research Institute, National Institute of Geophysics and Volcanology (INGV), Instituto Português do Mar e da Atmosfera (IPMA), Pacific Tsunami Warning Center (PTWC), and the Northwest Pacific Tsunami Advisory Center (NWPTAC). Figure 1 shows the area of coverage of the four regional systems and area of service of each TSP.

Key Components of a Tsunami Warning Center

In the following sections, key components and procedures followed by a Tsunami Warning Center are described with reference to the Indian Tsunami Early Warning Centre as an example. It may be noted that while the key components

broadly remain the same among different TWCs, procedures and products might vary to suit national or regional requirements. Further, the key elements integrated in a TWC become the essential and minimum requirements in dealing with other ocean-related hazards like: cyclone-related storm surges, and impacts of long-term coastal erosion and sea level rise.

In order to carry out its mission, a TWC must at least consist of five important components: a network of sensors (seismic and sea level) to detect earthquakes and evaluate its potential for tsunamis; tsunami modeling capability (generation, propagation, and inundation models); high-resolution database on bathymetry and coastal topography; communication infrastructure to receive data from observation platforms and issue timely dissemination to stakeholders to facilitate evacuation of coastal areas, and a 24 × 7 operational facility housing the infrastructure, decision support system (DSS) based on standard operating procedures (SOP), and experienced staff (Nayak and Kumar 2008a). A typical outlay of a warning center is shown in Fig. 2.

Observation Network

Seismic Network

TWCs use local and global seismographic networks transmitting seismograms in real time to continuously monitor seismicity, in order to locate and estimate the size of potentially tsunamigenic earthquakes. To produce accurate moment magnitude, NTWCs and TSPs require reliable, broad-frequency, low-noise, high dynamic-range, digital seismic data in real time. The timeliness of the data is crucial in issuing an initial bulletin within 5 min of an earthquake. This is especially important for centers with local tsunami sources. In terms of network density, it is recommended that at least eight stations must be operating in a radius of 900 km, with data latency not exceeding 30 s. IRIS Global Seismographic Network (GSN), Comprehensive Nuclear Test Ban Treaty Organization (CTBTO), and the German Research Centre for Geosciences (GFZ) Geofon Extended Virtual Network and stations from other national and regional networks are used in conjunction with national networks for earthquake detection. Focal mechanism of earthquakes that can lead to assessment of its tsunamigenic potential is generally derived through moment tensor inversion of seismic data. Limitations in assessing these parameters accurately enough within the timelines needed to provide tsunami warnings lead to several uncertainties. GNSS data is increasingly being used to estimate source parameters in real time (Blewitt et al. 2006; Sobolev et al. 2007) to reduce uncertainties in tsunami warning. Using high-rate (1 Hz or greater) dense GNSS network, large dynamic and static ground motions within few tens of seconds can be measured accurately. Also, strong motion accelerometer data are being used for estimating magnitude and derive displacements to complement GNSS-derived parameters.

Tsunami Watch and Warning Centers, Fig. 2 Typical components of an end-to-end tsunami early warning system. (Courtesy: ESSO-INCOIS)

Sea Level Network

In order to confirm whether the earthquake has actually caused a tsunami, it is essential to measure the change in water level as near to the fault zone as possible with high accuracy. TWCs use sea level networks (tide gauge, bottom pressure recorders, and coastal ocean dynamics applications radar (CODAR)) reporting data in real and near real time to verify the generation and evaluate the severity of a tsunami. Numerous international sea level monitoring networks provide essential real-time data that can be accessed by NTWCs and TSPs. Many of these networks are coordinated by the IOC-UNESCO. The most extensive and notable is the Global Sea Level Observing System (GLOSS), conducted under the auspices of the Joint Technical Commission for Oceanography and Marine Meteorology (JCOMM) of the World Meteorological Organization (WMO) and the IOC. A tsunami creates a signal component that is not normally present in the observed sea level in usual times. Fortunately, the signature of tsunami waves at sea level gauges is generally quite distinctive and thus recognizable (see Fig. 3) and can be differentiated from a signal due to storm surge (UNESCO-IOC Manual and Guides 2006).

Techniques to use open ocean sea level data from bottom pressure recorders to estimate the characteristics of source have significantly enhanced the capabilities of TWCs to issue accurate tsunami forecast information for regional and distant tsunamis. In addition to characterizing tsunamis triggered by earthquakes, this methodology can be applied to derive source characteristics of tsunamis caused by atypical sources such as volcanic eruptions and submarine landslides (Patanjali Kumar et al. 2015; Mulia et al. 2018).

Tsunami Forecast Modeling

Guesstimating the generation mechanism of tsunami from the earthquake information, identifying the wave propagation

scheme, forecasting the travel time, and mapping inundation zones are critical requirements in tsunami early warning, which can be accomplished using numerical models. Two of the most commonly used tsunami models presently are the Method of Splitting Tsunami (MOST) developed by Titov and Gonzalez (1997) and the Tohoku University's Numerical Analysis Model (TUNAMI) developed by Imamura et al. (1995). Both these models are capable of simulating the three processes of a tsunami: earthquake generation, trans-oceanic propagation, and inundation of land. These models basically take the seismic deformation as input to predict the run-up heights and inundation levels at coastal regions for a given tsunamigenic earthquake (Imamura et al. 1995). The seismic deformation for an earthquake is computed using Mansinha and Smylie (1971) formulation using the earthquake parameters like epicenter, focal depth, strike, dip and rake of the rupture plane, length, width of the rupture, and slip magnitude on the rupture plane.

Pre-run Model Scenario Database

The above models cannot be run in real-time situations because of the computational overheads and resources. Hence, a pre-run scenario database or look-up-table (LUT) approach is most suitable in operational conditions. The forecast strategy is based on a unit-source function methodology, whereby the model runs are individually scaled and combined to produce arbitrary tsunami scenarios. Each unit-source function is equivalent to a tsunami generated by a 7.5 Mw earthquake with a rectangular fault 100 km by 50 km in size and 1 m slip (Gica et al. 2008; Greenslade and Titov 2008; Nayak and Kumar 2008b, c). The faults of the unit functions are placed abutting each other. When the functions are linearly combined, the resultant source function is equivalent to a tsunami generated by a combined fault rupture with assigned slip at each sub-fault. These unit sources are located along the

Tsunami Watch and Warning Centers, Fig. 3

Sea level observations at different tsunami buoys and tide gauges installed in the Indian Ocean region showing water-level variations during the 11 April 2012 tsunami. (Srinivasa Kumar et al. 2012). STB – tsunami buoy deployed by India, 23401 – tsunami buoy deployed by Thailand

known fault zones for the entire Pacific Basin, Caribbean for the Atlantic region, and Indian Ocean. The key input source parameters are calculated using global relations from magnitude of the earthquake and fed to the model. In worst-case scenario, strike angle is considered as parallel to trench or coast, dip angle 45° , slip angle 90° . Figure 4 shows how the unit sources are set up in the Indian Ocean. A database of pre-run scenarios has been created for 50,000 unit sources covering all the tsunamigenic sources in the Indian Ocean region based on a finite difference code of Tsunami N2 model. Each scenario output contains the expected tsunami wave travel times, run-up heights, and directivity maps. At the time of earthquake occurrence, based on the location and magnitude, the basic unit-source open-ocean propagation scenarios are selected from the pre-run scenario database. These scenarios are then merged and scaled up/down using scaling relations

(Nayak and Kumar 2008c) to reconstruct a scenario representing the actual magnitude. The performance of the model is validated with the observations, and the model results are compared well with real-time observations (Srinivasa Kumar et al. 2010, ISPRS).

Inundation Modeling and Mapping

Most warning centers currently provide information on tsunami wave heights along the coastal regions, but not inundation extent on land. To achieve this, open-ocean wave from the scenario database, described in previous section, has to be extended over to the shallow waters and to the coastal area to simulate inundation over land. Knowing the coastal inundation zone is the first step in disaster management and mitigation, as it directly tells us the extent of population to be evacuated and the estimated economic loss due to an event.

Tsunami Watch and Warning Centers, Fig. 4 Modeling using “unit-source” approach and the resulting scenario database. (Courtesy: ESSO-INCOIS)

To perform accurate modeling of tsunami inundation and run-up, a detailed model of near-shore bathymetry and coastal topography is necessary. This is crucial as the accuracy of model predictions is directly related to the quality of the data used to create the bathymetry and topography of the model area. Coastal bathymetry is the prime determinant of the height of the tsunami wave or storm surge as it approaches the coast. Within the Indian Ocean context, topography of the region at 1:25,000-scale with contours at intervals of 0.5–2 up to 20 m has been acquired. Preliminary maps have been prepared of coastal topography using satellite stereo data (CARTOSAT-1) for the Indian coast. These datasets, along with airborne Light Detection and Ranging (LIDAR) data, were further used to create coastal vulnerability index (CVI) maps and multi-hazard vulnerability maps (MHVM) of coastline of India (Nayak and Kumar 2008c). Similar high-resolution geospatial database is being leveraged in the Atlantic and Pacific Oceans (Gica et al. 2008). With advances in techniques for near-real-time estimation of earthquake source

parameters and availability of high performance computers, it is now becoming feasible to run tsunami inundation models in real time.

Inundation mapping is not the only area where geospatial technologies are used, the inundation levels estimated and the subsequent threat status have to be accurately linked and conveyed to the respective administrative block within the coastal zones or within a province or a country. To implement such mechanism, the concept of coastal forecast points (CFP) and coastal forecast zones (CFZ) was developed (ICG/IOTWS) and implemented within the Indian Ocean region. Another major application of evolving geospatial trends is the application of 3D modeling or “video-grammetric” approach to visualize inundation and to identify evacuation routes and safe houses during inundation.

In India, Multi-hazard Vulnerability Mapping (MHVM) was carried out to identify highly vulnerable coastal zones along the Indian Coast. The multi-hazard vulnerability maps use blended and combined overlay of multiple hazards

(tsunami, storm surge, sea level rise, coastal erosion, etc.) affecting the coastal zone. These maps can aid as critical information during a disaster for the evacuation process and to evolve a management strategy (Mahendra et al. 2011). Further, high-resolution 3D GIS mapping in selected vulnerable areas was developed and integrated on 3D visualization application (3D-VAS). Three-dimensional GIS mapping comprised realistic 3D models of the buildings along with the attributed details of socio-demographic data. The major objectives of 3D GIS mapping are to visualize and effectively communicate the inundation threat at street level and to plan for evacuation routes.

Real-Time Tsunami Modeling for Propagation and Inundation
Most warning centers currently provide information on tsunami wave heights along the coastal regions, but not inundation extent on land. ITEWC is now warning on a finite element based shallow water and circulation model – ADvancedCIRCulation (ADCIRC) – to compute tsunami wave propagation and inundation (Luettich and Westerink 2004). Alternately, coastal high-resolution model grids can be run in real time by forcing them with wave heights along open boundary, extracted from an open ocean propagation simulation. Advances in the computing technology facilitated ITEWC to run the models on experimental basis successfully. The tsunami propagation of 24 h for the Indian Ocean Domain grid is tested for the Sumatra and Makran subduction zones and the simulation takes around 2 min of run time using 480 processors for 0.4 million computational grid. Tsunami open ocean propagation and inundation simulation of 12 h for the 2.8 million grid points is tested at the Sumatra subduction zone for 2004 tsunami, and it takes around 8.5 min (Fig. 5a, b).

Communication Infrastructure

Communication infrastructure is the most crucial and tangible aspect of any warning system for tsunami or any hazard. The ability to report and warn of an event is what makes and defines the warning system. Communication in terms of receiving all scientific data and disseminating information to the target audience within the required time needs a reliable communication infrastructure. During this process, warning centers must respond fast, be as accurate as possible, and be reliable in order to be effective. All tsunami warning systems feature multiple lines of communications (such as SMS, email, fax, radio, texting, and telex, often using hardened dedicated systems), enabling emergency messages to be sent to the emergency services and armed forces, as well as to population alerting systems.

Decision Support System

In simple words, when the standard operating procedures are coded into a program that can support organizational decision making, then such a program can be called as a decision

support system. It helps decision makers to compile useful information from a combination of raw real-time data, documents, personal knowledge, and tsunami scenarios models to accurately disseminate warning advisories to the needed area at the right time. The DSS encapsulates and foresees all the operations from the beginning of the event till the passage of threat by issuing timely advisories. Typical bulletins issued by the ITEWC are earthquake information, warning, watch, and alert, which are described in detail in the following sections. All the information gathering, decision-making process, and infrastructure are part of the operational monitoring center.

Typical Bulletins Issued by TWCs

Based on the earthquake information, tsunami modeling scenarios, and operational capability, different types of advisory products are issued to the disaster management officials and to the general public. Each bulletin has a distinct meaning and clearly suggests the action to be taken. The earthquake information bulletin issued solely on the earthquake information is a qualitative advisory while all others are quantitative advisories (Figs. 6 and 7) issued taking into consideration the modeling results and real-time sea level observations, along with the earthquake information.

1. Earthquake information bulletin is issued to inform the occurrence of an earthquake and to advise its potential to generate a tsunami based on the magnitude. The bulletin contains information about the earthquake parameters (origin time, latitude, longitude, focal depth, and magnitude) and the name of the geographical area where it has occurred.
2. Warning is the highest level where immediate action has to be taken. This advisory is issued when a potential tsunami with significant widespread inundation is imminent or expected. Warnings alert the public that widespread, dangerous coastal flooding accompanied by powerful currents is possible and may continue for several hours after arrival of the initial wave. Warnings also alert emergency management officials to take action for the entire tsunami hazard zone. Warnings may be updated, adjusted geographically, downgraded, or canceled.
3. Watch is issued to alert emergency management officials and the public of an event which may later impact the watch area. Immediate public evacuation is not required. Local officials should be prepared for evacuation if it is upgraded to warning status. The watch area may be upgraded to a warning or canceled based on updated information and analysis. Watches are normally issued based on seismic information without confirmation that a destructive tsunami is underway.
4. Alert contains information about the earthquake and a qualitative tsunami evaluation message indicating that a tsunami is expected. As conditions warrant, the bulletin will either be continued, upgraded to a watch or warning, or canceled. Alert implies public should avoid beaches since strong

Tsunami Watch and Warning Centers, Fig. 5 (a) Initial deformation of ocean surface due to 26 December 2004 earthquake. (b) Computed tsunami heights due to 26 December 2004 earthquake at different time steps

Tsunami Watch and Warning Centers, Fig. 6 Tsunami threat status map. (Courtesy: ESSO-INCOIS)

currents are expected. Local officials should be prepared for evacuation if it is upgraded to warning status.

5. Cancellation indicates the end of the threat due to tsunami. A cancellation is usually issued after an evaluation of sea level data confirms that a destructive tsunami will not impact the warned area anymore. A cancellation will also be issued following a destructive tsunami when sea level readings indicate that the tsunami is below destructive levels and is subsiding in most locations.

Service Levels

Based on the level of integration of key component into the TWC, each TWC has the capability to deliver products at certain operational level. Each higher service level represents much more detailed threat evaluation and will be directed to more specific agencies/population group for disaster mitigation with increased confidence levels. Presently, the implementation plan

of IOTWS (IOC-UNESCO 2016) classifies these product levels into three groups, based on incremental capacity development:

Service Level I: At this level of operation, the TSP disseminates only the earthquake information and a qualitative tsunami threat evaluation to other national warning centers.

Service Level II: This is a more robust service level that includes all of the elements of Service Level I but adds modeling and forecast elements so that Watches and Advisory products include: estimated wave height(s) (EWH) and estimated time(s) of arrival (ETA) for offshore forecast points, potential threat zones, advanced warning and notification products of threat status and zones in image format. At this service level of operation, real-time observations are included in the decision making and in advisory products.

Service Level III: This is the most advanced level of operational service. At this level, the advisory products include

Tsunami Watch and Warning Centers, Fig. 7 An example of quantitative advisory bulletin product. The product includes graphic of tsunami travel time, along with text indicating the forecast of wave heights

and arrival time along with threat status to each administrative zone in the Indian Ocean. (Courtesy: ESSO-INCOIS)

local risk and hazard assessment using inundation models, and they are more specifically directed to communities at risk. Service Level III operations take into account real-time inundation forecast in evaluating the threat status.

A TWC operating at this service level indicates a mature early warning system capable of detecting and evaluating tsunamigenic earthquakes occurring anywhere in the global oceans.

Conclusion

Tsunami warning systems have made significant progress in recent years, but challenges and uncertainties remain in meeting the information requirements for facilitating effective response of disaster managers and public due to very short timeframes available for tsunami warning. Current systems are capable of providing warning only for earthquake generated tsunamis but cannot provide warnings for tsunamis caused by atypical sources (submarine and coastal landslides, volcanoes, etc.) or near-field tsunamis, as witnessed from the 2018 Palu and Sunda Strait tsunamis in Indonesia. Tsunami warning for near-source regions that requires rapid public response (within few minutes) is extremely challenging considering scientific uncertainties involved in accurate assessment of source characteristics, gaps in warning chains and stakeholder Standard Operating Procedures (SOPs), and lack of public awareness and response.

The most important unknown information about a tsunami in real time is the nature of source. Efforts are underway for use of technologies such as GNSS and BPR data inversion for rapid estimation of source, but current observation networks are far from optimal. Another huge limitation in the accurate modeling and forecasting of tsunamis as they interact with the coast is due to the non-availability of high-resolution topography and bathymetry data. New and emerging ocean sensing capabilities such as increasing number of coastal sea level stations, BPRs on under-sea fiber-optic cables, GNSS networks, advances in seismology modeling, and computational resources present an opportunity to greatly reduce and/or quantify uncertainties associated with tsunami forecasting (Angove et al. 2019).

Strengthening warning capabilities to be able to detect, model, and monitor tsunamis from a wider range of sources is a challenging, but priority task. Further, stronger downstream, including community preparedness, initiatives to enable appropriate response to official warnings and more importantly natural signs of a tsunami are extremely important for saving lives of vulnerable people.

Acknowledgments The authors would like to specially thank Ms. Sunanda Manneela for compiling information in the preparation of the manuscript, and Mr. Ch. Patanjali Kumar, Mr. R. S. Mahendra, Dr. P. L. N. Murty, Mr. Ajay Kumar, and Mr. J. Padmanabham for providing graphical inputs and in developing the manuscript. The authors are grateful to Dr. S. S. C. Shenoi, Director, ESSO-INCOIS for encouragement and cooperation.

motion, and the Andaman Sea ridge transform fault system which is characterized by the normal and strike slip earthquakes of low magnitude ($M < 6.5$), do not pose tsunami hazard to the Bay of Bengal region. Tsunami hazard in the Bay of Bengal due to seismicity in the diffused plate boundary region between India and Australia in the Indian Ocean needs to be considered as this region produced two great earthquakes on April 11, 2012 (Yadav et al. 2013). Although these earthquakes, and a few more which occurred in the Wharton basin, were characterized by the strike slip motion and did not cause any significant tsunami, due to the complex tectonics involved in the diffused plate boundary region, possibility of a tsunamigenic earthquake may not be completely overruled.

Plate Motion Along the Northern Sunda Arc

In the northern Sunda arc relative motion between the India and Sunda plates is about 3.7 cm/year towards N15° in the northern part (i.e., Indo-Burmese arc region) and about 4.5 cm/year towards N25° in the southern part (i.e., the Sumatra region). The oblique motion between the India and Sunda plates is accommodated along the arc through slip partitioning in the frontal and back arc (Gahalaut and Gahalaut 2007; McCaffrey 2009). In the north, the north-south trending Indo-Burmese arc accommodates slip of about 1.6 cm/year through predominantly dextral motion (Gahalaut et al. 2013) and the remaining motion of about 2.0 cm/year is accommodated across the dextral strike slip Sagaing fault in the Myanmar (Maurin et al. 2010). However, Steckler et al. (2016), based on some additional GPS measurements from Bangladesh, proposed that some of the India-Shan plateau motion is accommodated through thrust motion on the detachment beneath the outer Indo-Burmese wedge. Further south in the Irrawaddy and Andaman region, the motion in the frontal arc becomes oblique. In the back arc, the dextral strike slip motion occurs along the north-south planes and normal motion occurs along the Andaman Sea-ridge transform fault system which is consistent with the Andaman sea opening. In the Sumatra region, the motion in the frontal arc is arc normal, leading to thrust motion on the plate boundary interface. Strike slip motion in the back arc is accommodated through dextral motion along the Sumatra Fault System. The Sumatra Fault System joins the Sagaing fault in the north through the Andaman Sea Ridge transform fault system.

Seismicity of the Northern Sunda Arc Region and Tsunami Hazard

For the convenience of discussion, the seismicity of the Indo-Burmese arc, Irrawaddy, and Andaman-Sumatra region is described separately.

Indo-Burmese Arc

The plate reconstruction models suggest that subduction probably occurred along the Indo-Burmese arc in the geological past (prior to about 50 Ma) when the arc was predominantly southeast-northwest trending. However, after the collision of the India plate with the Eurasian plate, the northern Sunda arc rotated clockwise to become predominantly north-south trending. Several geological and geophysical studies confirm that the subduction occurred across Indo-Burmese arc between India and Burma plates and there is evidence of the subducted Indian slab, but whether the subduction is still active, is debatable (Hall 1997; Guzman-Speziale and Ni 1996; Rao and Kumar 1999; Pesicek et al. 2010; Gahalaut et al. 2013; Steckler et al. 2016).

The historical records of earthquakes and tsunami in the Indo-Burmese arc are generally very poor. Although there are a few unverifiable reports of earthquake occurrence as early as 1548 in Tripura, Assam (two states in the northeastern India), or Bangladesh, there are large uncertainties in the location of historical earthquakes. The catalogue is probably reliable only after 1762. The most notable earthquakes are the April 2, 1762, August 24, 1858, Arakan earthquakes, and the January 10, 1869, Cachar earthquake (Richter 1958). Other than these earthquakes, several instances of damage due to earthquakes are reported from Chittagong, Sylhet, Manipur valley, and Cachar regions. However, it is possible that the high damage in these sediment filled valleys was due to relatively large population and local site effects. The April 2, 1762, Arakan earthquake has been considered as a great tsunamigenic earthquake (Cummins 2007). It caused extensive damage in the Chittagong region through shaking, liquefaction, damming of channels, seiches, etc. (Gulston 1763). The reported uplift of Cheduba Island due to this earthquake was not found to be singularly due to this earthquake (Oldham 1883; Martin and Szeliga 2010). Halsted (1843) reported the effects of the earthquakes which were mostly found to be highly exaggerated by Gupta and Gahalaut (2009). They found that the highly qualitative observations of the coseismic elevation changes are consistent with a predominant strike slip motion on the earthquake rupture which was located under the land and/or under very shallow water, and it was only a major earthquake (Martin and Szeliga 2010) which probably did not cause any major tsunami (Gupta and Gahalaut 2009). The August 24, 1858, Arakan earthquake was felt in many parts of Burma and was severely felt at Kyauk Pyu, Ramree Island, Myanmar. It caused liquefaction, damage to buildings and Pagodas. In this region, the distance between the Sagaing fault and the structurally mapped Arakan trench is less than 200 km, and hence based on the scanty reports of damage it is difficult to judge whether this one and the 1843 and 1848 earthquakes are linked with the Indo-Burmese arc or with the Sagaing fault. But none of these three earthquakes is associated with tsunami. The January

10, 1869, Cachar-Manipur earthquake is referred as the most severe earthquake in the available 2000 years of written historical records of Manipur state of India. However, recent examinations of the historical records suggest that even this earthquake was not a great earthquake and the damage was very much confined in the sediment filled valleys of Imphal and Cachar (Kundu and Gahalaut 2012). As this earthquake occurred on the land, far from the sea, there is no question of tsunami being generated by this earthquake. Based on the observations of recent earthquakes, which also include the 2017 Tripura (M 5.6) and 2016 Manipur earthquakes (Debbarma et al. 2017; Gahalaut et al. 2016), which exhibit strike slip motion at depth more than 25 km, it has been suggested that these earthquakes occur within the Indian plate and not on the interface between the Indian plate and the Indo-Burmese wedge.

Although precise motion on rupture during these historical major earthquakes is not known, the current seismicity and the results from crustal deformation studies suggest that these earthquakes in the Indo-Burmese arc might have occurred through predominant strike slip motion on steep planes within the Indian plate. These observations limit the possibility of a tsunamigenic earthquake in the coastal Indo-Burmese arc region. Lack of paleo-tsunami deposits in the coastal Myanmar region (Aung et al. 2006) further supports this argument.

Irrawaddy Region

Seismicity in the Irrawaddy frontal arc is extremely low as compared to that in the Andaman Nicobar arc in the south and the Indo-Burmese arc in the north. Earthquakes in the Irrawaddy region occur at depths less than 50 km, whereas in the Indo-Burmese arc and the Andaman Nicobar region, earthquakes occur down to a depth of up to 150–200 km (Guzman-Speziale and Ni 1996). From the limited available earthquake focal mechanisms, it is not possible to constrain sense of motion along this part; however, the regional plate motion models suggest that very oblique motion occurs along the frontal arc (Gahalaut and Gahalaut 2007). The reason for very low seismicity of the frontal arc at shallow depth (>50 km) could be that the region is either aseismic or accumulating strain. However, absence of seismicity even at depths greater than 50 km suggests that the subducting slab might not be continuing to that depth at all. In the Andaman and Indo-Burmese arc regions, occurrence of earthquakes at intermediate depths confirms the continuity of the Indian plate slab in those regions. The absence of seismicity at intermediate depth level of the Irrawaddy region is possibly due to the presence of tear in the subducting Indian slab, which has been confirmed from the tomographic studies of the region (Richards et al. 2007). Thus, it is the tear in the slab which is responsible for very low seismicity at shallow depth and no seismicity at deeper depth (Kundu and Gahalaut 2010). Presence of a tear and lack of slab in the region may substantially

reduce the potential of occurrence of a future great earthquake in the region. Accordingly, it may also reduce tsunami hazard in the nearby regions due to major and great earthquakes in this region. It is possible that this tear hindered the northward rupture propagation of the 2004 Sumatra Andaman earthquake. However, it is necessary to further confirm the presence of such a tear using marine deep seismic surveys, detailed tomographic studies, and analysis of earthquakes with the deployment of ocean bottom and land seismometers in the region.

Andaman Sumatra Arc Region

The state of knowledge about the Andaman-Sumatra region was very poor until the occurrence of the December 26, 2004, Sumatra-Andaman (M 9.2), March 28, 2005, Nias (M 8.6) and several other earthquakes since then. These earthquakes have provided immense information about the tectonics and seismogenesis of this region. These earthquakes suggest that Indian plate subducts obliquely beneath the Andaman arc while the subduction becomes arc normal in the Sumatra arc. Precise hypocentral locations of these earthquakes and their aftershocks have helped in mapping the subsurface plate boundary interface in the frontal arc region and its seismogenic width. The 2004 Sumatra Andaman earthquake occurred on a 1400 km long and 100–150 km wide rupture between the northern Sumatra and north Andaman Islands. The large coseismic displacement in the source region (Gahalaut et al. 2006) caused a devastating tsunami which propagated through the Indian Ocean and caused heavy destruction in the countries surrounding the Bay of Bengal, namely, Indonesia, India, Thailand, and Sri Lanka. There were a few remarkable aspects of this earthquake and tsunami caused by it. It is learnt that the rupture in the northern part, i.e., under the Andaman Islands, was slower (Lay et al. 2005) and that it did not reach the surface. Thus, this part of the rupture did not contribute in tsunami generation. It has been suggested that the subducting 90°E ridge probably slowed down the rupture under the Andaman Islands (Gahalaut et al. 2010) and the subducted unconsolidated sediments of Bay of Bengal probably did not allow the rupture to propagate to the surface. These aspects need to be explored further. Earlier, another earthquake occurred here on June 26, 1941, with M 7.7 (Pacheco and Sykes 1992), for which no seismological data exist to suggest whether slow rupture occurred during that earthquake as well. Though the reports are scanty, it appears that even that earthquake did not generate a tsunami (Rajendran et al. 2007). There may be various reasons for that earthquake for not being tsunamigenic, including slow rupture speed and rupture on blind fault. It may be possible that the Andaman segment may not generate major tsunami during future great earthquakes as well. However, it needs to be explored further by analyzing the frontal arc characteristics through deep seismic imaging and modeling.

An earthquake occurred on December 31, 1881 (M 7.9), in the Nicobar region. It caused a tsunami with less than 1 m height in the Andaman Islands and the coastal region of India (Ortiz and Bilham 2003). Unfortunately, the history of the Andaman Nicobar Islands is very poor. The intermittent colonial occupation of the Islands started in the middle of the eighteenth century by the Danish, followed by the British and continuous colonial occupation started only after 1869 until the independence of India in 1947. Prior to the nineteenth century, we do not know much about the history of the Andaman-Nicobar region as the indigenous tribes did not maintain any written records. Thus, prior to the occurrence of earthquakes on 31 October 1847, possibly near Nicobar Islands (Bilham et al. 2005), and the two earthquakes mentioned above, we have no knowledge of historical earthquakes or tsunami in the region. However, it is certain that the great and major earthquakes under the Nicobar and northern Sumatra arc have produced tsunami and are capable of generating tsunami during future great and major earthquakes.

In the northern Sumatra region, after the occurrence of the 2004 Sumatra-Andaman earthquake, another great earthquake occurred to the south on March 28, 2005, which is referred as the Nias earthquake. Despite its large magnitude and normal rupture speed, the earthquake could not generate a major tsunami. Majority of the slip on the rupture occurred under the shallow and no water and hence it could not displace large amount of water, causing only a localized tsunami whose amplitude faltered quickly as it moved in the open ocean. Nevertheless, this region has the potential to generate a tsunami during great earthquakes, though it may not affect the Bay of Bengal region due to rupture directivity. The arc region located further southeast, though capable of causing tsunami during great earthquakes, may not affect the Bay of Bengal region.

The intense earthquake activity in the Sumatra Andaman subduction zone probably triggered earthquakes in the outer rise and also in the diffused plate boundary in the Wharton basin. The largest earthquake in this region occurred on April 11, 2012, with a magnitude of 8.6 which was immediately followed by another large magnitude earthquake (M 8.2). However, both these and other earthquakes in the Wharton basin accompanied strike slip motion and hence were not tsunamigenic and the earthquakes in the outer rise were not so large to cause tsunami. The complex tectonic processes in the diffused plate boundary region do not necessarily warrant that large earthquakes with dip slip motion would not occur in future in that region.

Summary

The Arakan coast of the Indo-Burmese arc can produce a major earthquake. However, it is unlikely that a major

tsunami would be generated by the earthquake in this segment due to predominant strike slip motion on the plate boundary interface which is mostly located on the land and under very shallow water and dips eastward, away from the sea. The Irrawaddy frontal arc region may not produce great or even major earthquakes and hence the tsunami threat from this region is low. The Andaman arc which did not contribute in tsunami generation during the 2004 Sumatra-Andaman earthquake needs to be studied in great detail in view of the slow and blind rupture. The real and definite threat is from the Nicobar and northern Sumatra arc region, which has produced tsunami in the past and is capable of generating tsunami during future great earthquakes. The diffused plate boundary region in Wharton basin may also be considered as a possible region which may produce a tsunamigenic earthquake.

Synonyms

Ambivalence; Error statistics; Uncertainty quantification; Unpredictability; Vagueness

Definition

In order to be able to make reliable predictions about the quality and validity of geomodelling, the knowledge and quantification of uncertainties in input and output parameters is of increasing importance. For this purpose, the influence of the uncertainties and their extent on the result of the modelling is investigated by statistical methods. The evaluation of these uncertainties is specifically important when geomodelling is combined with geophysical inversion.

Introduction

In all Earth Sciences, scientific practice involves the construction, validation, and application of scientific models. A model is a construct (of equations, relations, imaginary bodies, etc.) that represents one or more (interesting and relevant) aspects of reality. Thus, a model is always a simplification and it is important that the aspect/parameter of reality to be modelled is also represented.

A geoscientific model is an image of a geoscientific process (4-D) or a structure (3-D) that can be verified on the object and is as consistent as possible in itself, which does not necessarily mean that it fully resembles truth. Since geoscientific processes are always four-dimensional and there are always too many equations and too few parameters available for modelling, models must always be simplified, which generally limits their informative value. Therefore, numerical methods are becoming more and more important, which can provide information about how close a model comes to reality and to what extent the input variables influence the modelling result. This leads to the explanation of the terms “uncertainty,” “sensitivity,” and/or “error.”

Uncertainty

The quantification of uncertainty describes an interdisciplinary field of research with the aim of quantitatively assessing input and output data of technical-scientific calculations, which are subject to high variability or are only partially known, and to determine their influence on relevant target quantities, so-called quantities of interest (e.g., material parameters such as velocities, densities, porosities, resistivities, but also the geometry of rock formations). The main focus is on the analysis of mathematical-physical models, which can be described by means of numerical relations (e.g., differential equations). If one concludes directly from the measured input variables (data) on the geometry and the distribution of parameters, one also speaks of inversion – and vice versa of forward modelling. In addition to verification and validation, the determination of uncertainty is an essential quality assurance measure for the evaluation of modelling results.

Error and Accuracy

Unlike uncertainty, which is understood to be the range of possible values within which the true value of a modelling (or measurement) lies, the term error, as it is normally used, means the difference between a “measured” value and the true

value for a measurement. Since the exact or “true” measured value of a quantity/model/inversion is often not known, the error for a measurement/modelling can rarely be determined. Since the true model is usually not known, the accuracy of a model is also usually not known.

Sensitivity

The sensitivity analysis provides general information on how changes in the input conditions influence a result/modeling, i.e., how sensitive, sensible, or fragile a modeling reacts. In principle, the representation as a sensitivity diagram can also be used in technical-physical disciplines. In all these processes, it is characteristic how much physical input variables such as sensitive temperature, pressure, petrological rock composition, or the quality of these variables affect the modelling result.

Uncertainties in the Transformations of Earth Science Problems into a Mathematical Model: Reasoning Behind Modeling and Basic Concepts

As already mentioned above, a distinction is made between forward modeling (see ► [“Gravity Modeling, Theory and Computation”](#)) and inversion. An example of forward modeling is the solution of differential equations under the assumption of constraints and/or initial conditions in a region whose geometry and physical properties are well known. Mathematically, inversion of geophysical data is always an ill-posed problem because it usually suffers from ambiguity. Data inversion is a central step in processing and interpretation of measured data (among many others references, e.g., Clauser 2014).

Geoscientific information for subsurface investigations is typically derived from diverse measurement types with varying quality, combined with aspects of geological knowledge concerning the geological evolution and the current setting (e.g., Wellmann and Caumon 2018). Based on these considerations, several decisions have to be made to derive a mathematical model about subsurface structures and property distributions, which can then be integrated into forward and inverse modeling workflows. We consider here four important decision steps to derive mathematical models of geological structures:

Reduction and Simplicity Concepts in Geosciences

In the past, it has been repeatedly argued that geological generalizations can be traced back to the basic laws of physics and chemistry. In the case of contradictions between geological observations and geological and physical laws, the physical laws are always regarded as the more fundamental. Geological laws therefore arise from the action of physical laws under certain boundary conditions of planet Earth. This

point of view has the great advantage of offering a unified view of nature; it thus also appears as a direct consequence of the principle of simplicity.

Interface Representations as Reduction of Reality

In subsurface investigations, we are often interested in the spatial distribution of specific properties. A logical approach would therefore be to simulate the evolution of this region from initial conditions and first physical principles. But due to the problem of the reductionist concepts described above, this is not (yet) possible on the typical scale of crustal investigations, where we are often interested in resolutions on the scale of meters (or, at least, hundreds of meters). We therefore need to find a meaningful simplification of the entire complexity of the evolution of the Earth.

A joint feature of most of these spatial elements is that they can be represented in a 2-D interface, and this realization has been at the core of geological mapping since the first geological maps. It has logically been extended into the 3-D domain with a wider application of 3-D modeling methods. Here, we will focus in more detail on this concept, describe methods for interface description, the treatment of uncertainties, as well as the link to geophysical forward modeling and inversion.

Scale and Typical Representations

Another important first step in any geoscientific investigation is the decision on the relevant scale of features that should be considered. This decision depends on the aim of the investigation, as well as on data availability and the measurement method with its respective resolution.

The distinction of scales described above is not only relevant for different types of investigations, as they are often investigated by several subdisciplines in geosciences, but also for practical modeling purposes and the specific methods, which developed often within these subdisciplines over many years.

It is important to point out that this distinction of methods to typical scales is not necessarily strict – for example, methods from two-point geostatistics have successfully been used also in large-scale investigations, and interface methods can also be applied to distinguish sedimentary features. Yet, this typical delineation is a useful starting point to select suitable methods for specific scales of investigation.

Considerations of Complexity

Geological interfaces appear in a variety of complexity in different geological settings. The consideration of the relevant level of complexity is important for each modeling study/inversion, as it may have an influence on the selection of suitable mathematical models. This aspect of complexity from the viewpoint of underground modeling is illustrated in Wellmann and Caumon (2018).

Due to this low level of complexity, a wide variety of existing interpolation tools, both conventional deterministic interpolations (e.g., inverse distance, spline surfaces), as well as a wide range of geostatistical methods can be applied to describe these surfaces.

As soon as we consider faults, this situation becomes more complex (Fig. 1). For normal faults and fault networks, “2.5-D”-approaches could still be used, but we obtain domains where no value is assigned. However, for reverse faults and thrust faults, we now obtain points with multiple z-values. For these cases, we now require geometric interpolation methods with more flexibility, and a variety of implicit and explicit interface representations have been developed for this purpose (see below).

The requirement for a more flexible interface description is even more obvious when we consider complex structures, for example, related to multiple deformed systems or dome structures. Here, it is obvious that a simple model is not anymore sufficient due to the complexity of the interface itself, and increasingly due to nontrivial interactions between multiple sequences and unconformities.

Mathematical Models of Interfaces

General Interface Description

Many commonly used geomodel representations are based on linear interpolation of basis functions, for example, from the class of Radial Basis Functions or Covariance functions (see Wellmann and Caumon 2018). The practical challenge is to decide on a suitable set of basis functions and the combination of multiple functions to describe the interaction in complex settings.

Map-Based Interpolation Approaches

As described above, in map-based “2.5-D” settings, a variety of spatial interpolation approaches can directly be utilized for the purpose of interface description. Here, the basis function is now centered at a location (x,y) in space. A simple choice for the basis function is then the inverse distance function. Other typical choices for the basis functions are Radial Basis Functions (RBF)'s and the related group of geostatistical interpolation approaches.

Explicit and Implicit 3-D Interpolations

An important distinction in the geometric representation of geological interfaces is the use of explicit or implicit methods. Explicit methods describe surfaces directly using either parametric descriptions or local interpolation approaches. The advantage of implicit approaches is that the interface position can directly be evaluated. However, the topological relationship between different geometric elements is fixed in these approaches – an aspect that may be desired in certain

Uncertainties in Geomodelling Related to Geophysical Inversion, Fig. 1 Complexity of interfaces in typical geological settings (modified after Wellmann and Caumon 2018)

circumstances, but a limitation in others. In implicit representations, interfaces are defined as isosurfaces of a scalar field of co-dimension one (i.e.: 2-D interfaces are defined as isosurfaces of a 3-D scalar field). A classic example for these approaches is the Level-Set method, see Wellmann and Caumon (2018).

Uncertainty in the Detection of Model Interfaces by Geological and Geophysical Methods

Modellers have stated the requirement to combine geophysical and geological information. Fullagar et al. (2008) describe geophysical inversion as an extension of geological modeling, and Jessell et al. (2010) express the same view, from the viewpoint of geological modeling. Wellmann and Caumon (2018) discuss similarities between the classical data-driven geophysical inverse workflows and the approaches integrating geological modeling, both centered around the integration of geoscientific knowledge into geophysical inversions.

The most widely used method to consider geological information in the form of geological models is the use of these models to initialize a subsurface parameterization for a geophysical inversion or process simulation. All of these approaches are based on the concept that domains with similar properties can be defined in the subsurface, based on similar geological processes in the formation of a region (Fig. 2). As described above, these geometric domains can be subject to uncertainties. Two general approaches can be distinguished at the moment on the consideration of these uncertainties in subsequent inverse studies: in the form of an

uncertainty identifier, assigned to subdomains (often voxels/cells), which contain the properties that are inverted; or in the form of fully integrated joint geological-geophysical inversions, where the 3-D geological model itself is continuously adjusted.

As Model Describing Initial State

Today's geophysical interpretation requires an interdisciplinary approach, particularly when considering the available amount of state-of-the-art information contained in comprehensive databases employing seismic, gravity, geothermics, and electromagnetic together with geological and petrological studies. The most widely used implementation of 3-D geological models into geophysical inverse approaches is the mapping of properties onto discrete voxels or cells, which contain the properties that are inverted.

An example of interdisciplinary 3-D structural modeling is given by Wehr et al. (2018) presenting a 3-D model of the entire Pyrenees and their forelands by different geophysical observations and data (seismics, borehole, gravity). In particular, basin modeling is part of this, which involves the construction of structures that contain an enormous number of natural deposits (see chapter ► “Sedimentary Basins” by

(b) Typical measurements

(c) Interpolation of important interfaces in space

Uncertainties in Geomodelling Related to Geophysical Inversion, Fig. 2 Example of the concept of interface description and the estimation on the basis of geological and geophysical observations and measurements

Magdalena Scheck-Wenderoth). In their study, the authors consider the initial structural setting and uncertainties in the form of constraints on the subsequent gravity and seismic tomography inversion steps. The analysis of misfits then allows for an iterative (manual) adjustment of the 3-D geological model.

The integration of human geo-expertise, different techniques, and different geo-disciplines play an important role. This aspect becomes particularly manifest in interactive modeling and automated techniques (Inversion). The interactive 3-D modeling software IGMAS+ (e.g., Alvers et al. 2014) can be viewed as an example. Instead of providing either voxel or grid-based and triangulated facet models, it has become more common now to use hybrid models where all three model types are combined. Single value grids are used to define simple density boundaries like sea bottom or top basement. Voxel-cubes can then be used to describe more complex density/velocity distributions in selected bodies.

Dealing with hybrid models and many different fields requires high-performance algorithms in order to shoot for real-time responses. For fast modelling, it is essential that after model changes the recalculation of the model is done immediately. An important aspect is resampling of model interfaces. By keeping the shape of a highly resolved, e.g., triangle interface, the algorithm should allow (e.g. Menzel 2016) depending on a user-given threshold – for the reduction of the number of triangles by factors of 10 to 100. An example is shown in Fig. 3.

Joint Inverse Frameworks

Another approach to combine geological and geophysical information is a full integration in a model-based inverse framework. Here, the geological parameters of the interpolation function (i.e., typically interface points, but orientation

measurements can also be used) are treated as model parameters. In a probabilistic setting, a prior distribution is assigned to these parameters. The geological model (in the form of the 3-D geometric interpolation) then links these parameters through a deterministic forward model to additional observations – both in the form of further geological measurements, which was not included in the interpolation step itself, but also to additional geophysical forward models – in combination with a suitable rock physics model. An example of such an approach is presented in Fig. 4, where a prior 3-D geological model (4a) is parameterized with interface parameters and associated prior distributions (schematically shown in 4b). The model is then linked to further geological observations through likelihood functions (4b, i-iii), as well as geophysical measurements (4c). Finally, the posterior distribution is obtained through a suitable sampling method (here: MCMC with Metropolis-Hastings). The final suite of generated models can then be used to obtain spatial representations of uncertainty, for example, using measures from information theory (Wellmann and Regenauer-Lieb 2012).

Uncertainties in the Output of Material Parameters

Relevance of Rock Physics Models

As described above, there is a need for multidisciplinary approaches to more complex issues. Especially in the analysis of lithospheric parameters (densities, velocities, electrical resistivity) an interdisciplinary approach is necessary, since a profound geological and petrological understanding of the near-surface units is needed to analyze and model the geophysical knowledge of the underground units; refer to, e.g.,

Uncertainties in Geomodelling Related to Geophysical Inversion, Fig. 3 A simplified outer structure of a salt dome in the Gifhorn Trough (Götze et al. 2017). Its geometry built by only 13 900 triangles (right) reduced from originally 380 000 triangles (left) which were obtained by high resolution 3-D-seismic surveys in the area (Menzel 2016). For 3-D gravity modeling 6 000 surface gravity stations (red points, surface stations) and 250 subsurface stations in a salt mine (blue points) were

needed. This structure causes a model gravity field which differs slightly from the gravity field of the original geometry; the differences are smaller than the error of the measurements. Since the distance between measurements and triangulated hull was used as a constraint for the reduction, the model shows a higher geometry resolution near the surface and near the subsurface measurements

(d) Inverted geometric model and representation of uncertainty

Uncertainties in Geomodelling Related to Geophysical Inversion, Fig. 4 Example of a probabilistic model-based joint geological-geophysical inversion (modified after Wellmann et al. 2018)

Sobolev and Babeyko (1984), Bousquet et al. (2005), Afonso et al. (2008), and Fullea et al. (2009).

When considering changes in physical rock parameters with depth, several factors must be considered, as temperature and pressure changes as well as differences in geochemical and mineralogical composition have a significant influence on rock density (see ► “Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity”).

Advanced computer technology and development of powerful modeling software enable the calculation of new models in which a complex consideration of pressure, temperature, and geochemistry is possible. These programs can also be used to model rock types that are not exposed at the surface. The significance of the parameter change in the lithosphere as

a function of chemistry and the resulting mineral paragenesis due to metamorphic reactions has been shown, for example, in the work of Bousquet et al. (2005), Duisterhoeft et al. (2012), and Semprich et al. (2010).

Visualization of Uncertainties as Output of Density Models: An Example from the Central Andes

To visualize model uncertainty of rock parameter density, we used the facilities of our inhouse 3-D-modeling software IGMAS to give an example from the Central Andes. The model is constrained by independent geophysical data (Kirchner 1997). We estimated the uncertainty in the density selected for each body as the tolerable variation in this parameter that would produce a variation in the calculated Bouguer anomaly equal to the estimated error of the observed anomaly,

i.e., $\pm 20 \times 10^{-5} \text{ m/s}^2$. The uncertainties of lithospheric density distribution are presented in Fig. 5. For more detailed information refer also to Tassara et al. (2006). To estimate these uncertainties, we calculated the vertical variation of the vertices defining each discontinuity that produce an average change in the calculated Bouguer anomaly equal to the tolerance limit of $\pm 20 \text{ mGal}$. The uncertainty associated with each discontinuity should be less than that of the vertices. This is because the 3-D effect on the gravity field produced by vertically moving the whole discontinuity is larger than the

effect of moving single vertices. We estimate the expected uncertainty in the depth of each discontinuity to be 20% of the average uncertainty calculated for single vertices.

This analysis gives an indication of the tolerable range of variation in densities for each body. The approach is by no means a tool to evaluate the accuracy of the whole model, and it does not guarantee the resolution of the method. However, this information can be used to analyze the meaning of the final geometry obtained for density discontinuities that are not constrained by independent information.

Uncertainties in Geomodelling Related to Geophysical Inversion, Fig. 5 This screenshot of the Central Andean model by Kirchner (1997) shows a vertical section approximately at the latitude of 21 deg south - from the Pacific to the Chaco of Argentina. The upper box contains the intercept line of the comparison gravity (complete Bouguer anomaly) and the intercept line of the model gravity curve. The lower part shows the density values used for the individual model bodies in white and black notation. The subducted Nazca plate can be clearly identified, the area of the crust and the lithospheric mantle to a depth of approx. 200 km.

The colors symbolize the range of variation possibilities of a density change in the respective rock bodies: dark blue areas show that the density can only be changed slightly in order not to exceed the threshold of $20 \times 10^{-5} \text{ m/s}^2$. The color spectrum then ranges from "light blue" and "green" to orange tones, which symbolize larger variations. The table on the right shows the colors of the lower box together with the "geological" descriptions of the model bodies and the range of variation in g/cm^3 ($1 \text{ g/cm} = 1000 \text{ kg/m}^3$). The smaller the geological body, the greater the possibility to vary the density

Summary

Geophysical inverse methods and geological modeling are increasingly combined to obtain better integrated models of the subsurface – with a consideration of uncertainties. We presented here the reasoning about the use of geological models as well as mathematical methods to represent relevant interfaces, the link to geophysical inverse approaches, as well as to rock physics models. All of these aspects are subject to improvement and addressed in current research.

An important area of future development is calculation and visualization of model uncertainties. Interactive inversion produces thousands of models while exploring the parameter space. Displaying all models with a “similar fit” on top of each other would give an immediate insight into model quality and show where the model is well defined by gravity/magnetic/other geophysical methods and where uncertainty is significant. The challenge is to develop a user-friendly 3-D-overlay technique. First experiments with “fog visualizations” and the possibility of making (low cost) 3-D-plots of even “complicated” underground structures became a promising challenge (e.g., Götte et al. 2017). Alternative methods are the use of transfer functions, for example, plots of probability or entropy (e.g., Wellmann and Regenauer-Lieb 2012). We expect that more interesting insights will come from the active field of uncertainty visualization and communication related to climate models.

Unified Scaling Law for Earthquakes that Generalizes the Fundamental Gutenberg-Richter Relationship

Vladimir Kossobokov

Institute of Earthquake Prediction Theory and Mathematical Geophysics, Russian Academy of Sciences (IEPT RAS), Moscow, Russia

Definition

The hierarchy of movable lithospheric volumes, from grains of rock to tectonic plates, composes a complex dynamical system (Keilis-Borok 1990). A sudden movement of the system volume that originates seismic waves is an *earthquake* which characteristics can be determined from interpretation of seismograms, if any, recorded by seismic instruments. Numerous approaches to sizing earthquakes provided definitions of earthquake *magnitude* (Richter 1935; Bormann 2011).

Naturally, due to hierarchical organization of the lithosphere, the number of earthquakes in a region is scaled by magnitude, in particular, according to the Gutenberg-Richter relationship for the worldwide seismicity (Gutenberg and Richter 1944, 1954):

$$\log_{10} N(M) = a + b \cdot (8 - M), M_- \leq M \leq M^- \quad (1)$$

where the coefficient a characterizes the average level of seismic activity in terms of the annual rate of magnitude 8 earthquakes, the coefficient b is the ratio $N(M)/N(M-1)$, and M_- and M^- are the limits of the magnitude range where the relationship holds.

Introduction

Seismic hazard assessment requires an adequate understanding of the distribution of earthquakes of different size. Until recently the Gutenberg-Richter relationship (1) was the one of common use in the estimation of earthquake hazard and risks, as well as in other researches aimed at investigation of seismic activity in an area of interest. The existing maps of seismic hazard are correlated to the local estimates of the coefficient a obtained from sampling the regional catalogue of earthquakes which data is usually too small for a reliable quantification at fine grid. Note that the probabilistic seismic hazard maps overestimate risks in aseismic areas and underestimate them in seismic areas due to (i) subjective choice of probability model (usually, Poisson distribution in time and Gauss

distribution in space) and (ii) underestimation of the role of standard scaling in proportion to the area, in km^2 .

Unified Scaling Law for Earthquakes

The abovementioned drawbacks of seismic hazard analysis and assessment were clearly recognized in the late 1980s. Kosobokov and Mazhenov (1988, 1994) suggested generalization of the Gutenberg-Richter relationship as follows:

$$\log_{10} N(M, L) = A + B \cdot (5 - M) + C \cdot \log_{10} L,$$

$$M_- \leq M \leq M^- \quad (2)$$

where the coefficient C is the fractal dimension of the set of epicenters that complements to the coefficients A and B which are similar to a and b from Equation (1). The coefficient C shows how the number of earthquakes, N , is changing with linear dimension, L , of an enveloping area. It was shown that C is significantly different from 2 and correlates with the geometry of tectonic structures; high values of C about 1.5 correspond to the regions with dense patterns of faults of different strike and high degree of fracturing, whereas the values of about 1 are related to regions with a predominant major fault zone. Moreover, it was demonstrated that in the case of the Lake Baikal region with the area of 1,500,000 km^2 and $C = 1.25$, the inclusion of aseismic areas leads to underestimation of seismic activity in an area of 1000 km^2 by a factor of 15 and to overestimation by a factor greater than 2 when a characteristic of seismic activity over 1000 km^2 is computed for a grid 10×10 km.

Bak et al. (2002), independently, gave an alternative formulation making use of the inter-event time between earthquakes in Southern California instead of their number. They measured $P_{S,L}(T)$, the distribution of waiting times T , between earthquakes occurring within range L whose magnitudes $M > m = \log(S)$. They found the data collapse onto a single function $f(x)$, which is approximately constant for $x = T \cdot S^{-b} \cdot L^{df}$ in range from below 10^{-2} to above 10^3 , i.e., about constant over 8 orders of magnitude. According to Bak et al. (2002), Equation (3) expresses the unified scaling law for earthquakes, USLE:

$$T^\alpha \cdot P_{S,L}(T) = f(T \cdot S^{-b} \cdot L^{df}) \quad (3)$$

where the Omori law exponent $\alpha \approx 1$, the Gutenberg-Richter value $b \approx 1$, and fractal dimension $df \approx 1.2$. Evidently, $S^{-b} \cdot L^{df}$ is the average number of earthquakes per time unit with magnitude $M > \log(S)$ occurring within the range L , and x is the average number of such earthquakes occurring within

a time interval T . Note that the average of waiting times between earthquakes of magnitude M within $L \times L$ in a unit time is in inverse proportion to $N(M, L)$; b and df are equivalent to B and C of Equation (2). Thus, the USLE, in either formulation (2) or (3), states that the distribution of waiting times depends only on the control parameter $10^{-BM} \cdot L^C$ or $S^{-b} \cdot L^{df}$, correspondingly.

Using the USGS/NEIC Global Hypocenters Data Base, 1964–2001, and a robust box-counting algorithm, Nekrasova and Kossobokov (2002) managed to map the values of A , B , and C in every place on the Earth marked by earthquake occurrence, where the catalog of shallow earthquakes permitted an estimation. Unlike the first studies (Kossobokov and Mazhenkov 1988, 1994; Bak et al. 2002), the values of A , B , and C were determined as averages of numerous estimates achieved in a hundred of randomly rotated box-counting settings at each of the 9276 seismic locations on a regular $\frac{1}{2}^\circ \times \frac{1}{2}^\circ$ grid. Figure 1 shows the global maps of the A , B , and C coefficients at 6753 grid points where reliable estimates based on the USGS Global Hypocenter Data Base system, 1964–2001, were possible; the values of A range from under -1.0 to above 0.5 , which correspond to the rates that differ by a factor of 30 or more; B resides mainly from 0.6 to 1.1 , while C changes from under 1 to 1.4 and larger. The error of the coefficient average estimate is below 0.01 for almost all sites of determination suggesting a high degree of agreement with observations in a wide range of earthquake magnitudes and spatial distances.

Expanding the application of the USLE, Baiesi and Paczuski (2004) introduced the space-time-magnitude proximity η_{ij} between any two earthquakes i and j based on the control parameter $\eta = \tau \times 10^{B \times (S-M)} \times L^C$. The properties of this proximity measure with physical motivations for cluster analysis of seismic phenomena at regional and global scales are discussed at length in Zaliapin et al. (2008) and Zaliapin and Ben-Zion (2016). They suggested for the foreshock and aftershock identification a split of η_{ij} into $R_{ij} \times T_{ij} = (\rho_{ij} \times 10^{-C \times p \times M_i}) \times (\tau_{ij} \times 10^{-B \times q \times M_i})$, where ρ_{ij} and τ_{ij} are the distance and time span between earthquakes i and j , correspondingly, and $p + q = 1$; unlike the Poisson model, the observed seismicity shows a bimodal distribution of $(\log_{10} T, \log_{10} R)$, as has been demonstrated in numerous regions worldwide. Moreover, this 2D presentation permitted to find out quantitative definitions of the burst-like and swarm-like clusters of earthquakes and to relate those with the Earth heat flow production. Thus, the effective viscosity of the lithosphere is proposed to be the main control of the style of earthquake clustering.

Analyzing variability of seismic activity at a regional scale, Nekrasova et al. (2011) have demonstrated a complex distribution of the USLE coefficients A , B , and C in Italy, which do not display any evident general correlation, although following well-organized attractor in the 3D domain of possible values.

Conclusion

The complexity of using the data from seismic catalogs, where quality differs by location, may affect the results of the USLE-based analysis and interpretation. However, the robust nature of computations confirmed by low values of errors in the bulk of seismic regions allows to conclude general agreement with the assumption of spatial self-similarity and to proceed further investigations into the problem using regional catalogs of earthquakes and separating events into the main-, fore-, and aftershocks. For example, the coefficient C at Los Angeles is about 1.21 both as estimated by Okubo and Aki (1987) for the system of faults in Southern California and as computed by applying the box-counting algorithm to one of the best regional earthquake catalogues; scaling down in proportion to the area from the entire Southern California of about 400 km to the region of Los Angeles, about 40 km in length underestimates the recurrence rate by a factor of $(L_{SCA}/L_{LA})^2 / (L_{SCA}/L_{LA})^{1.21} = 10^{0.79} = 6.2$. By analogy, the underestimation of seismic hazard in a region of about 40 km long at Petropavlovsk-Kamchatsky from the area of Kamchatka about 700 km in length where $C = 1.26$ rises to a factor $(L_K/L_{PK})^2 / (L_K/L_{PK})^{1.26} = 17.5^{0.74} = 8.3$. A comprehensive analysis of seismic hazard at 1140 cities and urban agglomerations in seismic regions worldwide due to scaling in proportion to the area (Nekrasova and Kossobokov 2005) reveals, in addition to abovementioned cases, potential underestimation of a factor of 5.4 for Tokyo (Japan), 7.2 for San Francisco (USA), about 20 for Ulan-Ude (Republic of Buryatia, Russian Federation), etc. Such a discrepancy in the evaluation of seismic hazard propagates nonlinearly into erroneous estimations of risks. An error in rate of a factor of 6 (in assumption of $B = 1$) corresponds to an error about 0.8 in magnitude, which explodes exponentially in the underestimation of seismic energy release by a factor 15 , corresponding to a factor above 4.5 for expected fatalities (Wyss et al. 2012). The confirmed multiplicative scaling of earthquakes changes the traditional view on the recurrence of catastrophic events and helps estimating seismic hazard in a more adequate way.

The analysis of space-time-energy distributions of seismic activity at regional scale confirms the existence of different, intermittent levels of rather long-term steady seismic activity characterized with a near constant value of the USLE control parameter η . The region switches from one level to another one in a shorter-term transition associated with strong, catastrophic events. During such a switch, seismic activity may follow very different scenarios with inter-event scaling of different kinds, such as constant, logarithmic, power law, exponential rise/decay, or a mixture of those as observed in the case of the 2016 strong earthquakes in Italy (Kossobokov and Nekrasova 2017). Evidently, these results do not support the presence of universality in seismic energy release, but the

Unified Scaling Law for Earthquakes that Generalizes the Fundamental Gutenberg-Richter Relationship,

Fig. 1 The global maps of the A , B , and C coefficients (Nekrasova and Kossobokov 2002). Cells at $\frac{1}{2}^\circ \times \frac{1}{2}^\circ$ regular grid with epicenters of $M \geq 4.0$ quakes were centers of the five-level hierarchies of square areas with the sides $\frac{1}{2}^\circ$, 1° , 2° , 4° , and 8° of the Earth meridian. The USGS Global Hypocenter Data Base system, 1964–2001, permitted to investigate systematically regions from a wide range of seismic activity. For earthquakes with hypocenters above 100 km, A varies mainly from below -1 to above 0.5 (the corresponding annual rate of magnitude 5 earthquakes differ by a factor up to 30 or more); the magnitude exponent B varies mainly from 0.7 to 1.2 with a sharp maximum of density at 0.9 , while the fractal dimension C changes from under 1 to 1.6 with a maximal density within 1.1 – 1.3 .

$$\text{Log } N(M, L) = A + B(5 - M) + C \text{Log } L$$

Log of recurrence rate = **A** -1.2 -0.7 -0.2 0.3 0.8 per year

Balance between Magnitude ranges = **B** 0.5 0.7 0.9 1.1 1.3 per unit of magnitude

Fractal dimension = **C** 0.5 0.75 1.0 1.25 1.5 per order of distance in degrees

existence of different statistics of scaling that cannot be uniformly rescaled onto a single, universal curve, even at nearby locations.

Thus, the observed variability of seismic activity provides important constraints on modelling earthquake sequences by geophysicists and can be used to improve local seismic hazard assessments including those of earthquake forecast/prediction techniques. The better understanding of the USLE opens new horizons in the investigation of earthquake occurrence.

Definition

Vertical seismic profiling A geophysical technology for measuring the seismic properties in a *profile* of the earth using a set of sources and receivers, either of which is placed along the depth (*vertical*) axis.

Introduction

Vertical seismic profiling (commonly abbreviated to the name VSP) is a major technique in geophysical exploration, which involves measuring downgoing and upgoing seismic wavefields through a stratigraphic sequence. Shortly after the first attempts of developing surface reflection seismology, where both sources and receivers were at the surface, the line of research sets out with the idea of burying either sources or receivers in boreholes. McCollum and LaRue (1931) proposed that local geologic structure could be determined from measuring the arrival of seismic energy from surface sources with buried receivers. This geometry forms the basic principle of determining seismic wave propagation velocities

from VSP measurements even today. The technology of VSP acquisition and processing was initially developed by researchers in the former Soviet Union in the 1950s through the 1970s. It was only later, in the mid-1970s, that non-Soviet geophysicists became systematically engaged in the advance of VSP technology for exploration applications. Today, the fruits of these efforts not only have served in the improvement of velocity analysis but have materialized numerous other applications ranging from structural imaging of complex 3D structures such as faults and salt domes in exploration studies, fracture characterization, and anisotropy measurement to directing drill operations, monitoring secondary recovery processes, CO₂ injection, and microseismic monitoring.

Acquisition Techniques

A variety of data acquisition techniques are currently employed, depending on the survey's application and financial budget. Figure 1 shows the main geometric configurations, which include (i) zero-offset VSP (ZVSP), where the source is near the wellhead above the vertical receiver array; (ii) offset VSP, where the source is located a distance away from the vertical borehole; (iii) multi-offset VSP, for multiple distances of the source to the borehole; (iv) walk-away VSP, where multiple sources are located on a line at the surface and the receivers in a vertical array; (v) walk-above VSP, where the sources are located over receivers buried in a deviated or horizontal well; and (vi) drill-bit SWD (seismic while drilling) VSP, where the drill bit acts as the seismic source and the receivers are on the surface. 3D VSP uses borehole receivers and a 2D surface source geometry (i.e., multi-azimuth, multi-offset, or walk-away VSP).

The common active seismic sources used in VSP include those used in land and marine surface studies (*seismic data acquisition and processing*, *qv*) as well as the noise of the drill bit in the case of SWD-VSP. Alternative sources include naturally occurring or induced microseisms, the latter

Vertical Seismic Profiling,

typically related to hydraulic fracturing or reactivation of fracture networks during hydrocarbon/geothermal production or CO₂ injection. In the case of hydraulic fracturing, perforation shots, which are seismic sources generated from perforation cluster stimulation, can further be used to calibrate the velocity/attenuation model for microseismic monitoring. There is a variety of geophone tools available for use in cased or uncased boreholes, which combine three orthogonal geophones, a hydrophone, and other borehole seismic tools at each recording level. The receiver spacing is set by the depth sampling interval to avoid spatial aliasing. To limit field acquisition time, most commonly multilevel receiver arrays are employed. While conventional 4C sensors are still broadly used, distributed acoustic sensing (DAS) is gaining popularity as a novel seismic acquisition system, which can be deployed for downhole seismic monitoring and imaging. DAS relies on a fiber-optic cable system which records strain changes in response to seismic wave propagation. DAS VSP is especially useful in the case of extreme wellbore conditions and can offer fine sampling along the entire length of the well and permanent monitoring, which makes it ideal for time-lapse VSP which may alternatively suffer from repeatability and higher cost/technical risks using conventional sensors.

The main source of noise in VSP studies are tube waves, which are generated when the fluid in the well is displaced by a seismic source, such as ground roll. Tube waves propagate up and down a well and create secondary tube waves in borehole anomalies, which may interfere with primary

reflections. As a coherent noise mode, tube waves cannot be attenuated by stacking; therefore, both field procedures, such as use of attenuating heavy mud and construction of ditches to attenuate the ground roll, and processing techniques, such as filtering and tube wave modeling, are commonly used to minimize their effect. Interesting applications of tube wave analysis as signal include full-waveform inversion (FWI) for effective hydraulic fracture aperture and compliance (Hunziker et al. 2019), as well as near-surface characterization via Mach waves, which are conical waves which can be generated by tube waves (Wu et al. 2017).

VSP Applications

The primary use of VSP is the integration of VSP and downhole logging to surface reflection surveys. Contrary to surface studies which infer subsurface conditions from measurement of the reflected wavefields with the source and receiver at the surface, a VSP configuration involves closely spaced direct physical measurements of the wavefield between the source position and the reflector. Zero-offset VSP measurements can be correlated with sonic logs and check-shot surveys in the borehole and improve the depth positioning of reflections recorded in surface data. From a velocity perspective, zero-offset VSP measurements are denser than check-shot surveys; hence they provide a finer interval velocity profile. On the other hand, VSP samples a

larger velocity body around the well than the high-frequency sonic log, which may be subject to cycle skipping and the effects of the washed-out zones. VSP also contains the signature of the near surface which is often absent in logging. Hence, synthetic seismograms computed from sonic logs may not accurately represent reflections recorded from surface measurements. Reflections from zero-offset VSP, however, can be matched to those from surface measurements via an appropriate static time-shift to account for the differential travel times of the two recording geometries.

Concerning seismic imaging, the recorded wavefield in a buried VSP array has higher signal-to-noise ratio across a larger seismic bandwidth than surface measurements for two reasons. First, surface cultural noise is suppressed in the borehole, and, second, upgoing reflections do not propagate through the near-surface material which is highly *attenuating* (*viscoelastic attenuation*, qv). In addition, the reflections recorded in a VSP suffer less attenuation as the distance to the target is shorter. This shorter distance also implies that the *Fresnel zone* (*waveform modeling and tomography*, qv) is smaller in the case of a VSP, leading to higher resolution compared to surface seismic studies. Given that downgoing and upgoing wave modes are separated in the f - k space, either an f - k filter or a trace by trace arithmetic subtraction of the estimated wave mode can isolate downgoing from upgoing waves. For horizontal wells, separation is achieved through geophone-hydrophone pairing. Estimation of the downgoing wavefield from VSP data is used in the design of deconvolution operators, which can be thereafter applied to surface data to improve the vertical resolution. On the other hand, upgoing reflections can be mapped to their origin position via either a CDP-VSP mapping or *seismic migration* (qv) algorithm or a combination of the two. A migration step is strongly advisable in the case of complex geologies.

In recent years, VSP seismic imaging has transformed from an analysis of acoustic reflections to migrating converted-wave reflections, as well as multiples, through mirror and interferometric migration (Hanafy et al. 2015; Guo et al. 2015). To meet the challenges of complex imaging, velocity estimation is critical. The most developed category of techniques to estimate complex subsurface velocity is full-waveform inversion (FWI) techniques, which have been successfully developed using acoustic/elastic/viscoelastic forward models, including formulations for VSP. Furthermore, FWI has been successfully applied to time-lapse VSP field data for reservoir and CO₂ injection monitoring (e.g., Liang et al. 2013). By integrating velocity estimation and migration, the technique of joint migration inversion (JMI) has been successfully developed for 3D VSP data, whereby both surface and internal multiples may improve illumination and expand imaging capabilities (Marhfoul and Verschuur 2017).

Another promising technique for seismic imaging applications is seismic interferometry, which through the creation of virtual sources (VS) in the location of the receivers eliminates the need for any knowledge of the complex overburden. In addition, unlike traditional migration schemes, interferometric imaging circumvents a priori knowledge of the velocity structure in the vicinity of targets, such as salt flanks, and can be applied to imaging complex structures above or below a receiver array or even by further exploitation of multiples. Further to seismic interferometry of VSP measurements, which can create virtual sources in the subsurface, the technique of Marchenko redatuming can move both sources and receivers in the subsurface, with the potential to reproduce a “virtual VSP” solely from surface seismic data and a background velocity model. Application of this technique to synthetic VSP data shows that the inverted reflectivity response from the Marchenko redatuming and imaging compares very well with true reflectivities and even better than conventionally processed VSP seismic data (Kiraz and Nowack 2018). Figure 2 shows a comparison between forward modeled VSP data (with source and receiver at depth) versus the wavefield from a virtual source at the same depth computed from Marchenko redatuming of synthetic surface seismic, which attests the similarity. Furthermore, Fig. 3 suggests that the inverted reflectivities from Marchenko imaging result in more correct reflectivity model compared to the reflectivity computed from conventional processing of VSP data, due to processing artifacts. Further testing in field data applications is work in progress.

Through the separation of downgoing and upgoing wavefields and their relative amplitudes, it is possible to extract the true *reflection coefficients* (*energy partitioning of seismic waves*, qv) used for lithological interpretation. Moreover, from multi-offset three-component VSP data, it is possible to determine the *AVO response* (*energy partitioning of seismic waves*, qv) with no assumptions to the path of the propagating wavefield, which is required in surface seismic AVO analysis. Another benefit of using VSP measurements is their robustness in estimating *seismic anisotropy* (qv), which improves lithologic interpretations as well as increases the quality of seismic imaging. Given the seismic velocity response to changes in reservoir porosity and fluid content, velocity *anisotropy* (qv) can also be applied in monitoring of fluid-drainage patterns during production. Fracturing will also affect seismic velocity; hence VSP velocity measurements can also be used for monitoring hydraulic fracturing. Byerley et al. (2018) used a downhole DAS array to monitor hydraulic fracturing stages, and observed appearing events, which are potentially converted waves of newly induced fractures. Furthermore, they observed that velocity perturbations, expressed as 4D time-shifts, increased

Vertical Seismic Profiling, Fig. 2 (a) synthetic wavefield for a source at the surface, (b) synthetic wavefield for a physical source located downhole, (c) wavefield using the Marchenko redatuming for a virtual

source located downhole at the same location as source for (b). (Adapted from: Kiraz and Nowack 2018)

before decreasing again, suggesting potentially that seismic responds to fractures that are fully opened but less so as they start to close. Using shear-wave splitting (SWS) analysis, fracture orientation and density can be determined from the polarization of the fast shear wave and delay time between fast and slow shear waves, respectively. Moreover, by estimating frequency-dependent anisotropy (FDA) linked to scattering and fluid flow in fractures, the size of fractures from micro to cm- and m-scale can be determined (Al-Harrasi et al. 2011).

With *attenuation* (*viscoelastic attenuation*, q_v) gaining increasing importance as a seismic parameter linked to lithological properties, VSP has proven to be a powerful tool for

Q (*viscoelastic attenuation*, q_v) estimation. Aside from true amplitude processing required in stratigraphic interpretation, VSP-derived Q profiles are also used in the design of inverse Q -filters to enhance seismic resolution. Studies also suggest a link between anisotropic attenuation and fracturing; hence VSP azimuthal measurements of attenuation may potentially be applied in monitoring hydraulic fracturing in hydrocarbon and geothermal applications. Using perforation shots, studies have successfully identified low S-wave attenuation zones linked to the growth of stimulated reservoir volume in the Marcellus gas shale (e.g., Tan et al. 2014). Their results suggest that it may be possible to monitor hydraulic stimulation with attenuation analysis.

**Summary**

VSP surveys have long been used for reducing risk in well placement and improving reservoir monitoring. Intrinsic to the complex geometry of the VSP, which poses several data acquisition and processing challenges, is the ability of the VSP to expand the spatial and time-lapse subsurface characterization potential of conventional downhole logging and surface reflection studies. Henceforth, following the success of VSP surveys and their increased benefits over their financial cost, the VSP technique is a rapidly developing area of geophysical research. In the last years, DAS technology has enabled time-lapse seismic monitoring in challenging environments with unmatched repeatability and fine spacing while reducing costs. Lastly, exciting mathematical and field applications of Marchenko redatuming and interferometry may soon change the acquisition and processing of VSP.

VLBI

Definition

Very Long Baseline Interferometry (VLBI) – correlation interferometry of celestial objects with separately operating radio antennas equipped with frequency standards, off-line data reduction remotely by a digital correlator.

e-VLBI – VLBI with transmission of data by a high-speed network instead of storage media.

Introduction

Very long baseline interferometry (VLBI) is a radio astronomical technique to achieve high spatial resolution in astronomical imaging (of the order of milliarcseconds), involving antennas separated by thousands of kilometers (a “VLBI network”). Because the reconstruction of the image depends on the precise knowledge of the vector (hereafter: baseline) connecting the two antennas of a station pair, the a priori knowledge of the image can be used to determine the baseline vector by inverting the measurement equation, with a precision corresponding to a fraction of the wavelength. Such an a priori knowledge is naturally given if the astronomical source on the sky is spatially unresolved and therefore a “point source.” Such sources – usually quasars, that is, the nuclei of bright radio galaxies – are spread over the entire sky and regularly observed in radio astronomy. Whereas VLBI in radio astronomy aims at resolving these active galactic nuclei, improper assumptions about source structure limit the accuracy of the determinations of antenna stations. This can be avoided by using appropriate source structure models (Tornatore and Charlot 2007). The importance of VLBI techniques in Geodesy and Geophysics is evident if the two antennas of a baseline are located on different tectonic plates, whose relative motion and deformation can therefore be determined with high accuracy (qv ► [“Geodesy, Networks, and Reference Systems”](#)).

A VLBI array can be thought as a fictive giant single-dish telescope whose aperture is synthesized while the baseline vector sweeps the sky thanks to the rotation of the Earth. The resulting image therefore depends on the angular momentum vector of the Earth. This dependency implies applications of VLBI in the measurements of the Earth’s spin axis in space and with respect to the solid crust as well as irregularities of the Earth Rotation.

Methods and Techniques in Very Long Baseline Interferometry

The idea of connecting several telescopes to an array in order to synthesize part of the surface of a single, large telescope dates back to 1946, when Ryle and Vonberg (1946) used for the first time a multielement radio telescope for solar observations. In both optical and radio astronomy, the idea turned out to be extremely fruitful for achieving the highest spatial resolutions. For a single telescope, the resolution (in radians) is given by the ratio of wavelength to aperture diameter (up to a factor of order unity). By consequence, a radio telescope working at a wavelength of 21 cm needs an aperture of about 50 km in order to achieve the same angular resolution as, for example, an optical telescope limited by atmospheric seeing. The largest, fully steerable radio telescopes have apertures of the order of 100 m and reach, at that wavelength, an angular resolution of 9 arc minutes. As an alternative to even larger single-dish radio telescopes, several telescopes can be connected by microwave or fiber optics cables in order to form a connected-element interferometer. If the telescopes of such an interferometer are suitably distributed, a sufficiently long observation of a celestial source can be reconstructed to form an image whose angular resolution is of the order of the ratio of the wavelength to the longest among the distance vectors (“baseline,” see Fig. 1) between telescope pairs. The advantage of connected-element interferometers is that the signals can be correlated in real time, such that the phase of the electromagnetic wave when it arrives at the different telescopes is preserved. This is achieved by mixing the incoming signal with that from a local oscillator. In a connected-element interferometer, the local oscillators in all antennas are driven with a common phase reference. The Very Large Array (VLA, New Mexico) and the British e-Merlin array have elements connected by optical fiber cables, with baselines of up to 50 km (VLA) and 200 km (e-Merlin). Despite modern communication technology sometimes used (e.g., satellite links), the physical connection of array elements becomes impractical beyond a certain limit.

The step from a connected-element interferometer to a VLBI experiment consists of abandoning (for practical and economical reasons) the microwave or optical fiber links; registering the data, together with time marks, on a suitable

Very Long Baseline Interferometry, Fig. 1 Schematic representation of an antenna pair on a baseline between Spain and China (distances not to scale). The electromagnetic wave from a distant point source (a quasar) is shown together with the position of the wave front when arriving in China (red line). The signal path corresponding to the time

delay τ_G is shown, as well as the correction for the latter in the data reduction. There is no physical connection between both antennas, each operating with an independent local oscillator (labeled LO). The dashed line separates the measurement from the off-line data processing. (Credits: Greve/IRAM/Rebus)

storage medium; and analyzing the data later with a digital correlator. While local oscillators are necessary to convert the observed frequency band pass to one at a lower frequency (for recording the data), they cannot be locked to a common phase reference because of the large separation between the antennas. Time marks are therefore necessary. This technique became feasible with the availability of reliable frequency standards for the time marks and magnetic tapes of sufficient storage capacity. The first VLBI observation correlated the data of a single baseline between the Hat Creek (California) and Green Bank (West Virginia) observatories (Bare et al. 1967). Since then, the major improvements in VLBI were mainly due to the increase of baseline length (i.e., spatial resolution) and collecting area (i.e., sensitivity) and due to the availability of more reliable clocks and faster digital samplers, leading to larger spectral bandwidth and thus sensitivity. Nowadays, hydrogen masers are used as frequency standards, while arrays of hard disks replace the tapes. The distinction between a connected-element interferometer and a VLBI network is somewhat imprecise. Using network connections of large bandwidth, VLBI data can now be transmitted in real time to the central correlator, while the local oscillators of the antennas participating in the network are

not synchronized. This technique has been demonstrated in 2005 with the European VLBI Network (EVN), involving a transatlantic baseline.

Physical Principles

Interferometric experiments detect both amplitude and phase of electromagnetic waves (conveniently described by complex functions) and combine them in a suitable way to provide images, spectra, and polarization information. Phase-sensitive detection is possible by measuring correlations (or coherence functions) in the incoming electromagnetic field. It has been shown (Sudarshan 1963) that for the case of two-point correlation functions, classical and quantum electrodynamics lead to equivalent results if nonlinear effects are ignored. We therefore limit our discussion to the case of ensembles of incoherent packets of quasi-monochromatic electromagnetic waves from different directions but confined to a small field of view.

The starting point of any interferometric imaging experiment is the van Cittert-Zernike theorem (van Cittert 1934; Zernike 1938), stating that the correlation of the

electromagnetic field at two points (two-point or mutual coherence function) is, up to a complex scaling factor, given by the Fourier transform (also called “visibility function”) of the spatial intensity distribution (e.g., the interference pattern observed on a screen behind an illuminated slit or a grid). The complex scaling factor involves a correction due to the fact that the antenna baselines are not parallel to the plane of the sky (and, for the case of VLBI, not coplanar among them). This so-called delay correction τ_G needs to be applied because of the lag between the arrival times of the front of the electromagnetic wave at the antennas of a given baseline (Fig. 1) and is equivalent to steering the fictive large single-dish telescope mentioned above to the source. The applied delay correction will differ from the theoretical one, owing to the clock error and to the inaccuracy of the assumed baseline length. In the absence of an error-free, absolute time scale, the data streams from an antenna pair rather have to be synchronized by maximizing the correlated signal, applying reasonably guessed delay corrections. A first synchronization is done by using the GPS time signal (qv ► “GPS, Data Acquisition, and Analysis”) to which the local oscillators in the antennas are locked. A refinement needs to be applied later when the data are cross-correlated. There are actually two free parameters per baseline pair, not only the delay correction, but also the frequency of the oscillations, due to the Earth’s rotation, in the interference pattern (“fringes”). This frequency has to be fitted, too, because it depends on the clock rate. For hydrogen masers, whose radio signal at a frequency of 1.4 MHz is now commonly used as a frequency standard for VLBI experiments, the fractional frequency drift (e.g., due to temperature drifts) after 100 s is of the order of 10^{-14} . Such a high precision is required if phase information is to be extracted once the signals are correlated. There is yet another difference between a connected-element interferometer with baselines of up to 10^6 wavelengths and a VLBI experiment: in the former case, the field of view of the interferometer is limited by the central lobe of the antenna reception pattern (“main beam”), whereas in VLBI the field of view is limited by the largest delay τ_G within which the signal from a given direction is coherent. This delay depends on the baseline length with respect to the wavelength, on the spectral bandwidth across which these signals are averaged, and on the accuracy required (e.g., astrometry or precise baseline determinations need a higher degree of coherence). Therefore, the field of view of VLBI observations is much smaller than that of observations with connected-element interferometers. However, nowadays more evolved data analysis techniques exist that permit to overcome this limitation (Garrett et al. 1999).

For each telescope of the VLBI network, the data from the receiving system are recorded on an array of hard disks, together with the time marks from the clock. Later these data are correlated with a digital correlator. Modern

correlators are purely software-based and run on clusters of commodity personal computers (e.g., DiFX, Deller et al. 2007). They allow us to analyze VLBI data for large frequency bands (for high sensitivity to continuum signals) or high-frequency resolution (for observing spectral lines).

Data Calibration and Imaging

After applying the aforementioned delay and fringe rate corrections, the phases of the complex data need to be recovered. The visibility functions are first smoothed to an integration time interval, which depends on the tolerated “visibility smearing”: owing to the rotation of the Earth during this time span, different spatial frequencies are measured at different times, even for a single baseline. Furthermore, at the highest frequencies, where atmospheric fluctuations become important (mm VLBI), the elementary integration times are kept below 20 s, which allows one to apply atmospheric phase corrections. Another upper limit to the integration time interval is given by the stability of the clock. However, the time constant of a hydrogen maser is longer than the two previous limitations.

Unlike connected-element interferometers, where the phase of the front of the incident electromagnetic wave is not too much distorted by atmospheric effects, the phase difference between signals received by different VLBI stations is completely lost. This is because the atmospheric fluctuations at the different antenna sites are uncorrelated and because the local oscillators in the antennas are not locked by a common phase reference. Fortunately, only phase differences with respect to a reference antenna are important. For a triangle of VLBI antennas, the phase errors due to atmospheric and instrumental fluctuations cancel out in the sum of the phase differences between the antennas of the three baselines involved (“phase closure”). Since the number of baselines scales roughly with the square of the number of antennas, whereas the number of phase errors increases only linearly with it, a considerable part of the phase information can be recovered (e.g., 89% for the 18 antennas of the EVN). This recovery of phase information can be improved by a “self-calibration” initially assuming a point source as model, calibrating the measured phases under this assumption, and then creating a new source model using an imaging algorithm. In the underlying theory, complex antenna gains are used, and closure relations also exist for their amplitudes.

Such imaging algorithms are needed because the VLBI stations cannot sample the visibility functions on a regular grid of spatial frequencies. Therefore, the brightness distribution resulting from a Fourier transform is convolved with the “synthesized beam,” which is the Fourier transform of the sampling of spatial frequencies. Iterative algorithms exist to

deconvolve the image such that the result is the brightness distribution as observed with a fictive single-dish telescope whose diameter corresponds to the longest available baseline. The CLEAN algorithm (Högbom 1974) considers the brightness distribution as a collection of spatially unresolved sources. Other deconvolution algorithms have been proposed and applied since then, depending on the nature of the observed brightness distributions. The combination of CLEAN and phase closure is known as hybrid mapping (e.g., Readhead et al. 1980). Global fringe fitting (Schwab and Cotton 1983) extends the closure relations to time delays and fringe rates and is iteratively used together with a deconvolution algorithm like CLEAN.

For high-precision work (e.g., measurements of the Earth rotation parameters, see below), general relativistic effects need to be considered. As an indication, the gravitational time delay due to the Earth's gravity amounts to up to ~ 0.02 ns on a 6000 km long baseline, and the positions of the celestial sources have to be corrected for light bending in the gravitational field of the Sun (4 milliarcseconds for an incidence orthogonal to the direction from Earth to Sun; for a summary and further references, see Heinkelmann and Schuh 2010; Fomalont et al. 2010).

VLBI Networks

VLBI networks now extend all over the world. The most sensitive network is the European VLBI Network (EVN), connecting 18 radio telescopes in Europe, Puerto Rico, and South Africa, operating together for more than 3 months per year. The American Very Large Baseline Array (VLBA) works for the whole year. Other national VLBI facilities exist in the UK (the Merlin array), Japan (Japanese VLBI network JVN), and Australia (long baseline array, LBA). Occasionally, some of these networks work together to form global VLBI networks (e.g., the EVN with the VLBA or Merlin, and the Asia-Pacific telescope APT with observatories in Australia, China, New Zealand, and Japan). Currently, the best angular resolutions (down to 0.1 milliarcsecond) are achieved with global VLBI at 3 mm wavelength. Future improvements of the spatial resolution scale are to be expected from VLBI below 3 mm wavelength and from networks including satellite stations (with the Japanese HALCA antenna, in operation from 1997 to 2005, to be replaced by the VSOP 2 mission). These VLBI networks are mainly used for astrophysical research. However, VLBI is also used extensively for geodetic and geophysical applications (see below). Owing to the importance of the VLBI techniques for these disciplines, the International VLBI Service for Geodesy and Astrometry (IVS, Nothnagel et al. 2017) coordinates the observations of a dedicated network of VLBI stations on all continents (Fig. 2), operated by national research agencies.

Geodetic and Geophysical Applications

The technique of VLBI is also used for geodetic and geophysical applications. In this context, the positions of compact extragalactic radio sources, like quasars, are considered to be known to sufficient accuracy, and the relative telescope coordinates are inferred from time delay observations which reflect the baseline-source geometry. In most cases, networks of 8 to 12 telescopes (Fig. 2) are employed in series of weekly sessions organized by the IVS for the determination of Earth orientation parameters (qv ► “Earth Rotation”) and radio telescope coordinates. Observing between 50 and 60 radio sources in a repeated sequence of scans of 50–100 s duration over a 24-h period provides enough redundancy and geometric stability to determine telescope coordinates and Earth orientation parameters.

Reference Systems and Tectonics

Geodetic and geophysical applications of VLBI have to do a lot with coordinates of the radio telescopes on Earth and in space. Through sophisticated engineering and constant developments in the theoretical models, the coordinates of radio telescopes around the world can be determined with a relative accuracy of a few millimeters today. These coordinates are always referred to a very specific point of the telescope structure which lies at or close to the intersection of the axes about which the telescope is rotated to aim at the quasars.

The coordinates of geodetically used radio telescopes are determined repeatedly over the years and are fed into the database of the International Earth Rotation and Reference Systems Service (IERS, qv ► “Earth Rotation”, see also <http://www.iers.org>). Together with observations of other space-geodetic techniques like the Global Navigation Satellite Systems (GNSS) or Satellite Laser Ranging (SLR), the VLBI results are merged into the International Terrestrial Reference Frame (ITRF, qv ► “Geodesy, Networks, and Reference Systems”). The last version of the ITRF, ITRF2014 (Altamimi et al. 2016), contains about 1500 points on Earth which are all accurate to sub-centimeter. The importance of VLBI for this endeavor is that VLBI is the technique which is used to determine the scale of the ITRF. Here, VLBI benefits from the fact that the geodetic VLBI measurements link radio telescopes over intercontinental distances with extreme accuracy. The observations of the other techniques are then used to densify the global reference frame.

Closely linked to the coordinates of the radio telescopes are the changes of the positions which are caused by global tectonics better known as continental drift. Geodetic VLBI was the first technique to verify Alfred Wegener's theory of continental drift through real measurements across the North Atlantic between 1979 and 1984 (Carter et al. 1985; Herring

Very Long Baseline Interferometry, Fig. 2 Locations of the VLBI antennas of the IVS network participating in the period of 2000 to 2019

et al. 1986). Today, a full global scenario of several plates and deformation zones exists for which geodetic VLBI has helped to determine the magnitude and direction of the tectonic movements. While the distance between North America and Europe extends by about 20 mm per year, the changes in the Pacific region reach 80 mm per year (Kondo et al. 1987).

Likewise, the positions in space of the Earth and of the quasars observed by VLBI are defined in the International Celestial Reference System (ICRS). The ICRS has been realized through the International Celestial Reference Frame (ICRF, Ma et al. 2009) and its latest successor, the ICRF3 (Charlot et al. 2019), which rely on the VLBI positions of many hundred extragalactic radio sources. Due to the large distances of the latter, the ICRF can be considered as definition of a local inertial system (or quasi-inertial system). The origin of the ICRF is the barycenter of the solar system. Systematic effects and additional random errors of the ICRF2 do not exceed 30–50 microarcseconds.

Earth Rotation

Polar motion and irregularities in the Earth's rotation: Geodetic VLBI is one of the few main techniques for the

determination and monitoring of the Earth's variable rotation. Through the direct link between the terrestrial and the celestial reference frames, VLBI is the only technique which permits to determine all components of Earth rotation without any input from other techniques. While today polar motion is regularly determined precisely with GPS observations (qv ► “GPS, Tectonic Geodesy”) on a routine basis, VLBI uniquely contributes the Earth's phase of rotation represented through the time UT1 (Universal Time 1). UT1 is quite variable, due to movements of the atmosphere and of the oceans, and information on UT1 is needed for a number of applications including orbit transformations of Global Navigation Satellite Systems. For this purpose, the International VLBI Service for Geodesy and Astrometry (IVS) runs daily observations providing UT1 with an accuracy of about 3–8 μ s.

Precession and nutation: Looking at the Earth's axis of rotation in space, one can see that it describes a cone with an opening angle of 23.45° , which needs about 25,700 years to complete. This phenomenon is called precession. Superimposed on the precession cone are periodic movements of the Earth's axis of rotation which have a magnitude of a few arcseconds and are called nutation. For historical reasons, precession and nutation are handled independently although

they are caused by the same phenomenon: The astronomical bodies of the Sun, Moon, and planets exert a torque on the equatorial bulge of the Earth trying to pull it toward the ecliptic. Through its desire to conserve angular momentum, the Earth reacts with a precession effect. Through the periodic rotations of the attracting bodies, superimposed periodicities result, and more than 1000 nutation periods can be identified covering a spectrum from 13.6 years down to a few days.

General relativistic effects in Earth Rotation: Owing to the orbital motion of the Earth, spin-orbit coupling leads to a “geodetic precession” of about 2 arcseconds per century (qv ► “Earth Rotation”, Klioner et al. 2010) that are measured by VLBI, which lends itself also to other tests of general relativity (Fomalont et al. 2010).

Today, geodetic VLBI is the only technique that is used to determine precession and nutation. The accuracy of the nutation offsets determined from 24 h of VLBI observations is on the order of 60–80 microarcseconds which correspond to about 2 mm when transformed to a metric displacement at the Earth’s surface. The agreement between these observations and a model which is derived geophysically using an elastic Earth model is on the order of 1 milliarcsecond. The main cause of the deviations is the effect of the so-called free core nutation (FCN). This phenomenon results from the fact that the Earth’s core has a slightly different ellipticity than the rest of the body resulting in different torques.

Summary

Over several decades, VLBI techniques have been refined up to a point where positions on the Earth’s surface can be measured to a precision of a few millimeters with respect to a system of radio-bright celestial reference sources. As of today, VLBI is indispensable for a range of geodetic applications and services, despite complementary techniques involving Global Navigation Satellite Systems (GNSS) or Satellite Laser Ranging (SLR). While combined results of routinely executed measurements employing VLBI, GNSS, and SLR constitute the foundation for the International Terrestrial Reference Frame (ITRF), VLBI is the only technique allowing for a self-contained description of the components of the Earth’s rotational velocity.

Wavelet Analysis

Mikhail Kulesh

Information Technology, DIS AG, Mahlow, Germany

Synonyms

Time-frequency analysis; Wavelet transform; Wavelets

Definition

Time-frequency representation (TFR)	A view of a time series represented over time and frequency.
Wavelet	A special function that is well localized in both time and frequency domains.
Continuous wavelet transform (CWT)	TFR of the analyzed signal obtained as a set of scalar products of all dilated and translated wavelets with this signal.
Discrete wavelet transform (DWT)	A wavelet transform for which the wavelet is dilated and translated discretely.

Introduction

Spectral analysis methods of the time series based on the Fourier transform are significantly limited in their ability to distinguish the waves with similar frequency content but having the different time of arrival. This limitation can be overcome using different time-frequency analysis techniques that allow us to examine how the frequency content of a given signal changes as a function of time.

A view of a time series represented over both time and frequency is called the time-frequency representation (TFR).

Time-frequency analysis means analysis into a TFR. There are different TFR methods each suitable for different applications:

1. The short-time (alternatively short-term or windowed) Fourier transform that is used to determine the sinusoidal frequency and phase content of local sections of a signal as it changes over time (Allen and Mills 2004).
2. The Gabor transform is a special case of the short-time Fourier transform that uses a Gaussian function to create a window of time from which the spectrum of the local signal values is computed (Allen and Mills 2004).
3. The Wigner (alternatively Wigner–Ville) distribution (Wahl and Bolton 1993) and the pseudo-Wigner–Ville distribution (Prosser et al. 1999; Andria and Savino 1996) that can be formulated by the multiplicative comparison of a signal with itself, expanded in different directions about each point in time.
4. The S-transform (Stockwell et al. 1996; Pinnegar and Mansinha 2003) that is similar to the short-time Fourier transform, but with a Gaussian window whose width scales inversely, and whose height scales linearly, with the frequency.
5. The continuous wavelet transform (CWT) of a real or complex signal with respect to a real or a complex analyzing wavelet that is a set of scalar products of all dilated and translated wavelets with this signal (Grossmann and Morlet 1984; Heil and Walnut 1989; Chui 1992; Daubechies 1992; Holschneider 1995; Mallat 1999; Antoine 2004). A wavelet is a special function that is well localized in both time and frequency domains.
6. The discrete wavelet transform (DWT) that is a wavelet transform for which the analyzing wavelet is dilated and translated discretely (Heil and Walnut 1989; Holschneider 1995).

The short-time Fourier transform has a fixed resolution dependent on the windowing function width. A wide window gives better frequency resolution (frequency components close to each other can be separated), but poor time resolution. A narrower window gives good time resolution (the time at

which frequencies change), but poor frequency resolution. Among all possible window functions, there is one signal in particular that shows the best performance regarding time and frequency localization: the Gaussian. Thus, the Gabor transform and the S-transform are the short-time Fourier transforms with the best joint time-frequency resolution.

Since the Wigner distribution is a correlation of the signal with a time and frequency translation of itself, there is no limitation in the time-frequency resolution. However, its distribution may show negative energy levels and exhibit interferences that do not have any physical meaning. To minimize the effect of these interferences, the smoothed pseudo-Wigner–Ville distribution can be used. Unfortunately, the use of the smoothing operator introduces time-frequency smearing in the resulting TFR and therefore downgrades its advantage over the Gabor or wavelet transform, namely, the exact localization over time and frequency.

The CWT and DWT are computed by correlating the signal with families of time-frequency atoms (wavelets). Therefore, the time-frequency resolution of this method is limited by the uncertainty relation bound to the simultaneous time-frequency resolution of the analyzing wavelet.

All of these above-mentioned methods are widely used in the geophysical applications. However, the wavelet transform gives a more general framework for the time-frequency analysis of geophysical data; this approach is powerful and elegant and has several remarkable properties that can be directly applied to the polarization and dispersion analysis of seismic waves in the time-frequency domain.

In the next sections, we briefly introduce the direct and inverse wavelet transforms and some of their properties. Then, we will demonstrate the applications of the CWT in the geophysical time-series analysis.

Continuous Wavelet Transform

Let us introduce the following notations:

1. $s(t)$ is a square-integrable (finite-energy) real or complex function over time from $L^2(\mathbf{R})$ space:

$$s(t) \in L^2(\mathbf{R}) \Leftrightarrow \int_{-\infty}^{+\infty} |s(t)|^2 dt < \infty.$$

2. $\omega = 2\pi f$ is the angular frequency (in radian/s) and f is the physical frequency (in Hz).

3. $\hat{s}(\omega) = \int_{-\infty}^{+\infty} s(t)e^{-i\omega t} dt$, $s(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \hat{s}(\omega)e^{i\omega t} d\omega$ are the direct and inverse Fourier transforms.

4. $g(t) \in L^2(\mathbf{R})$ is a real or complex function called analyzing (mother) wavelet (Grossmann and Morlet 1984).

5. $T_t : g(\tau) \mapsto g(\tau - t)$ is a shifting operator for the analyzing wavelet.

6. $D_a : g(\tau) \mapsto g(\tau/a)/a$ is a dilation operator for the analyzing wavelet.

7. $W_g s(t, a)$ are the complex wavelet coefficients dependent on the dimensionless scaling factor $a \in \mathbf{R}$ and dimensional time factor $t \in \mathbf{R}$ (in s).

8. The asterisk superscript means the complex conjugate.

The wavelet transform $W_g s(t, a)$ of the signal $s(t)$ with respect to an analyzing wavelet $g(t)$ is the set of L^2 -scalar products $\langle T_t D_a g, s \rangle$ of the signal with all dilated and translated wavelets:

$$W_g s(t, a) = \langle T_t D_a g, s \rangle = \int_{-\infty}^{+\infty} \frac{1}{a} g^* \left(\frac{\tau - t}{a} \right) s(\tau) d\tau. \quad (1)$$

Note that there are different possibilities to define the dilation operator D_a . We use the factor $1/a$ in this operator. For this factor, the amplitude of the wavelet spectrum is proportional to the amplitude of the signal for pure frequencies. Alternatively, the dilation $D_a : g(\tau) \mapsto g(\tau/a)/\sqrt{a}$ with corresponding adaptation of the transform (1) can be also used (Heil and Walnut 1989), but the relation between the amplitude of the spectrum and the amplitude of the signal will be in this case frequency (scale) dependent.

Using the properties of the Fourier transform, we can also define the shifting and the dilation operators as $T_t : \hat{g}(\omega) \mapsto e^{-i\omega t} \hat{g}(\omega)$ and $D_a : \hat{g}(\omega) \mapsto \hat{g}(a\omega)$ that allows us to rewrite the transform (1) as being used for Fourier-spectra of the analyzed signal and the analyzing wavelet (Holschneider 1995):

$$\begin{aligned} W_g s(t, a) &= \frac{1}{2\pi} \langle T_t D_a \hat{g} \hat{s} \rangle \\ &= \frac{1}{2\pi} \int_{-\infty}^{+\infty} e^{i\omega t} \hat{g}^*(a\omega) \hat{s}(\omega) d\omega. \end{aligned} \quad (2)$$

The last equation can be used for the fast computation methods to calculate the CWT of the discrete signals $s(t_n)$ with the signal length equal to 2^N points. In this way, a fast Fourier transform algorithm can be employed in practice to compute the integral in the Eq. 2.

The Inversion Formula

The wavelet transform preserves all information of the transformed signal since there is an explicit formula that allows us to recover the signal $s(t)$ from its wavelet spectrum (Holschneider 1995):

$$\begin{aligned} s(t) &= M_h W_g s(t, a) \\ &= \frac{1}{C_{g,h}} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \frac{1}{a^2} h \left(\frac{t - \tau}{a} \right) W_g s(\tau, a) d\tau da, \end{aligned} \quad (3)$$

where $h(t) \in L^2(\mathbf{R})$ is a reconstruction wavelet used for the inverse transform; it can differ from the analyzing wavelet that has been used to calculate $W_g s(t, a)$. The constant $C_{g,h}$ is the normalization coefficient having the same meaning as the coefficient $1/2\pi$ in the inverse Fourier transform. However, this coefficient depends on which pair of wavelets has been taken for direct and inverse transformation:

$$C_{g,h} = \int_0^{+\infty} \frac{1}{\omega} \left(\hat{g}^*(\omega) \hat{h}(\omega) + \hat{g}^*(-\omega) \hat{h}(-\omega) \right) d\omega. \quad (4)$$

Use of the Physical Frequency

In the practical applications, it is convenient to choose as the scaling parameter the physical frequency f instead of the dimensionless factor $a : f = f_0/a$, where f_0 is the characteristic (central) frequency of the analyzing wavelet. In this case, we can rewrite the direct and inverse transforms (1, 2, and 3) as follows:

$$\begin{aligned} W_g s(t, f) &= \int_{-\infty}^{+\infty} \frac{f}{f_0} g^* \left(\frac{(\tau - t)f}{f_0} \right) s(\tau) d\tau \\ &= \int_{-\infty}^{+\infty} e^{2\pi i t \varphi} \hat{g}^* \left(\frac{f_0 \varphi}{f} \right) \hat{s}(\varphi) d\varphi, \\ s(t) &= M_h W_g s(t, f) \\ &= \frac{1}{C_{g,h}} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \frac{1}{f_0} h \left(\frac{(t - \tau)f}{f_0} \right) W_g s(\tau, f) d\tau df. \end{aligned} \quad (5)$$

Wavelets

The analyzing wavelet, that is, wavelet used for direct wavelet transform, must satisfy the following conditions (Antoine 2004):

1. The wavelet must be well localized both in the time and in the frequency domain.

2. The wavelet must satisfy the admissibility condition, which guaranties the invertibility of the wavelet transform:

$$\int_{-\infty}^{+\infty} \frac{|\hat{g}(\omega)|^2}{|\omega|} d\omega < \infty, \text{ see also Eq. 4.}$$

3. In the most cases, the previous condition may be reduced to the requirement that the 0-th moment of the wavelet

$$\text{should vanish: } \int_{-\infty}^{+\infty} g(t) dt = 0.$$

4. The previous property can be generalized by requiring that some consecutive moments vanish, which improves the efficiency of the wavelet at detecting singularities in the

$$\text{signal: } \int_{-\infty}^{+\infty} t^n g(t) dt = 0.$$

The choice of the analyzing wavelet depends on what typical oscillation modes are present in the signal. For example, to analyze rectangular oscillations, the real Haar wavelet proposed in Haar (1910) or a similar but symmetric French hat (FHAT) wavelet is most suitable. The most convenient for the seismic signals are real wavelets based on different-order derivatives of the Gaussian or complex progressive wavelets. If a two-component signal presented in a complex form is analyzed, or the separation into prograde and retrograde wavelet spectrum is needed, the choice of a complex progressive wavelet is preferable.

A special set of progressive wavelets is the set of functions for which the Fourier transform is real valued. Let us consider two such wavelets:

1. The Morlet wavelet is represented in Fig. 1a. The solid line corresponds to the real part, and the dashed line to the imaginary part of the wavelet. The Fourier spectrum is plotted in Fig. 1c as the solid line. This wavelet can be written with its Fourier transform as:

$$g(t) = e^{i\omega_0 t} e^{-t^2/(2\sigma^2)}, \quad \hat{g}(\omega) = \sigma e^{-(\omega - \omega_0)^2 \sigma^2/2}, \quad (6)$$

where the parameter σ describes the variance of the

Wavelet Analysis, Fig. 1 (a) Morlet wavelet in the time domain, (b) Cauchy wavelet in the time domain, (c) Fourier-spectra of the Morlet wavelet (solid line) and Cauchy wavelet (dashed line)

wavelet, and $\omega_0 = 2\pi f_0$ is the central frequency. Strictly speaking, this function is not a wavelet because it is not of zero mean. However, the function values at negative frequencies are small compared to the values at positive frequencies that allow us to use it as a progressive wavelet with necessary precision in almost all practical applications.

2. The Cauchy wavelet is shown in Fig. 1b and can be written as:

$$\begin{aligned} g(t) &= \left(1 - \frac{2\pi it}{p-1}\right)^{-p}, \\ \hat{g}(\omega) &= \frac{(p-1)^p}{(p-1)!} \left(\frac{\omega}{2\pi}\right)^{p-1} e^{-(p-1)\omega/2\pi}. \end{aligned} \quad (7)$$

This wavelet has the unit central frequency, the parameter p describes the variance of the wavelet, and the Fourier spectrum is nonsymmetrical (Fig. 1c, dashed line). The wavelet transform with respect to this wavelet is closely connected to the analysis of analytical functions over the half plane (Holschneider 1995).

One can choose the translated δ -function $\delta_t = \delta(\tau - t)$ as the reconstruction wavelet $h(t)$ for the inverse wavelet transform, which gives us a rather simple and fast reconstruction formula (Holschneider 1995):

$$s(t) = M_\delta W_{g,s}(t, f) = \frac{1}{C_{g,\delta}} \int_{-\infty}^{+\infty} \frac{1}{f} W_{g,s}(t, f) df. \quad (8)$$

However, the δ -function is not a wavelet and its choice as the analyzing wavelet $g(t)$ for the direct CWT is not possible.

Wavelet Spectrum Amplitude and Phase

Because the wavelet coefficients are complex, when using a complex wavelet, we can write the spectrum $W_{g,s}(t, f)$ as a function of wavelet spectrum modulus $|W_{g,s}(t, f)|$ and phase $\arg W_{g,s}(t, f)$:

$$\begin{aligned} W_{g,s}(t, f) &= |W_{g,s}(t, f)| e^{i \arg W_{g,s}(t, f)}, \\ \arg W_{g,s}(t, f) &= \arctg \left(\frac{\operatorname{Im} W_{g,s}(t, f)}{\operatorname{Re} W_{g,s}(t, f)} \right), \end{aligned} \quad (9)$$

where $\arctg(x) \in [-\pi, \pi]$, which is implemented in most programming languages as $\operatorname{atan2}()$.

Thus, the complex wavelet spectrum contains information about the time-frequency distributions of the signal's amplitude and phase, and this amplitude and phase information can be analyzed separately as shown in the Fig. 2. In this example, we consider a wave propagating in the medium with dispersion and attenuation (see ► “Seismic Viscoelastic Attenuation”). This wave is represented by two signals, $s_1(t)$ and $s_2(t)$, which can be registered from two geophones (see ► “Seismic Instrumentation”) separated by a distance Δx (Fig. 2a).

The wavelet spectrum modulus $|W_{g,s}(t, f)|$ corresponds to the instantaneous amplitude. We can visualize it, for example, as contour line plot, where the horizontal axis corresponds to the time, and the vertical axis represents the frequency (Fig. 2b). The complex wavelets Morlet and Cauchy have a phase shift between the real and imaginary components that prevent here the high-frequency modulus oscillations.

At the same time, a contour line plot of the wavelet spectrum phase $\arg W_{g,s}(t, f)$ represents the instantaneous phase on the different frequencies. Because of practical reasons, the

Wavelet Analysis,
Fig. 2 Wavelet spectrum amplitudes and phases for two signals

phases must be only plotted for time-frequency areas where the modulus $|W_g s(t, f)|$ is not infinitesimal (Fig. 2c).

To analyze the dynamic behavior of multivariate signals using the CWT, one may be interested in investigating a diffeomorphic deformation of the wavelet space $W_{gs1}(t, f) \mapsto W_{gs2}(t, f)$ as shown in Fig. 2. Such a deformation corresponds to a pseudo differential operator acting on signal's wavelet spectrum:

$$D : s(t) \mapsto M_h D W_g s(t, f). \quad (10)$$

In this context, we will consider in the next sections how the wavelet transforms of the source and the propagated signal are related through a transformation operator that explicitly incorporates the phase and group velocities as well as the attenuation factor of the medium.

Prograde and Retrograde Wavelet Spectrum

Both Morlet and Cauchy wavelets are progressive, that is, their Fourier coefficients for negative frequencies are zero. This feature allows us to separate the wavelet spectrum into prograde $W_g^+ s(t, f)$ and retrograde $W_g^- s(t, f)$ components:

$$\begin{aligned} W_g s(t, f) &= W_g^+ s(t, f) + W_g^- s(t, f), \\ W_g^+ s(t, f) &= \begin{cases} W_g s(t, f), & f \geq 0 \\ 0, & f < 0 \end{cases}, \\ W_g^- s(t, f) &= \begin{cases} 0, & f \geq 0 \\ W_g s(t, f), & f < 0. \end{cases} \end{aligned} \quad (11)$$

To perform such a separation for nonprogressive (e.g., real) wavelets, one must first calculate the Hilbert transform of the source signal, which makes the numerical procedure more complex.

An example of the prograde and retrograde wavelet spectrum is shown in Fig. 3, where we consider a two-component synthetic seismogram related to a Rayleigh wave (see

► “Surface Waves”). From two signals, $u_x(t)$ and $u_z(t)$ that correspond to the orthogonal components of the record, we construct a complex signal $z(t) = u_x(t) + iu_z(t)$, as shown in Fig. 3a, where the solid line corresponds to the real part, and the dashed line to the imaginary part of this complex signal.

For this complex signal, we perform CWT using Eq. 5 with respect to Cauchy wavelet (7) and plot only the absolute values of the complex wavelet coefficients as contour line plots for the prograde and the retrograde components (11) separately (Fig. 3b). The analysis of the difference between these two spectra is exactly the idea to find out polarization properties of a signal as introduced in the next sections.

Discrete Wavelet Transform

As the CWT, the discrete transform also has a huge number of applications in science, engineering, mathematics, and computer science. In its basic form, the DWT employs a dyadic grid (integer power of two) in the timescale plane:

$$\begin{aligned} T_{jk} : g(\tau) &\mapsto g(\tau - k/2^j), \quad D_j : g(\tau) \mapsto 2^{j/2} g(2^j \tau), \\ \psi_{jk}(\tau) &= T_{jk} D_j g(\tau), \quad j, k \in \mathbf{N}. \end{aligned}$$

Actually, the transform integral remains continuous for the DWT, but is determined only on a discretised grid of frequencies and time points (Heil and Walnut 1989):

$$W_{g^s j k} = \langle \psi_{jk}, s \rangle = \int_{-\infty}^{+\infty} 2^{j/2} g^*(2^j \tau - k) s(\tau) d\tau. \quad (12)$$

For the DWT, the orthonormal wavelets are usually used. The wavelet $g(t)$ is called orthonormal, when the functions family $\{\psi_{jk}\}$ in the Eq. 12 corresponds to an orthonormal basis in the $L^2(\mathbf{R})$ space, that is, $\langle \psi_{jk}, \psi_{nm} \rangle = \delta_{jn} \delta_{km}$, where δ_{jn} is

Wavelet Analysis,

Fig. 3 Prograde and retrograde wavelet transform of a Rayleigh wave arrival

the Kronecker's delta. In this case, each function $s(t) \in L^2(\mathbf{R})$ can be represented as a sum of a convergent series:

$$s(t) = \sum_{j,k} W_{gsjk} \psi_{jk}(t). \quad (13)$$

The simplest possible orthonormal wavelet is the Haar wavelet:

$$g(t) = \begin{cases} 1, & 0 \leq t < 1/2, \\ -1, & 1/2 \leq t < 1, \\ 0, & t < 0, t \geq 1. \end{cases} \quad (14)$$

This function was proposed by Haar (1910) to give an example of a countable orthonormal system for the space of square-integrable functions on the real line. The technical disadvantage of the Haar wavelet is that it is not continuous, and therefore not differentiable.

Use of Wavelets in Geophysical Time-Series Analysis

Instantaneous Parameters

The concept of instantaneous parameters has been widely used in electric engineering and geophysics. Parameters such as instantaneous amplitude $|W_{gs}(t, f)|$, instantaneous phase $\arg W_{gs}(t, f)$, and instantaneous frequency $\Omega(t, f)$ are directly related to geometry and physical property variations of the medium through which the radar signal propagates. The instantaneous frequency, for example, responds to both wave propagation effects and depositional characteristics, hence it is a physical attribute and can be used as a hydrocarbon indicator by low frequency anomaly, a fracture zone indicator, or a bed thickness indicator. Using the wavelet spectrum, the instantaneous frequency is defined as follows: $\Omega(t, f) = \frac{\partial}{\partial t} \arg W_{gs}(t, f)$.

To avoid the numerical derivatives in the above expression, it is possible to derive an exact analytical formula for the computation of $\Omega(t, f)$ that involves the wavelet transforms of the signal with respect to the analyzing wavelet $g(t)$ and its derivative $g'(t)$. This approach is widely used for instantaneous frequency estimate with Gabor transform (Borum and Jensen 1999) and can be adapted to the case of wavelet transform as follows:

$$\Omega(t, f) = -\text{Im} \left(\frac{W_{g's}(t, f)}{W_{gs}(t, f)} \right). \quad (15)$$

Polarization Analysis

Perhaps the first successful attempt to combine the time-frequency analysis with the polarization analysis of multi-component signals was done by Keilis-Borok et al. (1989).

Afterwards, a great number of the different polarization methods working in the time-frequency domain has been proposed. Some of these methods are based on:

1. The DWT with respect to the orthogonal wavelets and the singular value decomposition (Lilly and Park 1995; Claassen 2001).
2. The S-transform and elliptical motion approximation (Pinnegar 2006; Schimmel and Gallart 2007).
3. The CWT with respect to the orthogonal Mayer's wavelets and the complex covariation method (Soma et al. 2002), the singular value decomposition method (Roueff et al. 2006), the adaptive covariance method (Kulesh et al. 2007), as well as using analytical signals (Burjanek et al. 2009).
4. The wavelet packet decomposition of three-component seismic traces (Lyubushin 2006).

As an example let us consider a simple polarization method based on the complex trace analysis. This method can be applied for the two-component signals. First, we construct a complex signal $z(t) = u_x(t) + iu_z(t)$ from two orthogonal components $u_x(t)$ and $u_z(t)$ of a record to be analyzed. Next, we perform CWT and split the obtained wavelet spectrum into prograde $W_g^+ z(t, f)$ and retrograde $W_g^- z(t, f)$ components using Eq. 11. Then, we can compute the phase difference $\Delta\phi(t, f)$, the major $R(t, f)$ and minor $r(t, f)$ half-axes, and the tilt angle $\theta(t, f)$ of the polarization ellipse in the time-frequency domain as follows

$$\begin{aligned} \Delta\phi(t, f) &= \arg \left(\frac{W_g^+ a(t, f) + W_g^- z(t, f)^*}{W_g^+ z(t, f) - W_g^- z(t, f)^*} \right) + \pi/2, \\ R(t, f) &= |W_g^+ z(t, f)| + |W_g^- z(t, f)|, \\ r(t, f) &= |W_g^+ z(t, f)| - |W_g^- z(t, f)|, \\ \theta(t, f) &= \arg \left(W_g^+ z(t, f) W_g^- z(t, f) \right) / 2. \end{aligned} \quad (16)$$

Thus, the particle motions can be represented by instantaneous attributes that show distinct features for waves of different polarization characteristics. These attributes are explicitly related to the wavelet transform coefficients of the analyzed signal that can be used to perform the complete wave mode analysis (Pacor et al. 2007) and separation/filtering (Diallo et al. 2006) of two-component seismograms in the wavelet domain.

Dispersion Analysis

Surface wave propagation in heterogeneous media can provide a valuable source of information about the subsurface structure and its elastic properties. For example, surface waves can be used to obtain subsurface rigidity through inversion of the shear wave velocity. The processing of

experimental seismic data sets related to the surface waves is computationally expensive and requires sophisticated techniques in order to infer the physical properties and structure of the subsurface from the bulk of available information.

One of these techniques is the calculation and interpretation of the phase and group velocities from the experimental seismograms. The time-frequency representation is today commonly used for the phase and group velocities computation (Levshin et al. 1972; Abbate et al. 1995; Prosser et al. 1999; Niethammer et al. 2001; Pedersen et al. 2003). Most of the methods are essentially based on the study of the square modulus of the representation, which can be interpreted as the energy density in the time-frequency plane. These methods provide only partial information that cannot be directly used to characterize the phase velocities and the different propagation modes.

In order to analyze the dynamical behavior of multi-arrived signals using the model (10), it is also possible to develop a wavelet transformation operator that approximates the wave propagation in the dispersive medium and explicitly incorporates the phase and group velocities as well as the attenuation function (Kulesh et al. 2005):

$$W_g s_m(t, f) = e^{-\alpha(f)D_{mj}} \left| W_g s_j \left(t - \frac{D_{mj}}{C_g(f)}, f \right) \right| \times e^{i \arg W_g s_j(t - D_{mj}/C_p(f), f)}. \quad (17)$$

In this operator, $C_p(f) = f/k(f)$ is the phase velocity, $C_g(f) = 1/k'(f)$ is the group velocity, and $\alpha(f)$ is the attenuation function. The signals $s_m(t)$ and $s_j(t)$ correspond to records obtained from two geophones placed with distance $D_{mj} = D_m - D_j$ apart, and $k(f)$ is the frequency-dependent wave-number function.

The relationship (17) has the following interpretation. The group velocity is a function that “deforms” the image of the absolute value of the source signal’s wavelet spectrum, the phase velocity “deforms” the image of the wavelet spectrum phase, and the attenuation function determines the frequency-dependent real coefficient by which the spectrum is multiplied (see also Fig. 2b, c). Based on this property, one can construct the optimization (Holschneider et al. 2005) and correlation (Kulesh et al. 2008; Waltisberg and Raišutis 2008) methods that allow us to extract both phase and group velocities from the wavelet spectra of multi-arrived signals containing waves with several wave modes.

Summary

In contrast to the Fourier transform, the CWT provides a two-dimensional spectrum of the analyzed signal, where the frequency and the time are treated as independent variables. As a

result, we can investigate the signal in the time domain and in the frequency domain at the same time. The fact that the time-frequency-dependent polarization attributes are explicitly related to the wavelet transform of the signals enables us to perform the wave mode separation in the wavelet domain. It is also possible to construct the wavelet-based dispersion operators that can be used to model wave propagation in a dispersive and attenuating medium.
